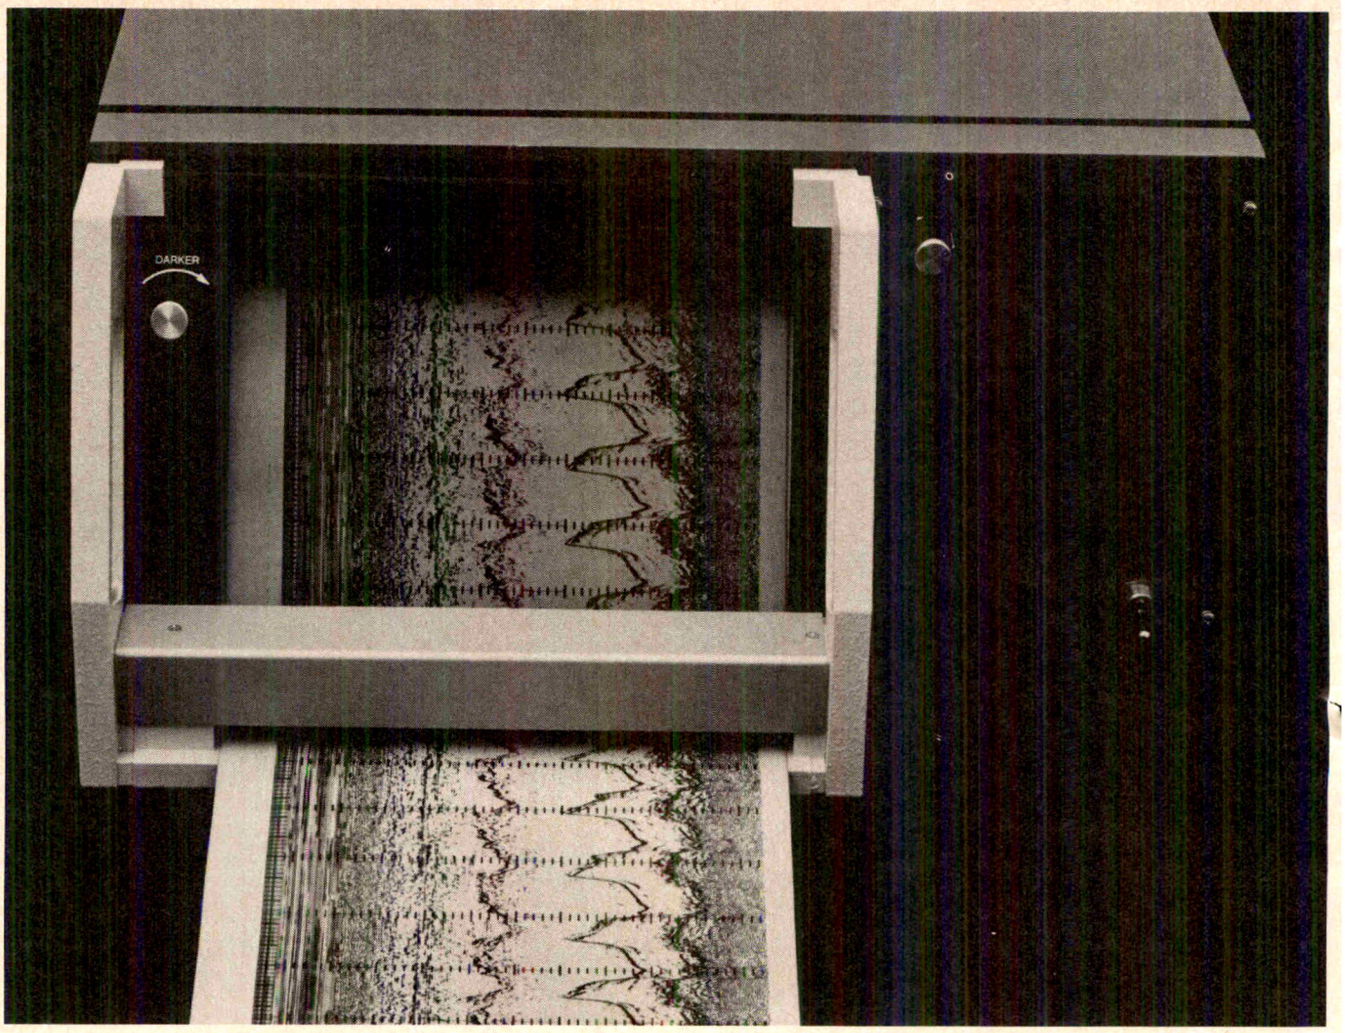
Ativan® (IV)
for (lorazepam)
Anxiety



TAKE A LOOK AT HONEYWELL'S NEW RECORDER AND SEE WHAT YOU'VE BEEN MISSING IN ECHOCARDIOGRAMS.

If you're not seeing everything you expect from your present system, you should be looking at the LS-8—a totally new concept in presenting diagnostic information for echocardiography.

It delivers crisp black and white echocardiograms that won't fade. Echocardiograms that are developed dry, without chemicals, and without any warm-up delay caused by speed changes. So you get an instant echocardiogram for immediate evaluation.

And what an echocardiogram! Sharp and clear, with automatic intensity compensation for paper speeds from 5 to 100 mm/sec and the kind of high resolution and superior contrast that comes only from a wide and accurate gray scale range. Optional with direct print paper at 5 to 500 mm/sec.

Specific application modules provide optimum performance in a wide variety of applications, including M-mode echo, video for real time, and B-scan. Other modules can interface with up to six physiological data channels and provide timelines. The 2 kHz frequency response of the data channels provides diagnostic-quality phonocardiography recordings. And since the LS-8 is convection-cooled, there's no fan noise, no acoustical interference on sensitive phonocardiography channels.

Now add operation that's simpler than ever, a design that's quick and easy to service, and you have the LS-8, backed by the experience and expertise of people whose business is graphic recorder technology.

Honeywell's new LS-8 Stripchart Recorder will deliver every bit of image quality your ultrasound system is capable of. Ask your echo system supplier. Or contact Bob Shipman, Honeywell Test Instruments Division, Box 5227, Denver, Colorado 80217, phone 303/771-4700.

WE'LL SHOW YOU A BETTER WAY.

Honeywell

How oral nitroglycerin therapy works

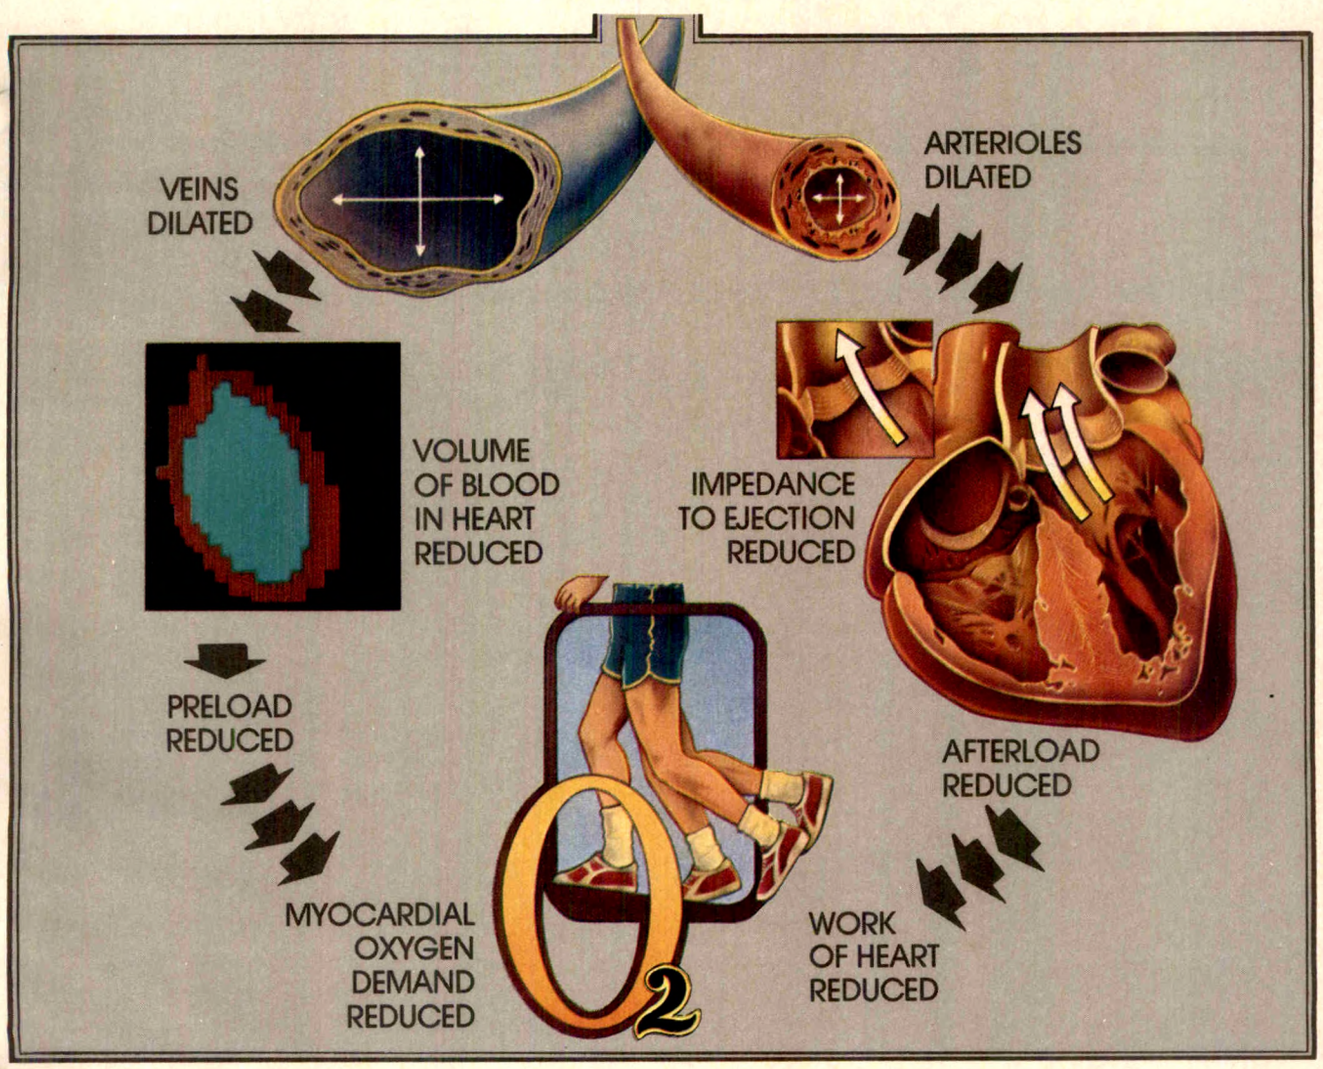
"After ONTG [controlled-release oral nitroglycerin, 6.5 mg to 19.5 mg] ingestion left ventricular filling pressure (LVFP) diminished in 20 min.... declined maximally within one hour...and remained decreased...throughout the four hours."*

"Mean blood pressure was 3-10 mm Hg less than control (88 mm Hg) throughout the four hour period after ONTG therapy, and diastolic blood pressure was 2-8 mm Hg below control (66 mm Hg) during this interval [Afterload reduction]."*

"Consonant with the hemodynamic effects of the preparation...has been its antianginal efficacy demonstrated in a controlled clinical trial."*

*Amsterdam EA, Awan NA, DeMaria AN, et al: Sustained salutary effects of oral controlled-release nitroglycerin on ventricular function in congestive heart failure. *Clinical Cardiology* 2:19-25 (Feb) 1979.

NITRO-BID® Plateau CAPS®
(nitroglycerin) 9 mg, 6.5 mg and 2.5 mg



INDICATIONS: Based on a review of oral nitrate drugs by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows: "Possibly" effective when taken by the oral route, Nitro-Bid Capsules are indicated for the management, prophylaxis or treatment of anginal attacks. Final classification of the less-than-effective indications requires further evaluation.

CONTRAINDICATIONS: Patients with marked anemia, increased intraocular pressure, increased intracranial pressure, glaucoma, hypotension, and idiosyncrasy to this drug.

WARNINGS: Nitro-Bid is not intended to abort the acute anginal episode. Nitro-Bid Capsules must be taken orally, not sublingually.

PRECAUTIONS: Headache is a sign of overdosage, and therefore, dosage should be reduced. Occasionally, elderly patients may have no untoward symptoms while recumbent, but may develop postural hypotension with faintness upon suddenly arising.

ADVERSE REACTIONS: With use of nitrates, transient headache, postural hypotension, flushing, tachycardia and dizziness may occur.

Consult full product disclosure before prescribing.

THERMODILUTION CARDIAC OUTPUT COMPUTER

MODEL 3500E

Latest bedside cardiac output computer monitoring technology.

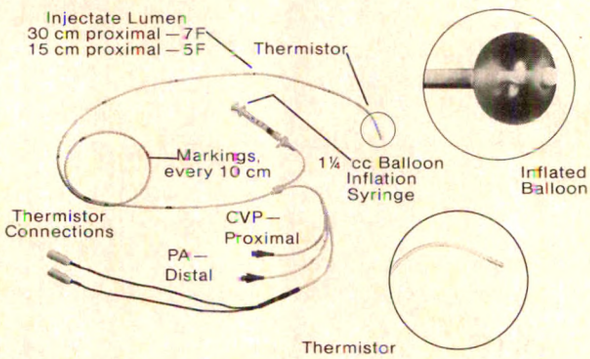
MODEL 3501

Companion automatic recorder for thermodilution curve.

Features:

- ACCURATE cardiac outputs — adult and pediatric ranges
- SIMPLE pushbutton operation
- ADJUSTABLE test calibration
- AUTOMATIC body and injectate temperatures
- AUTOMATIC thermal curve recording
- CHOICE of injectate volume and temperature
- SERVICEABLE — interchangeable circuitry

THERMODILUTION CATHETERS



Features:

- Convenient and complete sterile packaging
- Precalibrated and interchangeable
- Adult, pediatric and direct placement sizes
- Tapered tip — pressure fidelity and introduction
- Thermistor located inside J curve — prevents P.A. wall contact
- Balloon protection shield

PACESETTERS for the 1980's

from SPRINGER-VERLAG

SYSTOLIC TIME INTERVALS (International Boehringer Mannheim Symposia) Edited by *W.F. List*, Austria, *J.S. Gravenstein* and *D.H. Spodick*, USA

The first comprehensive review of STI measurement methods and their clinical applications. Included are reports on the use of computer system measurement and evaluation, comparisons of echocardiography and STI measurements, and studies of achieved results. Concise and varied in angles of approach, this new book provides solid ground for studying the use of systolic time interval measurement as a pre-selection technique in patients where invasive morbidity and mortality may be a risk. Cardiologists, internists, physiologists, and anesthesiologists will find *Systolic Time Intervals* a valuable guide to current research on the value of STI measurements before and after drug intervention or cardiac surgery.

ATHEROSCLEROSIS V (Proceedings of the Fifth International Symposium) Edited by *A.M. Gotto, Jr., Barbara Allen*, and *L.C. Smith*, The Methodist Hospital/Baylor College of Medicine, Houston

Devoted in part to the latest advances in surgery for atherosclerotic disease, this new book includes papers presented in Houston, November, 1979, by such noted surgeons and physicians as David Blankenhorn, William Castelli, Michael DeBakey, John Goodwin, William Kannel, John Leragh, Robert Levy, and David Sabiston. It covers such topics as hypertension, the role of diet in prevention and treatment, risk factors in children, effectiveness of aspirin in coronary disease, drug treatment of hyperlipidemia, and epidemiology of atherosclerotic lesions. Available now for the first time in print, these proceedings are outstanding.

Find out more about our books on cardiology. Stop by Springer-Verlag booth #1348 at the American College of Cardiology convention in Houston. Or write for more information to: **SPRINGER-VERLAG NEW YORK INC.**, Dept S1980

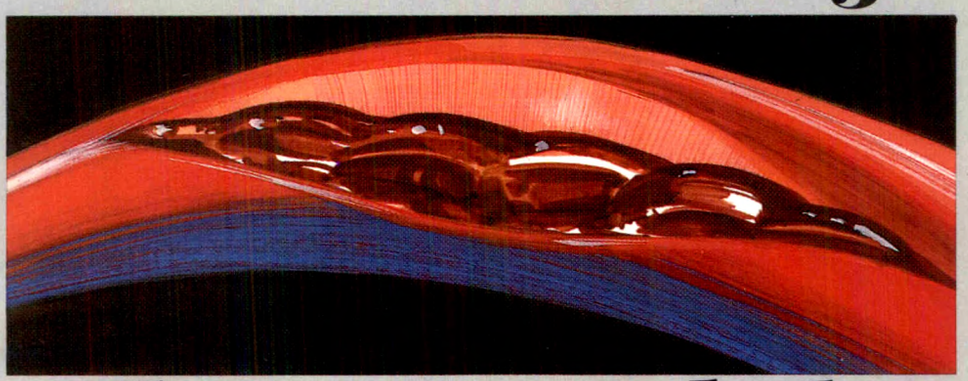
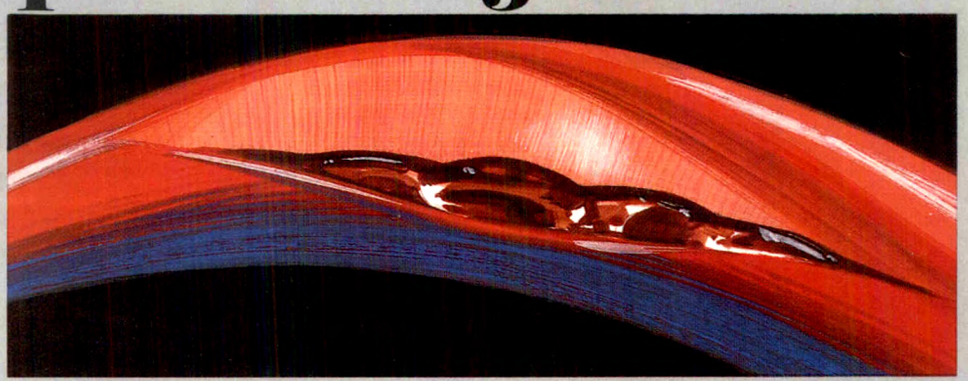
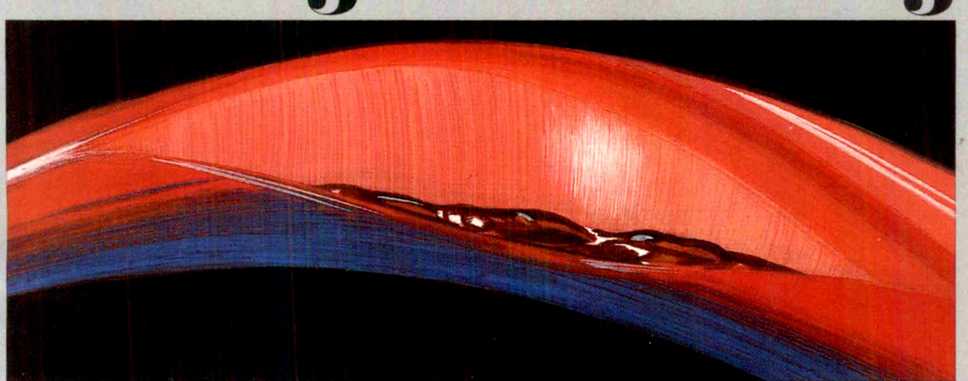
A life-threatening



pulmonary embolus



is being dissolved by

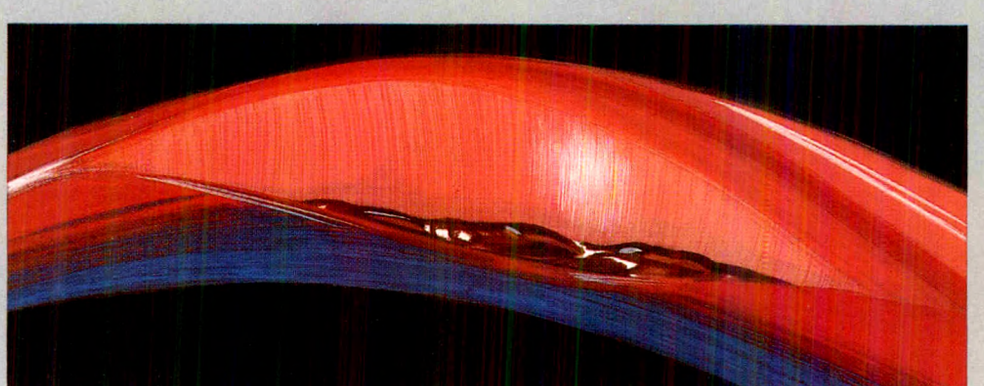


Artist's conception, based on changes in pulmonary angiography following Breokinase infusion.[1]

NEW BREOKINASE®
(urokinase)
for injection

NEW BREOKINASE®
(urokinase)
for injection

Rapid and effective dissolution of pulmonary emboli.



- Proven by controlled clinical studies.[1]
- More rapid and effective than heparin alone during the first 24 hours after start of therapy.[2]

1. Sasahara AA, Hyers TM, Cole CM, et al: The urokinase pulmonary embolism trial. *Circulation* (Suppl II) 47:1-108, 1973.
2. Fratantoni JC, Ness P, Simon TL: Thrombolytic therapy: Current status. *N Eng J Med* 293:1073-1078, 1975.

Please see prescribing information on last page of this advertisement. It is important to pay close attention to WARNINGS and CONTRAINDICATIONS sections to minimize the risk of bleeding.

New Breokinase® is highly purified human protein.

- Lower incidence of fever.[3,4]*
- Can be used effectively in patients with recent streptococcal infections or high titers of streptococcal antibodies.
- Less risk of allergic reactions than streptokinase.†

Now urokinase therapy at lower cost

- Offers substantial savings to both hospital and patient.
- Convenient. Ask your Breon representative for a list of depots. There is one near you.

*Febrile episodes occurred in about 2-3% of urokinase-treated patients. A causal relationship to urokinase has not been established.

†In vitro and intradermal tests gave no evidence of induced antibody formation. However, the possibility of serious allergic reactions occurring cannot be excluded. There have been rare reports of relatively mild allergic reactions such as bronchospasm and rash.

Doctor: Before prescribing or administering Breokinase® (urokinase for injection) please read the following product information.

BREOKINASE®

(urokinase) for injection

Breokinase (urokinase for injection) should be used only by physicians with adequate experience in the management of thrombotic disease in hospitals where necessary clinical and laboratory monitoring can be performed (see Warnings, Precautions and Dosage and Administration).

The physician should carefully assess the overall clinical status and history of the patient before beginning urokinase treatment. Urokinase produces more profound changes in hemostasis and a greater frequency of bleeding than heparin or oral coumarin anticoagulant therapy. Bleeding when it occurs is more severe and more difficult to manage. Such factors as patient's age, physical condition, and underlying bleeding tendency (as described under Warnings and Precautions) should be taken into consideration when the potential risk of serious hemorrhage is weighed against the potential benefits of urokinase treatment.

Indications

Breokinase is indicated for the thrombolytic treatment of:

—acute massive pulmonary embolism, defined as obstruction or significant filling defects involving two or more lobar pulmonary arteries or an equivalent amount of emboli in other vessels, as seen on pulmonary arteriography;

—pulmonary embolism accompanied by unstable hemodynamics, i.e., inability to maintain blood pressure without supportive measures.

The diagnosis of pulmonary embolism should be confirmed by objective means, preferably pulmonary arteriography.

Urokinase treatment should be started as soon as possible after diagnosis of pulmonary embolism, but no later than five days after onset. Under these circumstances, angiographic and hemodynamic measurements and perfusion lung scans demonstrate a more rapid improvement during the first 24 hours after initiation of therapy than with heparin therapy. However, it has not been established that urokinase treatment decreases morbidity or mortality compared to heparin therapy alone.

Contraindications

Thrombolytic therapy increases the risk of bleeding. The risk of hemorrhage in the conditions listed below should be weighed carefully against the anticipated benefits of urokinase therapy in each patient. The benefits and risks associated with urokinase therapy should be compared to the benefits and risks associated with other forms of treatment.

1. Surgical procedures within preceding ten days (including liver or kidney biopsy, lumbar puncture, thoracentesis, paracentesis, extensive or multiple cutdowns).
2. Intraarterial diagnostic procedure within ten days.
3. Ulcerative wound.
4. Recent trauma with possibility of internal injuries.
5. Visceral or intracranial malignancy.
6. Pregnancy and the first ten days post-partum.
7. Actively bleeding lesion of the gastrointestinal or genitourinary tract, or a condition with significant potential for bleeding (including ulcerative colitis, diverticulitis).
8. Severe hypertension.
9. Acute or chronic hepatic or renal insufficiency.
10. Uncontrolled hypocoagulable state (including coagulation factor deficiency, thrombocytopenia, spontaneous fibrinolysis, any purpuric or hemorrhagic disorder).
11. Chronic pulmonary disease with cavitation, e.g., tuberculosis.
12. Subacute bacterial endocarditis or rheumatic valvular disease.
13. Recent cerebral embolism, thrombosis or hemorrhage (within at least two months) to avoid risk of bleeding into infarcted cerebral tissue.
14. Any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to locate or control.

Warnings

Bleeding: Activation of the fibrinolytic system with urokinase causes a more profound change in the hemostatic status of the patient than does anticoagulant therapy with heparin or coumarin agents. The objective of urokinase therapy is the production of sufficient amounts of plasmin to lyse intravascular deposits of fibrin; however, fibrin deposits which provide hemostasis, for example at sites of needle punctures, will also undergo lysis, and bleeding from such sites may occur. The possibility of bruising or hematoma formation, especially with intramuscular injections, is substantial during thrombolytic therapy. Unnecessary clinical or diagnostic procedures should be avoided. It is important that close attention be paid to this section and the Contraindications section in order to minimize the risk of bleeding.

Intramuscular injections should be avoided during urokinase therapy, as with heparin therapy, because of the high risk of hematoma formation. Bleeding may occur at sites of recent invasive procedures. Therefore, arterial punctures must be avoided before as well as during treatment with urokinase. If arterial puncture is *absolutely* necessary, the radial or brachial artery should be used and the femoral artery must be avoided. Arterial puncture should be performed with great care by an experienced physician and pressure should be applied for at least 15 minutes. This should be followed by the application of a pressure dressing, and the puncture site should be checked frequently for evidence of bleeding.

Venipunctures should also be performed as carefully and infrequently as possible. If bleeding from an invasive site occurs during urokinase infusion, but is not severe, treatment may be continued with close clinical observation. Local pressure and other measures should be initiated immediately.

Spontaneous internal bleeding that is not accessible for the application of pressure may also occur. The risk of spontaneous bleeding is greater in patients with pre-existing hemostatic abnormalities, including patients whose histories are suggestive of prior bleeding problems whether or not there are demonstrable abnormalities in platelet count, prothrombin time, partial thromboplastin time, or bleeding time. The relative risks and benefits of urokinase treatment must be carefully assessed in such patients before initiating treatment.

Plasmin degrades fibrinogen, Factor V, Factor VIII, and other proteins in addition to fibrin. The products of plasmin degradation of fibrinogen and fibrin (FDP/fdp) possess an anticoagulant effect which may make bleeding difficult to control.

If serious spontaneous bleeding occurs, the infusion of urokinase should be terminated immediately, and treatment instituted as described under Adverse Reactions.

Risk of Cerebral Embolism

Urokinase treatment of patients with atrial fibrillation or other conditions which predispose to cerebral embolism may be hazardous because of the risk of bleeding into the infarcted cerebral area.

Use of Anticoagulants

Concurrent use of anticoagulants with urokinase may be hazardous and is not recommended. Before beginning urokinase infusion in patients being treated with heparin, the effects of heparin should be allowed to decrease, as evidenced by a thrombin time of less than twice normal or an activated partial thromboplastin time (APTT) of less than one and one-half times normal. Similarly, heparin should be withheld for four hours following urokinase therapy unless the prothrombin time is in the normal range.

Rethrombosis has been observed after completion of urokinase treatment. In order to minimize this risk, administration of intravenous heparin followed by oral anticoagulant therapy is considered a necessary adjunct following urokinase therapy (see Dosage and Administration).

Use in Pregnancy

See Contraindications.

Use in Children

Safety and effectiveness of urokinase therapy in children have not been established; therefore, treatment of such patients is not recommended.

Precautions

Drug Interactions

Drugs that may alter platelet function, e.g., aspirin, indomethacin, and phenylbutazone, should be avoided during urokinase treatment. The interaction of BREOKINASE with other drugs has not been studied.

Laboratory Monitoring

In patients who have received heparin, the thrombin time or APTT should be measured prior to starting urokinase. (See Warnings.) Similarly, the prothrombin time should be monitored during and following urokinase therapy prior to instituting heparin. (See Dosage and Administration.) During urokinase administration the levels of fibrinogen, plasminogen, Factor V, and Factor VIII are usually substantially decreased, and the level of fibrin and fibrinogen degradation products (FDP/fdp) is increased. Reduced fibrinogen and increased FDP/fdp result in a prolongation of the prothrombin time. Changes in these tests serve as confirmation of the existence of a lytic state. There are no data to indicate that alteration of dosage is required on the basis of these tests, although as a general rule the prothrombin time should not be allowed to increase above 30 seconds.

Urokinase infusion should be terminated immediately if serious bleeding occurs.

Adverse Reactions

Careful observance of the contraindications, warnings, and precautions to the use of urokinase is essential to minimize the incidence and severity of adverse effects.

Bleeding

Incidence

In controlled clinical trials of streptokinase and urokinase, severe bleeding (requiring a transfusion of greater than two units of blood) was seen in 4% of streptokinase patients and 6% of patients receiving urokinase. Several fatalities due to cerebral hemorrhage have occurred during urokinase therapy.

Spontaneous bleeding of a less severe degree has been observed during urokinase treatment at about twice the frequency as that occurring during heparin therapy. Oozing of blood from sites of skin puncture is frequent; therefore, all invasive procedures, especially arterial punctures and intramuscular injections, should be avoided and intravenous punctures kept to a minimum before and during treatment with urokinase.

A moderate decrease in hematocrit not accompanied by clinically detectable bleeding was observed in about 20% of patients treated with urokinase.

Management of Severe Bleeding

Urokinase therapy must be discontinued if serious bleeding occurs. Packed red cells are indicated for large blood loss. Plasma volume expanders (other than Dextran) may be used to replace blood volume deficit. Whole blood may also be used if it alone is available. The use of aminocaproic acid (ACA, AMICAR®) in humans as an antidote for urokinase has not been documented, but its use may be considered if the hemorrhage is unresponsive to blood replacement (see Warnings).

Allergic Reactions:

Urokinase is a protein of human origin, and *in vitro* as well as intradermal tests in humans gave no evidence of induced antibody formation. However, the possibility of serious allergic reactions (including anaphylaxis) occurring during its use cannot be excluded. There have been rare reports of relatively mild allergic reactions, e.g., bronchospasm and skin rash.

Fever:

Febrile episodes occurred in about 2-3% of urokinase treated patients. A causal relationship to urokinase has not been established. Symptomatic treatment with acetaminophen rather that aspirin is usually sufficient.

Dosage and Administration

Preparation

Reconstitute each vial of Breokinase by aseptically adding 8.0 ml of Sterile Water for Injection, U.S.P. (It is important that *only* Sterile Water for Injection, U.S.P., *without* preservatives, be used. Bacteriostatic Water for Injection or other diluents should not be used.) Swirl gently to avoid foaming. **Do Not Shake.** Because Breokinase contains no preservatives, it should not be reconstituted until immediately before using. Any unused portion of the reconstituted material should be discarded.

Each ml of reconstituted Breokinase contains 31,250 C.T.A. Units of urokinase activity.

Dosing

Breokinase is Intended for Intravenous Infusion Only

Urokinase treatment should be begun as soon as possible after the occurrence of pulmonary embolism, and no later than five days after onset. A priming or loading dose of 2000 C.T.A. Units/lb (4400 C.T.A. Units/kg) of reconstituted Breokinase is given over a period of ten minutes. This is followed by a continuous infusion of 2000 C.T.A. Units/lb/hr (4400 C.T.A. Units/kg/hr) for 12 hours.

A constant infusion pump independent of all other intravenous systems should be used. Do not expose reconstituted solution to excessive heat, such as high intensity lights, during administration.

Anticoagulation Following Breokinase Treatment

At the end of Breokinase infusion, treatment with heparin by continuous intravenous infusion followed by oral anticoagulant therapy is recommended to minimize rethrombosis. Heparin treatment should begin 4 hours after Breokinase infusion, or sooner if the prothrombin time has returned to normal. See manufacturer's prescribing information for proper use of heparin.

How Supplied

Breokinase is supplied as a sterile lyophilized preparation. Each vial contains 250,000 C.T.A. Units of urokinase activity and approximately 0.9 millimoles sodium phosphates. The vials should be stored at or below 4° C.

Nongeometric Determination of Left Ventricular Volumes From Equilibrium Blood Pool Scans

GREGORY J. DEHMER, MD

JAMES T. WILLERSON, MD, FACC

Dallas, Texas

This study assesses the utility of a scintigraphic, nongeometric technique for the determination of left ventricular volumes. Accordingly, gated blood pool scintigraphy and cineangiography were performed within a 24 hour period in 22 patients. Scintigraphic volume measurements were calculated from individual frames of a modified 35° left anterior oblique projection using an algorithm designed to consider (1) the background-corrected left ventricular activity normalized for activity per milliliter of peripheral venous blood; (2) total study time; (3) number of frames acquired per cardiac cycle; and (4) percent of the cardiac cycle acquired. Angiographic volumes were calculated by the area-length method and the Kennedy regression equation. There was an excellent correlation between scintigraphic and angiographic methods for all volume measurements grouped together ($r = 0.985$, standard error of the estimate [SEE] = 14.6 ml) as well as for segregated end-diastolic volumes ($r = 0.985$, SEE = 16.2 ml) and end-systolic volumes ($r = 0.988$, SEE = 14.7 ml). Prospective testing of the independent ability of scintigraphy to estimate ventricular volumes was provided for by studying an additional 13 patients, and good agreement was found between scintigraphic and angiographic determinations of left ventricular end-systolic and end-diastolic volumes. Thus, radionuclide techniques, which are independent of geometric assumptions, may be utilized for the quantitation of left ventricular volumes.

The determination of absolute left ventricular volumes is a useful method in the evaluation of cardiac function.[1] Previous studies have demonstrated its value in predicting prognosis in patients with valvular heart disease[2] and in assessing the effects of various pharmacologic interventions on the left ventricle.[3,4] Ideally, a method for the determination of left ventricular volumes should be safe, relatively rapid, noninvasive and easily reproducible both at rest and during exercise.

At present, there are several methods for the quantitation of left ventricular volumes; each entails the geometric analysis of assorted spatial measurements, including those obtained from cineangiography of the left ventricle,[5–7] surgically implanted epicardial metallic markers,[8,9] echocardiographic area-length determinations[10] and left ventricular outlines obtained from gated equilibrium blood pool scintigrams and first pass studies.[11] Although widely utilized, contrast ventriculography is an invasive procedure that involves some risk, and multiple determinations of left ventricular volumes cannot be performed over a short period of time. Left ventricular volume determinations based on the analysis of epicardial metallic markers implanted at the time of cardiac surgery are useful for postoperative studies of patients, but this method cannot be employed in patients who have not had surgery. The echocardiographic determination of left ventricular volumes is also useful, but asymmetric wall motion abnormalities, especially prominent in patients with ischemic heart disease, preclude the use of single di-

mension echocardiography for accurate determination of both left ventricular ejection fraction and end-systolic volumes.[12] Although two dimensional echocardiography eliminates some of these problems, it also relies on geometric principles for the determination of left ventricular volumes, and satisfactory studies cannot be obtained in all patients.

With the development of multigated equilibrium blood pool scintigraphy, a practical and noninvasive means of visualizing the heart has become available. Numerous studies have documented the utility and accuracy of dynamic scintigraphy in assessing left ventricular ejection fraction and in the qualitative or semiquantitative evaluation of regional left ventricular wall motion.[13,14] In addition, recent studies have demonstrated the value of gated blood pool imaging for the evaluation of left ventricular performance after myocardial infarction,[15] the assessment of ventricular dysfunction in patients with aortic regurgitation[16] and the identification of ischemic heart disease.[17] Although it is possible to calculate left ventricular volumes from scintigraphic images utilizing the area-length geometric formula routinely applied in cineangiography, such determinations are hampered by the miniature display size used for most gated images, so that a small error in the measurement of area or length causes a substantial alteration in the calculated ventricular volumes. Scintigraphic images of cardiac blood pools have edges that are often indistinct, yet accurate detection of the ventricular boundaries is vital for reliable geometric volume determinations. Even when imaging quality is excellent, discerning the left ventricular boundary is difficult. The expansion of gated images to a size large enough to allow easier measurement of area and length results in a sizable loss of resolution and further complicates accurate determination of the ventricular border.

The purpose of the present study was to assess the utility of a nongeometric method for determining left ventricular volumes from the time-activity data obtained during gated equilibrium blood pool scintigraphy.

Methods

Patients: Initially, gated equilibrium blood pool scintigraphy and single plane left ventricular cineangiography (right anterior oblique projection) were performed in 22 patients within a 24 hour period for correlation of left ventricular volume determinations. The group comprised 12 men and 10 women with a median age of 50 years (range 24 to 68). Indications for cardiac catheterization included some sequelae of coronary artery disease in 15, valvular heart disease in 4 and congestive cardiomyopathy in 3. By subjective angiographic evaluation, 10 of the 22 patients had normal wall motion, whereas 6 demonstrated diffuse hypokinesia. The remaining six patients demonstrated segmental wall motion changes, four in either the anterolateral or anteroapical segments and two in the inferior wall segments. There was no change in the patients' clinical condition or medication regimen between the scintigraphic and angiographic determinations of left ventricular volumes.

Subsequently, 13 additional patients were evaluated prospectively to determine further the accuracy of the scintigraphic estimation of ventricular volumes when angiograms and scintigrams are obtained within a short time of one another.

Technique for angiographic left ventricular volume determination: Cardiac catheterization was performed utilizing either the Sones[19] or Judkins[20] technique. Single plane right anterior oblique ventriculograms were obtained at the start of each catheterization and subsequently analyzed to allow calculation of left ventricular ejection fraction and absolute ventricular volumes. Angiographic volumes were determined by the area-length method[5] and the Kennedy regression equation.[7]

Technique for multigated equilibrium blood pool scintigraphy: In vivo labeling of red blood cells was accomplished by the administration of unlabeled stannous pyrophosphate (Pyrolite, New England Nuclear) before administration of 30 mCi of technetium-99m sodium pertechnetate, as previously described.[15,18] Data collection was performed with a standard gamma scintillation camera (Ohio Nuclear Series 100) equipped with an all-purpose parallel hole collimator and interfaced with a dedicated on-line computer system (Ohio Nuclear VIP 450). Equilibrium gated blood pool scintigrams were obtained in multiple projections including a 35° left anterior oblique projection modified to include a 15° caudad angulation of the collimator surface. Although this projection frequently separates the right from the left ventricle, the angle of obliquity was always readjusted to allow the clearest separation between the ventricles while minimizing the interventricular septal thickness. All studies were gated for 28 frames per cardiac cycle and collected for a preselected percent (90 to 100 percent) of the cardiac cycle. Before imaging in the modified 35° left anterior oblique projection, an anterior imaging projection was acquired to an average count density of 175 counts per pixel over the left ventricle. This typically required 5 to 8 minutes and resulted in approximately 250,000 counts per frame of the study. The imaging time of the anterior projection was utilized as a guide to program image acquisition of the modified 35° left anterior oblique view to occur for a time period long enough to ensure adequate data collection. All data were stored on magnetic tape for subsequent analysis.

Rationale and equation for the calculation of scintigraphic left ventricular volumes: Several concepts are fundamental to the extraction of quantitative data from equilibrium blood pool images. If an intravenously injected radioactive tracer is uniformly distributed throughout and confined to the vascular space, then the spatial distribution of absolute tracer is identical to that of the blood. The radioactivity per unit volume of tissue is then proportional to the volume of blood contained within that volume of tissue. External monitoring of the changing spatial distribution of radioactivity within the cardiac blood pool is then analogous to visualizing the deformations of the blood within the cardiac chambers. Changes in regional radioactivity are then proportional to changes in regional blood volume.

Bidimensional gamma scintillation camera recordings of the tridimensional radioactivity within the cardiac blood pool produce single plane projections of the central vascular anatomy. The density (or recorded activity) of each picture element (pixel) in the resulting image matrix represents the activity of the blood contained within the volume defined by the projection of the pixel area through the patient. If photons originating from any region of this volume were detected with equal sensitivity, then the number of detected counts per pixel would be proportional to the total blood volume within the pixel projection. If the detectable radioactivity originating from the left ventricle could be isolated from radioactivity originating from other major vascular structures by suitable

selection of projection angle, then the total activity of those pixels constituting the left ventricular silhouette should be proportional to left ventricular blood volume. Absolute ventricular volume could then be obtained by normalization of left ventricular activity for the activity of peripheral venous blood.

Practical implementation of such an analysis is complicated by several factors. A significant portion of the total activity detected by the left ventricular pixels is contributed by nonventricular, or background, activity. Photons originating from periventricular structures may undergo Compton tissue interaction and be scattered into the left ventricular silhouette. Vascular activity in the chest wall interposed between the ventricle and the detector undoubtedly contributes to apparent left ventricular activity. For our analysis to be effective, total left ventricular activity must be corrected for this nonventricular component. A reasonable estimation of background activity may be obtained from an analysis of periventricular pixels chosen so as not to overlie another major vascular structure. The difficulty lies in the consistency and reproducibility of such an analysis. This is underscored by the following example: Suppose a study is acquired in a zoom mode so that the left ventricle occupies a 32 × 32 segment of a 64 × 64 matrix. A change in calculated background activity of only 5 counts/pixel would alter left ventricular activity by some 20,000 counts. Reproducible background determination is therefore imperative.

A more complicated problem is that of attenuation. Attenuation refers to the partial absorption of photons traveling through the body. Attenuation is dependent on several factors, including photon energy and the thickness and specific gravity of tissue. For the 140 keV photons of technetium-99m, more than 85 percent are transmitted through 2 cm of water but less than 35 percent can penetrate 10 cm of water.[21] This would seem to compromise severely our analysis because photons in the regions of the ventricle more distant from the detector will have a reduced probability of detection compared with that of photons originating in regions closer to the detector. Correction for such attenuation is extremely difficult because the correction is dependent not only on actual measurements in the patient of attenuation, but also on a geometric analysis of left ventricular shape. One approach might be to ignore attenuation factors completely. There is actually some justification for this approach because left ventricular time-activity curves and left ventricular volume curves in the same patient are virtually superimposable.

Calculation of left ventricular volumes then requires only the determination of background-corrected left ventricular activity normalized for the activity of peripheral venous blood. The equation for calculation of left ventricular volume is then simply:

$$\text{Volume (ml)} = \frac{\text{Background-corrected ventricular activity (counts/s)}}{\text{Peripheral blood activity (counts/s/ml)}} \times A,$$

where A is an attenuation factor that may be complex. Peripheral blood activity is obtained by counting a known volume of peripheral venous blood under conditions of similar detector geometry and correcting for isotope decay to reflect the actual blood activity during the image acquisition. Ventricular activity is further defined as follows:

$$\text{Ventricular activity (counts/s)} = \frac{\text{Left ventricular counts at end-systole or end-diastole} - \text{Background counts}}{\text{Total acquisition time (s)/Individual frame}}.$$

Total acquisition time per individual frame of the study (T_{frame}) *is equal to:*

$$T_{frame} = \frac{\text{Percent of cardiac cycle acquired} \times (\text{total study time} - \text{"off time"})}{\text{Number of frames per cardiac cycle}},$$

where "off time" refers to that segment of the study during which no data are acquired (input halted because of variations in R-R intervals or arrhythmia). In short this can be expressed as:

$$T_{frame} = \frac{\text{Percent of cycle}}{\text{Number of frames}} (T_{total} - T_{off}).$$

If the heart rate is perfectly regular and image acquisition continuous, T_{off} equals zero. Because this is the exception rather than the rule, T_{off} must be determined in some fashion. The computer system utilized for this study allows the acquisition of an image for any specified time interval. Should an interruption of image acquisition occur, the computer automatically compensates by lengthening the specified acquisition time interval by a time equal to the "off time." Hence, in the system used for this study, T_{off} always equaled zero. Thus,

$$T_{frame} = \frac{\text{Percent of cycle}}{\text{Number of frames}} \times T_{total}.$$

Therefore, in final form the equation for the calculation of scintigraphic volumes is:

$$\text{Volume (ml)} = \frac{\text{Left ventricular counts} - \text{Background counts}}{\dfrac{\dfrac{\text{Percent of cycle}}{\text{Number of frames}} \times T_{total}}{\text{Peripheral blood activity} \times e^{-\lambda t}} \times A},$$

where $e^{-\lambda t}$ is the general equation for isotope decay, $\lambda = 0.693/T^{1/2}$, t = time (in minutes) from counting the peripheral blood sample to the midpoint of the gated study, and $T^{1/2}$ for technetium-99m is 360 minutes. It should be emphasized that differences in heart rates between individual subjects are accounted for by these calculations.

Technique of scintigraphic left ventricular volume determination: Left ventricular volumes were determined from the isolated end-diastolic and end-systolic frames of the study. The location of these frames in the gated sequence was determined by the generation of a left ventricular time-activity curve for the 28 frames of the study. The end-diastolic frame was that associated with the peak of the curve, and the end-systolic frame was that associated with the nadir of the curve. Once isolated, these frames were digitally filtered with a nine point weighted smoothing routine. In order to determine the background activity the end-diastolic frame was utilized to generate horizontal count profiles (counts per pixel versus distance) at three levels through the left ventricular cavity (Fig. 1). Each curve typically manifests two peaks, representing the maximal right and left ventricular activity, separated by a valley indicative of diminished activity in the region of the interventricular septum. A plateau in the count profile curve is noted in the area immediately adjacent to the left ventricular free wall. These curves can be sampled to determine the number of counts per pixel at any point along the curve. For each of the three curves the count values at the points where the plateau portions intersected with the adjacent regions reflecting diminishing activity at the ventricular borders were averaged to obtain the background activity. In the occasional curve that did not exhibit an abrupt change in this region, a count value representing the average between

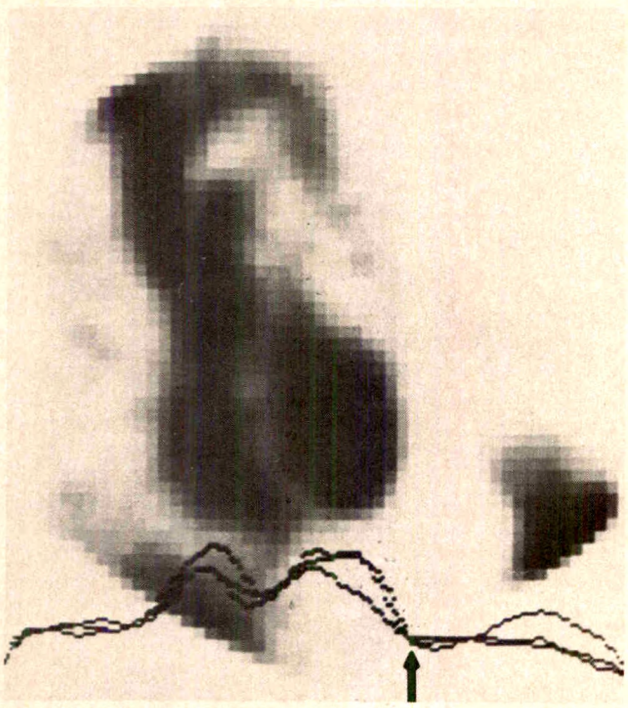

FIGURE 1. End-diastolic image with horizontal count profile curves. Curves are constructed through the high, mid and low portion of the area of left ventricular activity. These curves can then be sampled to determine the number of counts per pixel at any point along the curve. In general, the count value at the point where the plateau portion intersected with the portion reflecting diminishing activity at the ventricular border was used as the value for the background activity. An **arrow** indicates where background was chosen.

the plateau value and a value clearly within the ventricle was used for the background activity. Each of the three curves was sampled in order to arrive at an activity value that adequately represented the activity in the area immediately adjacent to the left ventricular free wall. The background activity subsequently was subtracted from the end-diastolic and end-systolic frames.

The left ventricular cavity was outlined and a region of interest constructed over the left ventricle (*Fig. 2*). Careful attention was given to constructing the region of interest so that left atrial activity was excluded if left ventricular and left atrial activity were clearly separated. If the mitral valve plane was not clearly delineated, the valve plane was assumed to be perpendicular to the plane of the interventricular septum, originating at the uppermost definable point of the septum. The septal border of the left ventricle was constructed so as to course down the middle of the area of diminished activity representing the interventricular septum. The region of interest was completed so as to include all left ventricular activity (Fig. 3). The end-systolic region of interest was constructed in the same fashion and its activity was computed. This process was repeated and the average number of counts for the two determinations was used in the calculation of scintigraphic left ventricular volumes.

The activity of a peripheral venous blood sample was determined after a minimum of 10 minutes was allowed for in vivo red cell binding and equilibration within the blood pool. A 3 cc sample of blood was then withdrawn in a standard Stylex syringe and counted with the gamma camera. Care was taken in the choice of a venipuncture site so that it was anatomically isolated from the site of either pyrophosphate or isotope administration. We routinely used a vein in the right antecubital fossa for administration of pyrophosphate and isotope and a vein in the left antecubital fossa for venous

FIGURE 2. Outline construction for a left ventricular region of interest. The outline bisects the plane of the interventricular septum and is constructed to include all activity along the left ventricular free wall. The background has been subtracted in this representative figure.

FIGURE 3. Completed left ventricular region of interest. The mitral valve plane has been constructed to lie perpendicular to the plane of the interventricular septum originating at the uppermost definable portion of the septum.

sampling. The venous blood samples were counted in a consistent fashion using a holder designed to insure placement of the syringe at a constant distance of 5.08 cm from the surface of the collimator and in the center of the field of view. The blood in the syringe was counted twice, each period of counting being 2 minutes in length. The activity of the blood sample was determined by the construction of a region of interest over the image produced by the syringe and by the subsequent determination of the number of counts within the region of interest. The average of these two determinations was used in the equation to calculate left ventricular volumes.

Correction of the left ventricular activity determined for radioactive decay during the study period is necessary because the half-life of technetium-99m pertechnetate is relatively short (approximately 6 hours) and because combination resting and exercise examinations may require approximately 2 hours to complete. As part of the routine protocol, a stopwatch was started at the time of isotope administration and an accurate record of time intervals between the various phases of the study was kept. For calculation of the amount of isotope decay, the time period from the midpoint of the syringe blood-counting period to the midpoint of the gated acquisition period was used. Decay was calculated using the standard equation:

$$R_t = R_0\, e^{-0.693t/T^{1/2}},$$

where R_t is the activity at any time (t), R_0 is the activity of the sample at time zero and $T^{1/2}$ is the half-life of the isotope administered.

Total acquisition time of the study was chosen so as to ensure at least 250,000 counts per frame of the gated study. Accurate determination of the acquisition time period was provided by programming the computer to acquire the gated study for that preselected period of time. The intrinsic timing module of the computer allowed for automatic correction of any disruption of the imaging period due to cardiac arrhythmias. In a similar fashion, the acquisition phase was preset to run for a specified number of frames per cardiac cycle (28 frames/cycle) and a percent of the cardiac cycle (90 to 100 percent), thus ensuring uniformity in these variables.

Scintigraphic left ventricular volumes were calculated utilizing these six variables and using the final equation described earlier. In addition to the scintigraphic variables, body surface area and chest circumference and diameter (both measured in the fifth intercostal space) were determined in 20 patients to ascertain whether there was any predictable attenuation factor relating body to chest size to scintigraphic volume determinations.

Results

Angiographic volume determinations: Angiographic and scintigraphic volume determinations along with patient data are presented in Table I. The angiographic data were analyzed independently by two investigators and the average of their two determinations was used for volume correlation with the scintigraphic data. The left ventricular angiographic end-diastolic

* Scintigraphic and angiographic volumes are presented as the average of two determinations. All angiographic volume measurements are in milliliters; scintigraphic volumes are calculated using the formulas described in the Methods section.

BSA = body surface area; CABG = coronary arterial bypass graft surgery; IHSS = idiopathic hypertrophic subaortic stenosis; LV = left ventricular; SD = standard deviation; — = not measured.

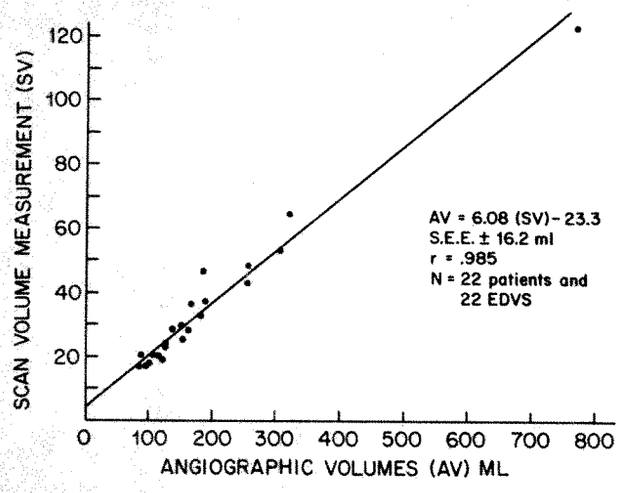

FIGURE 4. Relation between scintigraphic (SV) and angiographic (AV) end-diastolic volumes (EDVS) in milliliters (ML).

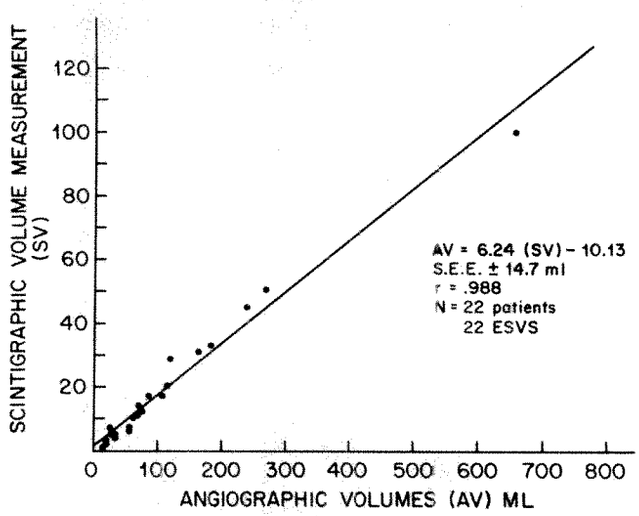

FIGURE 5. Relation between scintigraphic (SV) and angiographic (AV) end-systolic volumes (EDVS) in milliliters (ML).

volumes ranged from 85 to 768 ml and the left ventricular angiographic end-systolic volumes from 13.5 to 660 ml. The overall interobserver variation in determinations of angiographic volume was 8.2 percent. The interobserver variation was 9.7 percent for end-systolic volume and 6.8 percent for end-diastolic volume.

Scintigraphic volume determinations: The analysis of scintigraphic data was performed independently by two investigators, and the average of their two determinations was used for correlation with angiographic volume data. The left ventricular scintigraphic volumes ranged from 16.6 to 123.6 ml at end-diastole and from 1.4 to 99.1 ml at end-systole. The overall interobserver variation in the scintigraphic volume measurements was 7.5 percent. The interobserver variation for end-diastolic volume was 6.3 percent and that for end-systolic volume, 8.7 percent.

Correlation of the two methods: The scintigraphically estimated left ventricular volumes were consistently lower than those determined with angiography because of the attenuation encountered between the left ventricular cavity and the detector surface. However, no predictable attenuation factor could be determined by relating the measurement of body surface area, chest circumference or chest diameter to the scintigraphic volumes.

Nevertheless, there was an excellent correlation between the angiographic volume measurements (AV) and the scintigraphic volume (SV) measurements. For left ventricular end-diastolic volumes the relation, shown in Figure 4, was AV = 6.08 (SV) − 23.3 ml ($r = 0.985$, SEE = 16.2 ml, $p < 0.01$).

For left ventricular end-systolic volumes, the relation, shown in Figure 5, was AV = 6.24 (SV) − 10.13 ml ($r = 0.988$, SEE = 14.7 ml, $p < 0.01$).

Prospectively evaluated group: We have more recently evaluated 13 additional patients in whom separate scintigraphic and angiographic measurements of ventricular volumes were obtained using similar methods within several days of one another (Table II). There was generally good agreement between the volume measurements obtained with both techniques. End-diastolic volumes correlated with one another at $r = 0.94$, and end-systolic volumes at $r = 0.98$; all volumes taken together also correlated well ($r = 0.95$).

Means ±SD	176.0 ±132.2/ 85.4 ±87.05	0.61 ±0.18	169.2 ±85.88/ 86.5 ±70.43	0.54 ±0.14

* Scintigraphic volumes were calculated using the formulas described in the Methods section and are presented as the values obtained after substitution into the derived regression equations.

EDV = left ventricular end-diastolic volume; EF = left ventricular ejection fraction; ESV = left ventricular end-systolic volume; SD = standard deviation.

Discussion

The present study demonstrates that time-activity data derived from equilibrium gated blood pool imaging may be utilized to estimate left ventricular end-diastolic and end-systolic volumes in patients with various types of cardiovascular diseases. These scintigraphic volume determinations are independent of currently used

geometric assumptions regarding the shape of the left ventricular cavity. Geometric volume determinations, whether from cineangiographic or scintigraphic silhouettes, assume that the left ventricle is shaped like an ellipsoid; therefore, there may be substantial error at the extremes of left ventricular size or with unusual ventricular configurations.

Reliability of method: The ability to estimate left ventricular volumes scintigraphically depends on the quantitation of several variables. First, care must be taken to measure the number of radioactive events within the left ventricular cavity as well as within a venous blood sample of known volume. Second, attention must be paid to a consistent method of background activity subtraction and to the correction of left ventricular activity for the decay of radioisotope that occurs between the counting of the venous blood sample and the imaging of the left ventricle. The method we have used for background subtraction is empirically derived, but we believe that it is more suitable than a simple determination of background activity at a randomly chosen region lateral to the left ventricle. Third, one must measure accurately the total acquisition time of the study and correct this for any interruptions caused by arrhythmias. Lastly, one must have knowledge of the number of frames over which the R-R interval was gated as well as the percent of the R-R interval that was gated. Background activity can be determined in a consistent manner by generating a horizontal count profile of the number of counts per pixel in several slices taken at various levels through the left ventricular cavity. Similarly, the construction of a region of interest for the determination of the total amount of left ventricular activity must be done in a consistent fashion. The excellent correlation between the scintigraphic and angiographic volume measurements in this study was obtained only after strict criteria were adhered to for the determination of left ventricular and background activity. Inconsistency in the measurement of these two variables will cause substantial errors in estimation of absolute left ventricular volume by the scintigraphic method. By paying careful attention to these details of scintigraphic analysis, we obtained excellent correlations between the cineangiographic and scintigraphic measurements of end-diastolic and end-systolic volumes.

It is surprising that there was no substantial increase in attenuation at larger ventricular volumes. Theoretically, this effect would be predicted. Further modeling experiments are necessary to clarify this discrepancy. One possible explanation may be that the total attenuation (of chest wall and lungs, for example) is of such magnitude that any change in attenuation due to changes in ventricular size is insignificant. Presumably, attenuation by soft tissues explains the considerably lower scintigraphic than angiographic estimates of ventricular volumes.

The comparison of the scintigraphic and angiographic left ventricular volume determinations yielded regression formulas for the estimation of actual left ventricular volumes from the scintigraphic volume measurements. These relations have been compared separately for end-diastolic and end-systolic left ventricular volumes. There is an excellent correlation for each group, and the standard error of estimation for each correlation falls within an acceptable range.

Clinical applications: The ability to measure left ventricular volumes using noninvasive scintigraphic techniques without the need for geometric assumptions is of potential importance. Quantitation of left ventricular volumes, and in particular left ventricular end-systolic volume, can be used to estimate global contractility,[22] to predict prognosis in patients with hemodynamically important valvular heart disease[23] and to assess the influence of various physiologic and pharmacologic interventions on left ventricular function.[1,2] Furthermore, these measurements can be used in patients with ischemic and valvular heart disease to characterize serially left ventricular function both at rest and during exercise.

Although data provided by others[24,25] appear to be in agreement with those described in this report, there is continued need to correlate scintigraphic and angiographic measurements of left ventricular volumes in larger numbers of patients with various cardiac abnormalities. In addition, the further development of a computer-assisted, accurate, highly consistent method of left ventricular edge detection, valve plane definition and background activity determination will make scintigraphic time-activity volume determinations less vulnerable to operator-induced errors. If the relations shown in the present study and in the studies by Slutsky et al.[24,25] can be substantiated by additional studies in larger numbers of patients, this approach will be very useful. This imaging approach requires no additional equipment or time above that already necessary for gated blood pool imaging. Further, this technique is relatively noninvasive, is easily repeatable both at rest and during exercise and can be performed in essentially all patients who require clinical cardiovascular evaluation.

Acknowledgment

We are indebted to R. Scott Lyons, Norman Vance and Jean Cruz for their technical assistance in performing the gated blood pool imaging, to Richard Browne, PhD, for his help in the statistical analysis of the data, to Belinda Lambert and Laurie Grey for their secretarial assistance, and to the nurses, medical house officers and cardiac fellows at Parkland Memorial Hospital for their cooperation and help in the performance of these studies.

A New Approach to Visualize the Left Main Coronary Artery Using Apical Cross-Sectional Echocardiography

Patients undergoing coronary arteriography were studied to evaluate the feasibility of use of cross-sectional echocardiography to detect the left main coronary artery. Visualization of the left main coronary artery from the cardiac apex was attempted using a cranial transducer angulation. With this approach, the left main coronary artery was adequately visualized in 27 of 35 consecutive patients (77 percent) who were prospectively evaluated; in 12 of the 27 the bifurcation was clearly seen. In 26 of the 27 patients cross-sectional echocardiography correctly assessed the patency of the left main coronary artery as judged with coronary angiography. One patient had a false positive echocardiographic study; there were no false negative studies. A comparison of the short axis versus apical cross-sectional techniques in another group of 30 patients revealed the superiority of the apical approach in visualization of the left main coronary artery and its bifurcation; combined use of both techniques allowed for a 93 percent (rate of) success. Thus, apical cross-sectional echocardiography permits visualization of the left main coronary artery and its bifurcation and, therefore, has the potential for detecting left main coronary obstructive lesions.

Obstructive atherosclerotic disease of the left main coronary artery has an ominous natural history with a high yearly mortality rate. Clinicians strive to detect its presence in symptomatic patients to determine the need for coronary angiography and possible bypass graft surgery.[1-12] Unfortunately, the clinical history, findings on physical examination and the results of exercise stress tests when compared with coronary angiographic data are not specific for the presence of left main coronary artery disease. Weyman et al.[13] described the use of cross-sectional echocardiography to visualize the left main coronary artery, but no further reports have appeared on the potential applicability of their technique to clinical use. In this study we describe a new approach to visualize the left main coronary artery using the modified apical or four chamber view on phased array cross-sectional echocardiography.

Methods

Study Group

The study consisted of three separate investigations of nonoverlapping patients identified as Groups A, B and C.

Group A: The 15 patients in this group were subjected to cross-sectional echocardiography after coronary angiography was performed to define coronary arterial anatomy. All 15 patients had coronary arterial obstruction, and 3 demonstrated more than a 75 percent transluminal obstruction of the left main coronary artery. In one patient in this group, cross-sectional echocardiography was performed at the time of coronary angiography to visualize the tip of a Judkins coronary catheter as it moved from the root of the aorta into the ostium of the left main coronary artery.

Group B: Thirty-five consecutive patients referred for cardiac catheterization were prospectively evaluated with cross-sectional echocardiography immediately before the catheterization study. Echocardiographic studies were interpreted without knowledge of the clinical, laboratory or electrocardiographic data or the results of cardiac catheterization in order to avoid observer bias. In this group, there were 28 men and 7 women aged 38 to 73 years. Left main coronary artery disease was considered present when there was a 50 percent or greater decrease in luminal diameter.

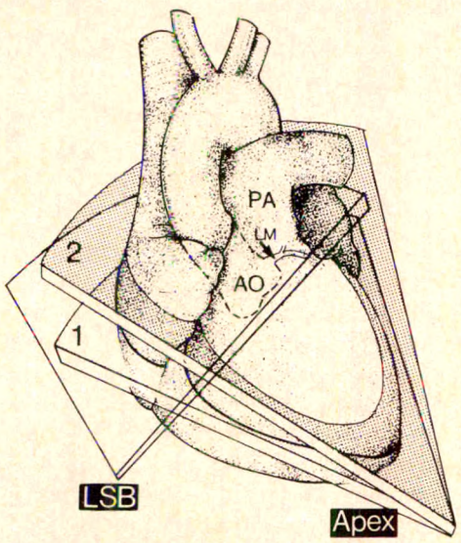

FIGURE 1. Schematic drawing of the heart depicting the aorta (AO), pulmonary artery (PA) and left main coronary artery (LM). Both the apical (Apex) and the short axis view at the left sternal border (LSB) are shown.

Group C: Thirty patients were evaluated prospectively using the short axis cross-sectional echocardiographic technique of left main coronary arterial visualization of Weymen et al.[13] as well as the apical approach to compare the technical feasibility and results of these two techniques. The echocardiographic evaluation was performed before cardiac catheterization.

Cross-Sectional Echocardiographic Techniques

Cross-sectional echocardiography was performed using a commercially available real time, phased array imaging system[14] (Varian V-300 Ultrasonograph or Toshiba SSH-11A). The transducers contained 32 precisely mounted piezoelectric crystals in a tight linear array operating at a 2.25 (Varian) or 2.4 (Toshiba) megahertz frequency. The ultrasonic beam was electronically swept through an angle of 84° or 78°, producing a fan-shaped cross-sectional image. The image was displayed in real time at a rate of 30 frames/s, and permanently recorded on a 1 inch (2.54 cm) video cassette (International Video Corporation IVC-XV 815/816 or Victor CR6060). The stored image was subsequently reviewed in real time slow motion or frame by frame presentation. Individual frames of the videotape recording were photographed using a Polaroid® camera.

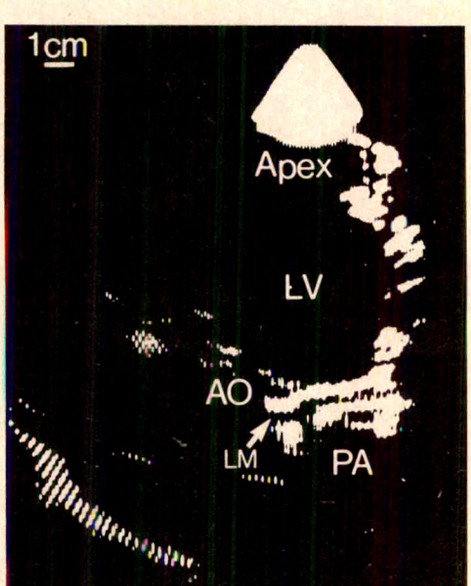

FIGURE 3. Representative cross-sectional echocardiogram of a patient with a normal left main coronary artery. The **white arrow** identifies the ostium of the left main coronary artery (LM) and the location of the aorta (AO), pulmonary artery (PA) and left ventricle (LV).

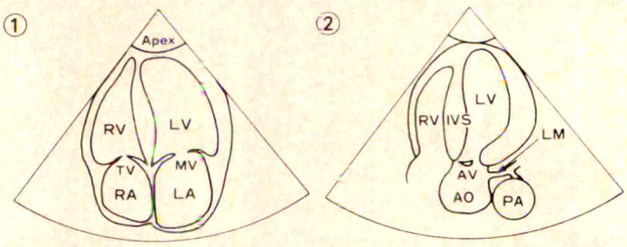

FIGURE 2. Diagrammatic illustration of the transected heart as seen from the apical view. The right ventricle (RV), left ventricle (LV), tricuspid valve (TV), mitral valve (MV), right atrium (RA), and left atrium (LA) are shown. **Panel 1** corresponds to the beam 1 tomographic view from Figure 1. **Panel 2** represents an anterior projection from the apical view demonstrated in beam 2 of Figure 1. In this view the interventricular septum (IVS), aortic valve (AV), aorta (AO), pulmonary artery (PA) and left main coronary artery (LM) are shown.

Echocardiographic studies were performed with the patient in the left lateral position with the transducer positioned at the cardiac apex for visualizing the apical view of the heart, according to the technique described by Schiller and Silverman[15] (Fig. 1, beam 1). After the standard four chamber view (Fig. 2, panel 1), in which both the ventricles and atria are imaged along with their respective atrioventricular valves, was obtained, the transducer was angled slightly anterior to visualize the left ventricular outflow tract, aorta and pulmonary artery (Fig. 2, panel 2 and Fig. 1, apex, beam 2). The transducer was then rotated clockwise to bring the echocardiographic beam parallel to the course of the left main coronary artery. Careful control of the gain, rejection and contrast controls were essential in detection of the left main coronary artery.

In Group C, the transducer was then rotated to the standard echocardiographic window along the left sternal border and a short axis cut of the heart at the level of the great vessels and left main coronary artery (Fig. 1, LSB) was obtained. The left main coronary artery was imaged using the technique of Weyman et al.[13]

Results

Normal coronary arteries: Figure 3 illustrates a representative cross-sectional echocardiogram demonstrating the left main coronary artery as detected with the apical approach. The lumen of this artery appears as two parallel bands of echoes enbracing an echo-free space. The ostium of the left main coronary artery must be shown to be contiguous with the root of the aorta. In Figure 3 the left main coronary artery was measured to be 1.0 cm in length.

Left main coronary artery disease: Group A: The three patients with left main coronary arterial obstruction on cineangiography had their obstruction identified in the apical view of the cross-sectional echocardiogram as a disruption of the continuous

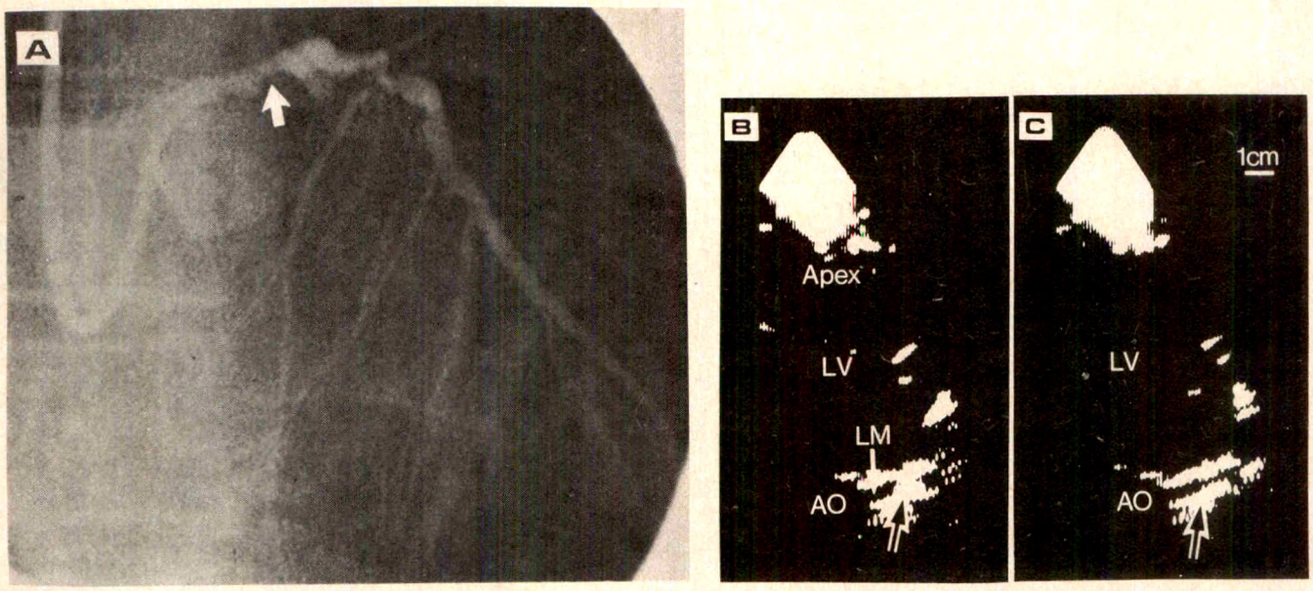

FIGURE 4. A, coronary arteriogram demonstrating a high grade obstruction in the left main coronary artery at the tip of the **white arrow. B,** same patient. Cross-sectional echocardiogram taken from the apex in which the aorta (AO) and left ventricle (LV) are seen. The left main coronary artery (LM) is seen arising from the aorta. The ostium is identified by the tip of the **white arrow.** The **black arrow** demonstrates an apparent break in the continuous echo free space of the left main lumen. In **panel C,** the transducer is angulated slightly clockwise and the lumen appears narrowed at the tip of the **black arrow** rather than 100 percent obstructed. The bifurcation point is seen distal to this point.

echo-free space. Coronary arteriograms and cross-sectional echocardiograms from one such patient are demonstrated in Figure 4. Figure 4, panel A demonstrates a high grade obstructing lesion in the left main coronary artery approximately 1 cm from its origin. Panel B shows an apparent total obstruction of the artery as visualized on apical cross-sectional echocardiography. In panel C (from the same patient), the transducer is angled slightly more clockwise so that the bifurcation point can be identified and the lumen appears to be definitely narrowed but not totally obstructed. Thus, proper angulation of the transducer is required to identify the left main coronary artery so that actual clear luminal integrity can be seen.

A potential source of false positive echocardiographic left main luminal obstruction is demonstrated in Figure 5. This echocardiogram was obtained from a patient with a normal left main coronary artery. The left panel demonstrates a possible break in the continuous echo-free space of the left main coronary lumen (black arrow). The right panel was obtained with the transducer angulation altered slightly so that the bifurcation point (small white arrow) and the lumen can be more clearly seen. No luminal irregularity is seen in this echocardiographic image of the left main coronary artery, which was more properly obtained.

Prospective identification of left main coronary artery disease: Group B: Twenty-seven of the 35 patients studied prospectively and consecutively with cross-sectional echocardiography had adequate visualization of the left main coronary artery. This artery was not visualized in eight patients. In six of the eight, technical limitations due to chest wall deformity made it impossible to obtain an adequate apical view; in two patients interference by intense echocardiographic reflections from a calcified aortic valve and aortic root prohibited the evaluation of the left main coronary artery. In 12 of the remaining 27 patients, the bifurcation point could clearly be seen.

Twenty-three of the 27 left main coronary arteries visualized on cross-sectional echocardiography were judged normal on this study and on coronary angiography. In the four patients considered to have an abnormal left main coronary artery on cross-sectional echocardiography, angiography revealed obstruction of this artery in two, an abnormally short or cloacal left main coronary artery with a high grade obstruction of the proximal left anterior descending coronary artery

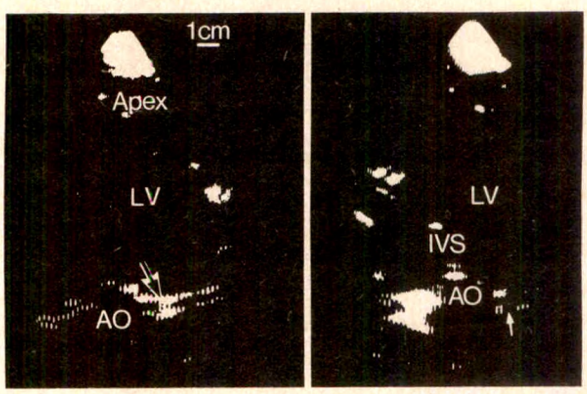

FIGURE 5. Cross-sectional echocardiogram taken from the apex in which the left ventricle (LV), aorta (AO), interventricular septum (IVS) and left main coronary artery (LM) are identified. The **black arrow** in the **left panel** demonstrates an apparent break in the left main luminal free space (**arrow**). However, with careful angulation as shown in the **right panel** the left main lumen appears to be patent and the **white arrow** identifies the bifurcation point.

in one and a normal left main coronary artery in one (a false positive study). There were no false negative studies.

Short axis versus apical approach for the echocardiographic identification of the left main coronary artery (Group C): Use of the short axis cross-sectional echocardiographic approach[8] clearly identified the left main coronary artery in 16 of the 30 patients (53 percent). The apical cross-sectional approach resulted in adequate identification of this artery in 21 of the 30 patients (70 percent). In 28 patients (93 percent) the left main coronary artery was visualized echocardiographically with either one of these techniques. The bifurcation point of the artery was identified in 7 of 16 patients (44 percent) with the short axis technique and in 14 of 21 patients (67 percent) with the apical technique.

Discussion

The diagnosis of left main coronary artery disease is important in the management of patients with symptomatic coronary artery disease.[1-12] The prediction of left main coronary obstruction before coronary arteriography is important in light of the potential for sudden death or at least greater morbidity during arteriography in patients with such obstruction.[7] Unfortunately, no clinical symptom, sign or laboratory test is specific for the presence of left main coronary artery disease. Furthermore, visualization of calcification of this artery by fluoroscopy is an insensitive indication for this disease because only approximately 28 percent of patients with left main atherosclerotic obstruction have this finding.[7,10]

Apical versus short axis view: Cross-sectional echocardiography has the potential for identifying noninvasively the left main coronary artery. The short axis tomographic view of a cross-sectional echocardiogram has demonstrated the left main coronary artery as verified with contrast injection.[13] However, the short axis approach appears to be limited because this artery and its bifurcation lie in different planes with this method and therefore extensive visualization of the artery is technically less feasible than with other approaches. Use of the apical or hemiaxial approach in our study allowed the optimal alignment of the echocardiographic beam parallel to the left main coronary artery and its bifurcation. As demonstrated in Group C, the comparison of the short axis and apical approaches in 30 patients revealed a greater prevalence of successful visualization of the left main coronary artery and its bifurcation with the apical approach.

The actual identification of left main coronary arterial obstruction with cross-sectional echocardiography is clear. False positive changes in the luminal free space may be due to a bend in the direction of the artery, cardiac motion or calcification along the left main vessel. However, by careful analysis of frame by frame recording, false positive diagnoses can be minimized. True obstruction of the left main coronary artery can consistently be recognized utilizing a frame by frame analysis. The arterial lumen should be in continuity with the aortic lumen and an area of narrowing of the luminal free space of the left main artery should be evident in multiple sequential frames. The potential usefulness of other criteria for identifying of the left main obstruction, including a distinct break in the luminal free space, should be further investigated.

Clinical implication: The application of both the short axis and apical cross-sectional echocardiographic approaches to identification of left main coronary arterial obstruction appears to offer a high degree of success in the noninvasive evaluation of patients with suspected coronary artery disease. Prospective studies utilizing these noninvasive techniques to evaluate such patients may be rewarding.

The Occurrence of Hyperaldosteronism in Infants With Congestive Heart Failure

BARRY G. BAYLEN, MD*
GREGORY JOHNSON, MD
REGINALD TSANG, MD
LAXMI SRIVASTAVA, PhD
SAMUEL KAPLAN, MD, FACC

Cincinnati, Ohio

Serum aldosterone and plasma renin were measured in 20 normal infants and 15 infants with congestive cardiac failure. Serum aldosterone was significantly increased (151 ± 38 ng/dl mean ± standard error of the mean) in patients before treatment when compared with aldosterone in normal infants (29 ± 7 ng/dl). Increasing serum aldosterone was related to increasing plasma renin. The response to furosemide appeared to be inversely related to serum aldosterone concentrations. In four infants, administration of an aldosterone antagonist (spironolactone) resulted in improved diuresis and decreased serum aldosterone. Hyperaldosteronism is an important factor contributing to fluid and sodium retention in infants with heart failure.

Many investigators[1–4] have demonstrated the role of the renin-angiotensin-aldosterone system in the accumulation of fluid and sodium associated with cardiac failure. Elevated plasma aldosterone levels[5] have been observed in adults with heart failure, and increased urinary excretion of aldosterone metabolites[6] was found in infants with heart failure. Furthermore, relatively high levels of aldosterone production and increased excretion of aldosterone metabolites have been demonstrated in the normal newborn and very young infant.[7–9]

Optimal medical management (primarily administration of digoxin and diuretic drugs) is essential for reducing mortality and morbidity associated with congenital heart disease and severe heart failure. It has been suggested[1,10] that excessive circulating aldosterone may lead to a diminished response to diuretic drugs, because this hormone increases tubular reabsorption of sodium and water at a site distal to the action of diuretic agents such as thiazides or furosemide.[11–13] These considerations prompted us to study the possible role of the renin-aldosterone system in the pathogenesis and management of cardiac failure in young infants.

Methods

Study patients: Fifteen male infants were studied (Table I). Eleven had "moderate" to "severe" congestive heart failure secondary to congenital cardiac disease. Patients with "moderate" congestive heart failure had tachypnea, sweating, poor nutritional status, tachycardia, gallop rhythm, hepatomegaly and roentgenographic evidence of cardiomegaly or venous congestion, or both. When heart failure was severe, the prior findings were present in addition to clinical signs of diminished peripheral perfusion or metabolic acidosis, or both. The ages of the infants ranged from 1 week to 10 months; weights ranged from 2,650 to 6,190 g.

Four additional infants (Patients 4 to 6 and 15) had cor pulmonale secondary to bronchopulmonary dysplasia as a consequence of the respiratory distress syndrome of prematurity. Their ages ranged from 4 to 9 months and weights from 3,260 to 6,450 g. All infants with cor pulmonale had cardiomegaly on chest

roentgenography, right ventricular and atrial enlargement on electrocardiography and right ventricular hypertrophy or dilatation, or both, on echocardiography. Two of these four infants had fluid retention, oxygen dependency and marked pulmonary hypertension suggested by the echocardiogram[14] and confirmed at cardiac catheterization in one.

Treatment: The 15 study infants were treated with digoxin appropriate for age and weight (loading dose: 0.04 to 0.06 mg/kg body weight per 24 h; maintenance dose: 0.005 to 0.015 mg/kg per 24 h). The patients were on a maintenance regimen of fluid, 1,500 to 2,000 ml/m^2 per 24 h; sodium, 2 to 3 mEq/kg per 24 h; and potassium, 1 to 2 mEq/kg per 24 h.[15] All infants, except two with moderate cor pulmonale, received furosemide, 2 to 5 mg/kg per 24 h, daily; furosemide was given orally, except on study days.

The response to parenterally administered furosemide (1 mg/kg) was evaluated as follows: (1) study day 1—before administration of digoxin or diuretic drugs, (2) study day 2—mean 6 days (range 4 to 12 days) of digoxin and diuretic therapy. A third study was obtained 72 hours after the administration of spironolactone (1 to 3 mg/kg per 24 h) in four infants with clinical, roentgenographic and biochemical evidence of persistent or increasing heart failure (Table I; Patients 12 to 15).

Laboratory determinations: Laboratory values, including hemoglobin, hematocrit, osmolality, serum creatinine and electrolytes, were obtained before administration of furosemide on the study day. Two ml of blood was obtained for serum aldosterone and plasma renin levels before intramuscular administration of furosemide (between 0800 and 1300 hours in supine infants). Void to void, timed urine specimens were collected for serum creatinine, sodium and potassium concentrations before (3 to 5 hours) and after (2 to 4 hours) administration of furosemide. Male infants were chosen to facilitate urine collection.

Sodium and potassium concentrations were measured with a digital flame photometer (Instrumental Laboratory, Lexington, Massachusetts 1972). Serum osmolality was measured with an automatic osmometer (Precisions Systems, Waltham, Massachusetts 1968). Plasma renin activity and serum aldo-

sterone were measured with radioimmunoassay microtechniques.[16,17] The interassay coefficient of variation for plasma renin was 9.5 percent and for serum aldosterone 10.5 percent.

Normal control group: Serum aldosterone and plasma renin levels were obtained at the time of routine blood sampling in 20 normal infants presenting for well child care and for elective surgical procedures. Their ages ranged from 1 1/2 to 9 1/2 months; their weights ranged from 3,118 to 8,200 g. Their diet consisted of standard commercially available infant formula supplemented by proprietary baby foods. Also, their serum sodium and potassium levels were within normal limits. There were no significant age or weight differences between the study infants and the control group (Wilcoxon-Mann-Whitney test).[18]

Statistical methods: Because the data were not normally distributed, all analyses utilized rank testing. However, for illustrative purposes all data are reported as mean ± standard deviation or standard error of the mean. The Wilcoxon-Mann-Whitney test was used for comparison of groups; Wilcoxon ranked paired *t* for paired studies, and the Spearman rank correlation for regression analysis.[18]

Results

General observations: The mean weight of the study infants decreased from 4,474 g before treatment to 4,430 g before the second study (Table II). Serum osmolality values were normal and did not change significantly (Table II). Serum sodium and potassium concentrations (Table I) on the 1st and 2nd study days did not differ; these concentrations in patients with increased aldosterone did not differ significantly from those of patients with normal aldosterone (Table I). On both study days, before administration of furosemide, urinary sodium to potassium concentration ratios were reversed (less than 1) (Table II). After intramuscular injection of furosemide on the 1st and 2nd study days, mean urinary volume increased 3.6- and 2.9-fold, respectively; sodium excretion increased 22- and 29-fold and potassium excretion increased 2.7- and 2.3-fold, respectively, with restoration of sodium/potassium ratios to more than 1 (Table II).

Aldosterone data: Serum aldosterone before treatment (151 ± 38 ng/dl [mean ± standard error of the mean]) and on the 2nd study day (260 ± 70 ng/dl) was significantly increased when compared with levels in control infants (29 ± 7 ng/dl; Wilcoxon-Mann-Whitney test, $p < 0.001$). Aldosterone values did not change significantly between the first and second studies. In four infants (Patients 12 to 15) with persistent moderate to severe heart failure, mean aldosterone levels were initially elevated (426 ng/dl) and decreased in all (139 ng/dl) after administration of spironolactone (Fig. 1).

Diuretic response: The response after intramuscular administration of furosemide is summarized in Table III. On the 1st study day, urinary volume and sodium and potassium excretion after furosemide in those patients with increased serum aldosterone levels (greater than mean + 2 standard deviations) did not differ significantly from responses in patients with normal serum aldosterone. However, on the 2nd study day, the mean urinary volume and sodium and potassium excretion after furosemide were significantly less in patients with increased serum aldosterone levels than in those with normal levels (Wilcoxon-Mann-Whitney test, $p < 0.05$). Decreased postdiuretic sodium excretion was related to increased serum aldosterone levels by Spearman rank correlation ($r = 0.589$, $p < 0.01$; Fig. 2).

Plasma renin: In the 11 infants with heart failure whose plasma renin concentrations were obtained, serum aldosterone concentrations were significantly correlated with plasma renin values (Spearman rank correlation $r = 0.4$, $p < 0.01$, Fig. 3). Plasma renin values of the patients with heart failure did not differ significantly from values in control subjects and no significant difference was found between renin values in the first and second studies.

M = mean; post = after; pre = before. Na/K = ratio of urinary sodium and potassium concentrations; R = range; SEM = standard error of the mean; ↑ = increase (ratio post- versus pre-furosemide value).

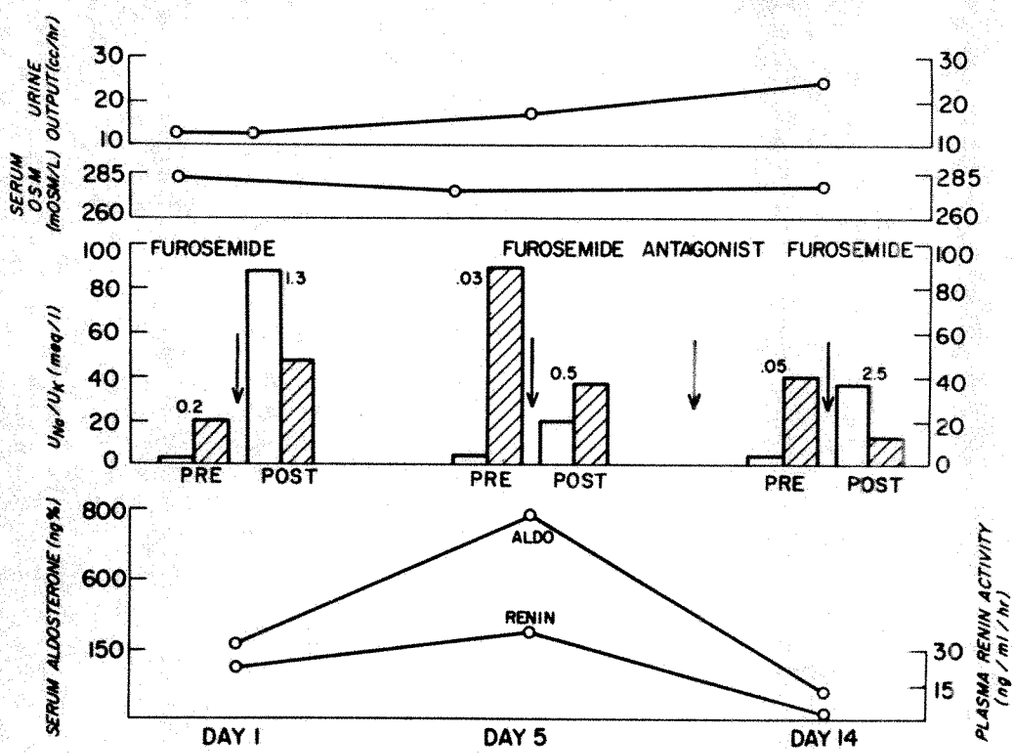

FIGURE 1. Example of an infant under study (Patient 15). **Day 1** (before treatment), the patient's serum aldosterone (ALDO) and plasma renin levels are elevated; urine and sodium and potassium excretion are relatively decreased after administration of furosemide; ratio of urinary sodium (U_{Na}) concentration (**stippled bar**) to urinary potassium concentration (U_K) (**clear bar**) is 1.3. **Day 5,** aldosterone and renin levels are increased further, serum osmolality (OSM) is decreased; the urinary sodium/potassium ratio before furosemide (0.03), is markedly reversed after (0.5) furosemide. Treatment with spironolactone (an aldosterone antagonist) was added. **Day 14,** aldosterone and renin levels are normal; osmolality is normal; urine and sodium/potassium ratio are relatively increased after furosemide.

Discussion

Role of hyperaldosteronism in cardiac failure: In this study, significant elevations of aldosterone blood levels were observed in infants with heart failure. In animal models of heart failure,[19,20] increased secretion of renin and aldosterone has been observed. Cardiac failure and diminished perfusion pressure have been equated with a diminished "effective" systemic blood volume.[1] It is postulated that diminished "effective" systemic blood volume stimulates the renin-angiotensin-aldosterone system.[1,3,19–21] Aldosterone augments fluid and sodium retention and angiotensin II acts on systemic-resistance vessels, helping to restore "effective" systemic blood volume.

In mild experimental heart failure, renin-angiotensin and aldosterone levels are initially elevated, with an early return to normal.[19,20] With more severe cardiac failure, renin-angiotensin-aldosterone levels may remain increased.[3,5,19,20] In advanced cardiac failure, inhibition of the renin-angiotensin-aldosterone system may cause marked systemic hypotension.[19,21] In the present study, as in other investigations,[5,19] hyperaldosteronism was observed before therapy. Hyperaldosteronism was apparently more common in patients with more complicated lesions and in patients with persistent heart failure (Table I). The resolution of heart failure after diuretic therapy often resulted in decreased renin or aldosterone levels, or both. We speculate that infants with increasing or persistent el-

evations of renin or aldosterone, or both, may represent patients with more severe heart failure and inability to maintain "effective" systemic blood volume. If cardiac output does not improve adequately with therapy, the stimuli for aldosterone secretion might persist. Diuretic therapy might result in a further reduction of "effective" systemic blood volume with additional stimulation of aldosterone production.

Causes of increased aldosterone secretion: Several factors might provoke greater aldosterone secretion in infants with heart failure than in adults. Although absolute rates of secretion have not been determined, levels of renin and aldosterone[7–9] in infancy are greater than levels in adults. Congenital cardiac lesions such as those associated with significant left to right shunting or outflow tract obstruction are usually associated with reduced systemic blood flow. The maintenance of "effective" systemic blood volume or vascular tone is further compromised by a relative immaturity of the autonomic nervous system.[22] In infants, the effect of hepatic maturation on the degradation of aldosterone[23,24] is uncertain. Hepatic dysfunction secondary to congestion and altered hepatic blood flow could decrease the hepatic degradation of aldosterone[23,24] and result in increased concentration of serum aldosterone. In our study, although plasma renin concentrations were not significantly elevated in the study subjects, serum aldosterone concentrations were correlated with plasma renin concentrations, a finding consistent in part with stimulation of the renin-angiotensin-aldosterone system.

Factors affecting response to diuretic drugs: It has been proposed that excessive aldosterone may reduce the response to diuretic agents.[1,10–12,25,26] In our study, as in others,[25–27] infants with congestive heart failure were oliguric and had diminished urinary sodium excretion. Marked reversal of the urinary sodium/potassium ratio was observed before therapy with furosemide. Urinary volume and sodium excretion after administration of furosemide was lower in infants with increased aldosterone concentrations.

Other important variables affecting the response to diuretic drugs include the nature of the cardiac lesions, cardiac output, glomerular filtration rate and renal blood flow.[1,19,20,25–30] Early in the course of moderate to severe heart failure, the glomerular filtration rate may be diminished and the effects of increased aldosterone on distal tubular fluid and sodium transport would be less important.[25,26,30] After therapy for heart failure glomerular filtration increases and the effects of increased aldosterone might become more apparent, as probably observed in this study (Table III). As expected,[1,10,11,25,26] improved diuresis and reversal of the urinary sodium/potassium ratio was observed in four infants with hyperaldosteronism after the administration of an aldosterone antagonist (Fig. 1).

Therapeutic implications: The factors regulating the renin-angiotensin-aldosterone system in infants with heart failure are complex and remain to be investigated. Because we have observed hyperaldosteronism in infants with a wide variety of congenital and acquired cardiac lesions, we postulate that it is an important contributing factor in fluid and salt retention in infants with "heart failure." Therefore, the occurrence of hyperaldosteronism should be considered in the management of infants with such failure and signs of fluid retention refractory to treatment. In infants with hyperaldosteronism a trial of aldosterone antagonists such as spironolactone might be evaluated.

Pulmonary Artery Sling

CARL H. GUMBINER, MD
CHARLES E. MULLINS, MD, FACC
DAN G. MCNAMARA, MD, FACC

Houston, Texas

Pulmonary artery "sling" indicates the vascular anomaly wherein the left pulmonary artery arises from the right pulmonary artery and traverses between the esophagus and trachea to enter the left lung. Respiratory symptoms may result from compression of the trachea and right mainstem bronchus by the anomalous vessel as well as by associated tracheobronchial defects. Six cases are described. The distinctive radiologic features include anterior indentation of the barium esophagogram and a characteristic pulmonary angiogram. Surgery is the usual recommended treatment for life-threatening airway obstruction, but results are often poor. In patients with less severe symptoms the physician's approach may be modified by the presence of associated intracardiac defects and intrinsic airway disease.

The origin of the left pulmonary artery from the right pulmonary artery (pulmonary artery sling) presents distinctive radiologic features and clinically resembles vascular ring. Airway obstruction of various degrees of severity results from narrowing of the trachea and right mainstem bronchus by the aberrant artery as it courses from the right pulmonary artery, superior to the right mainstem bronchus, and between the trachea and esophagus toward the left lung (Fig. 1). To date, 66 cases have been described in publications in English.[1–40] The majority of patients have undergone surgery. In this report we describe six additional cases and point out that in certain circumstances operation may not be indicated.

Case Summaries

Since 1968, six children with pulmonary artery sling have been seen at the Texas Children's Hospital. Table I summarizes the clinical findings and therapeutic results. Four of the six patients were girls (Cases 1 to 4). Three children (Cases 1 to 3) were of Latin American descent; one child (Case 4) was black.

In two children (Cases 2 and 3) without symptoms of airway obstruction, pulmonary artery sling was identified at the time of cardiac catheterization for other congenital defects. Both children remain free of airway obstructive symptoms after surgical correction of the intracardiac defects. Patient 1 had evidence of airway obstruction with wheezing and recurrent pneumonia that began in the newborn period. Surgical correction of the sling at age 8 months provided no improvement, and she died with pneumonia 4 years later.

Patients 4 and 5 presented with obstructive airway symptoms at ages 5 months and 1 day, respectively. Both are now in clinically stable condition. Patient 4 manifests mild wheezing without respiratory distress and has been free of pneumonia for 6 months. Patient 5 is asymptomatic at age 6 weeks; the chest roentgenogram, which formerly suggested right pulmonary emphysema, is now normal.

Patient 6 was referred at age 4 months. Dyspneic since birth, he had undergone right pneumonectomy at age 1 month for congenital lobar emphysema suspected on the basis of the chest X-ray film. Airway obstruction persisted after operation.

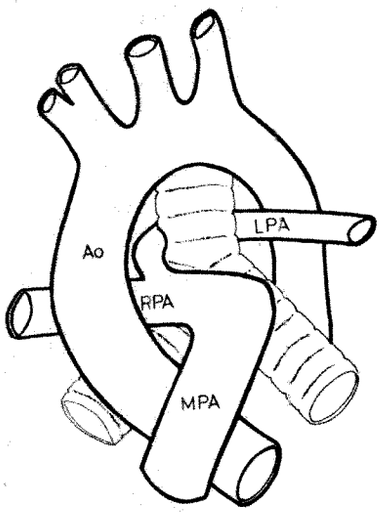

FIGURE 1. Schematic representation of structural relations in pulmonary sling anomaly. AO = aorta; LPA = aberrant left pulmonary artery; MPA = main pulmonary artery; RPA = right pulmonary artery.

A barium esophagogram and pulmonary angiogram at age 4 months revealed the pulmonary sling anomaly. The child died at age 5 months with progressive respiratory failure.

Clinical Features

Previous reports: The vascular anomaly later termed vascular "sling" or "pulmonary artery sling" was first described by Glaevecke and Doehle[2] in 1897 in a report of their findings in a necropsy specimen from an infant who died of a respiratory illness. The first premortem diagnosis of aberrant left pulmonary artery was made in 1949 by Quist-Hanssen.[3] Surgical therapy was first undertaken by Potts et al.[4] in 1954. Their patient was a 5 month old boy who underwent exploratory thoracotomy for an extrinsic mass compressing the trachea and producing severe airway obstruction. Their surgical procedure, similar to the current surgical approach, yielded dramatic results, and on follow-up examination in 1967[5] the boy was totally asymptomatic. Since then more than 63 cases have been reported.[1–40] The vast majority of patients have presented with respiratory symptoms either at the time of birth or before age 6 months. In Clarkson's review[16] of 38 cases in 1967, she observed that *all* patients had respiratory symptoms before the age of 2 months. Subsequently, pulmonary artery sling has been reported in a child whose symptoms developed in the 2nd year of life,[7] in two asymptomatic children[8,11] and in four adults.[8–10,12] The latter four all presented with paratracheal mass lesions. One adult patient[10] had complained of wheezing since early childhood.

Associated defects: Associated congenital defects are common. Additional cardiovascular lesions are found in 58 to 83 percent of patients[6,7] and include most often persistent left superior vena cava (20 percent of all cases),[1,7,16–20] atrial septal defect (20 percent),[16–20] ventricular septal defect (10 percent)[16] and patent ductus arteriosus (25 percent).[16,20] Tetralogy of Fallot,[19] persistent atrioventricular canal,[1] single ventricle[21] and coarctation of the aorta[17] have also been reported. Associated gastrointestinal malformations include imperforate anus,[1,23] Hirschsprung's disease[22] and biliary atresia.

Associated malformations of the tracheobronchial tree include left eparterial bronchus,[19] bronchus suis,[7] tracheomalacia[16] and complete tracheal cartilage[15,24] ("napkin ring cartilage"). Overall, tracheobronchial abnormalities have been described in 48 percent of autopsy specimens.[7] It is not clear whether the bronchial abnormalities producing obstruction represent independent associated lesions or result from the vascular

TABLE 1

Case Summary of Six Cases

Case	Obstructive Airway Symptoms (Age)	Sling Demonstrated		Associated Defects	Operation (Age)	Outcome (Age)
		Esophagogram	Angiogram			
1	Wheezing, recurrent pneumonia (newborn)	Yes	Yes	None	Implant LPA into MPA (8 mo)	No improvement. Died (4 yr postop)
2	None	. . .	Yes	Pulmonary stenosis and VSD (closed spontaneously)	Resection of PS (6 yr)	Normal (10 yr)
3	None	. . .	Yes	ASD	Closure ASD (9 yr)	Normal (14 yr)
4	Wheezing (5 mo)	Yes	Yes	Persistent left SVC, PDA, imperforate anus, skeletal anomalies	None	Mild wheezing (2 yr)
5	Tachypnea, right pulmonary emphysema (newborn)	Yes	. . .	- - -	None	Asymptomatic (6 mo)
6	Right pulmonary emphysema, respiratory distress (newborn)	Yes	Yes	None	Right pneumonectomy (1 mo)	Died (5 mo); persistent airway obstruction

ASD = atrial septal defect; LPA = left pulmonary artery; MPA = main pulmonary artery; PDA = patent ductus arteriosus; PS = pulmonary stenosis; postop = postoperatively; SVC = superior vena cava; VSD = ventricular septal defect.

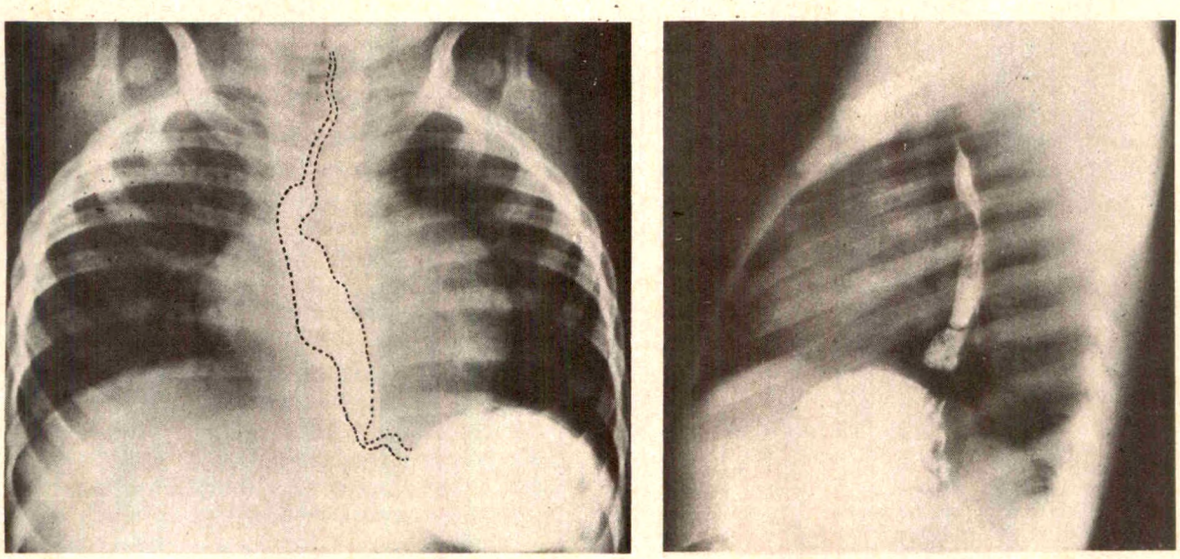

FIGURE 2. Case 4. Barium swallow study. **Left,** anteroposterior projection demonstrating deviation of the trachea to the left and left-sided indentation of the esophagus. **Right,** lateral projection showing indentation of the anterior edge of the esophagus just above the level of the carina.

anomaly itself. However, they are a major determinant of symptoms, and the associated tracheobronchial disease commonly accounts for the lack of improvement after surgical repair.

Diagnosis: The diagnosis of pulmonary artery sling depends on clinical awareness and appropriate investigative procedures. Persistent wheezing by an infant, especially without evidence of infection, should provoke further study. The chest X-ray film often suggests airway obstruction. There may be evidence of recurrent infection or atelectasis, especially of the right lung. More common is the picture of hyperlucency, greater on the right than on the left side, and deviation of the trachea to the left (Fig. 2, left).[26,27] The tracheal air column may be narrowed just above the carina.

A barium esophagogram is often diagnostic of pulmonary artery sling.[26,27] The lateral view discloses an anterior indentation of the esophagus (Fig. 2, right)—a finding described with no other vascular lesions, although it has been found with bronchial cyst, esophageal reduplication and enlarged lymph nodes.[28] In the anteroposterior projection the esophagus is usually indented on the left side, but indentation on the right has been observed.[11]

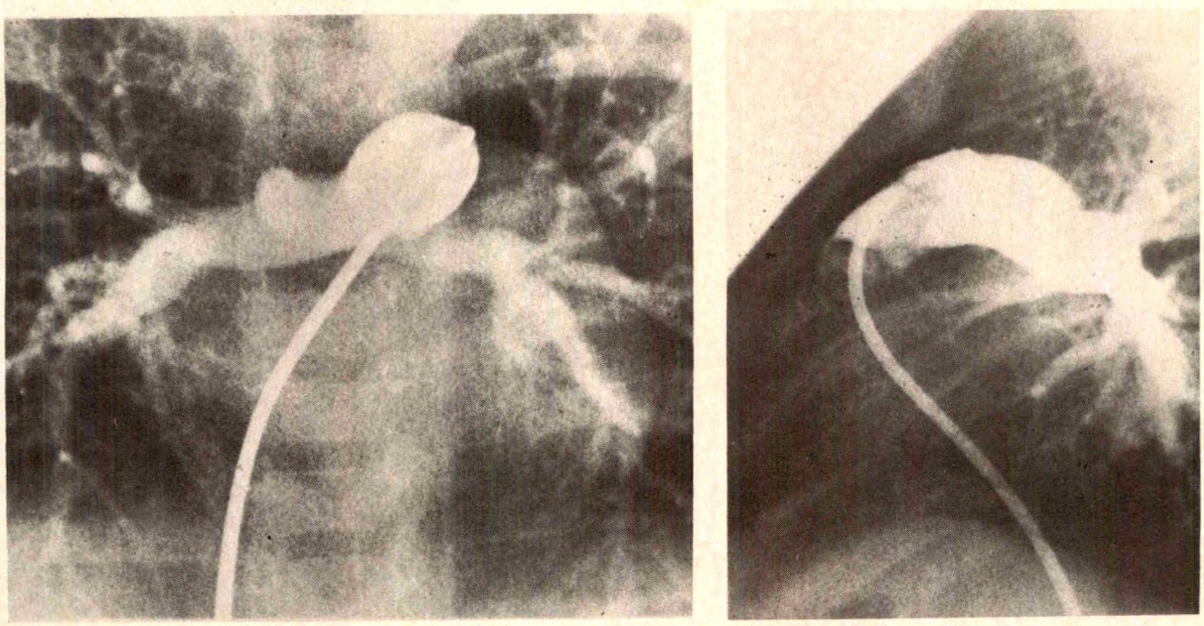

FIGURE 3. Case 4. Pulmonary angiogram. **Left,** anteroposterior projection demonstrating superimposition of right and left pulmonary arterial shadows and a "knob" on the right pulmonary artery. **Right,** lateral projection demonstrating the caudal position of the left pulmonary artery as it leaves the hilum.

Bronchoscopy may be helpful in the diagnosis of aberrant left pulmonary artery and is important in the assessment of tracheobronchial abnormalities. Right-sided or posterior compression of the trachea, especially by a pulsatile mass, is very suggestive of aberrant left pulmonary artery. The presence of tracheomalacia, bronchomalacia or complete cartilaginous ring ("napkin ring" cartilage) lessens the likelihood of successful surgical relief of airway obstruction.

We recommend cardiac catheterization and selective pulmonary angiography, even though some workers believe that a barium esophagogram and bronchoscopy constitute an adequate diagnostic evaluation of this lesion.[22] The appearance of the pulmonary angiogram is pathognomonic and the large incidence of associated intracardiac defects warrants cardiac catheterization, especially if surgery is contemplated. In the antero-posterior projection the pulmonary angiogram usually demonstrates a deformity of the right pulmonary artery at the origin of the left artery and their superimposition during its proximal course (Fig. 3). The "sitting-up" projection (Fig. 4), in which the patient is elevated 60° to 70° from a horizontal position with the X-ray beam directed vertically is advantageous. It permits separation of dorsal-ventral structures that overlap in the straight anteroposterior view; hence, the anomalous left pulmonary artery can be distinguished in its posterior course around the trachea.

Natural history: The first description[2] of pulmonary artery sling was based on an infant who died of respiratory obstruction. Among the next 13 cases reported, 11 children died before the age of 6 months.[1,3,4,17,18,25,21,29–31] With the exception of the four adults[8,9,10,12] and two previously described asymptomatic children,[8,11] nearly all children recognized as having a pulmonary artery sling have undergone surgery or died.[14,6,16,32] There are few reports of a sling as an incidental finding and no report of incidental autopsy demonstration of this lesion.

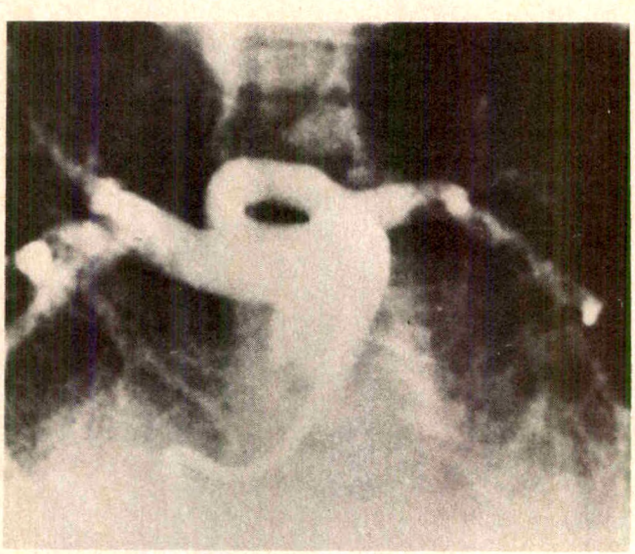

FIGURE 4. Case 4. "Sitting up" view of the pulmonary angiogram. The left and right pulmonary arteries are separated to demonstrate the origin and posterior course of the former.

Patient Management

Pulmonary artery sling remains a condition that is generally manifested in infancy, often with severe symptoms. Death from airway obstruction has been observed as early as age 2 days[1] and is common before age 6 months in untreated patients. Vascular surgery provides the only definitive approach to these severely symptomatic children.

Surgical repair: The recommended approach to symptomatic patients with pulmonary artery sling has been surgery. Since Potts et al.[4] reported their dramatic result in 1954, surgical therapy has been reported in 40 patients.[13] The most common procedure has been ligation, division and reimplantation of the left pulmonary artery as described by Potts et al.[4] and modified by Clarkson et al.[6] Division of the trachea with repositioning,[32] division of the left mainstem bronchus[13,32] and division of a patent ductus arteriosus or ligamentum have also been attempted.[33]

Surgical results have generally been less dramatic than the initial cure obtained by Potts et al. The overall surgical mortality rate has been 50 percent.[13] Patency of the repaired left pulmonary artery is unusual.[14] Persistent respiratory obstruction is frequently encountered. Of 20 patients surviving operation, only 11 are reported to be free of major airway symptoms.[31] Airway obstruction in patients with associated anomalies of the tracheobronchial tree is seldom relieved by surgery.

Other therapeutic measures: Not all children require operation. Our two asymptomatic patients, as well as other patients reported to have mild symptoms, demonstrate that an aberrant pulmonary artery need not obstruct the airway significantly; such patients are not surgical candidates. Most patients with pulmonary artery sling who present very early in life with critical respiratory symptoms demand prompt diagnosis and usually vascular correction. Management is less clear-cut for patients whose symptoms occur later. In this group associated anomalies need to be taken into account. Intracardiac shunts, for example, may significantly aggravate the patient's respiratory symptoms. Careful attention to congestive heart failure, pulmonary toilet and respiratory infections may be of critical importance. Bronchoscopy may reveal the presence of associated bronchotracheal disease, which may prevent relief of symptoms despite surgical repair of the anomaly.[15]

Results of surgery for aberrant left pulmonary artery may be dramatic, but are often tempered by associated cardiovascular and tracheobronchial anomalies. If the patient's symptoms are not life-threatening, he may not benefit from surgery. Attention should be directed to associated defects and particularly to the findings of bronchoscopy. When surgery is indicated, the outcome may often be influenced by the treatment of associated lesions including aggressive management of abnormalities of the tracheobronchial tree.

Aberrant Left Pulmonary Artery (Pulmonary Artery Sling): Successful Repair and 24 Year Follow-Up Report

CHARLES D. CAMPBELL, MD
JORGE A. WERNLY, MD
PIPIT CHIEMMONG KOLTIP, MD
DELORES VITULLO, MD
ROBERT L. REPLOGLE, MD

Chicago, Illinois

A case of anomalous left pulmonary artery arising from the right and coursing behind the trachea and anterior to the esophagus (pulmonary artery sling) is reported. The therapy currently advocated for this disorder is ligation of the anomalous vessel and performance of a left pulmonary to main pulmonary arterial anastomosis anterior to the trachea. A median sternotomy incision allows total mobilization of the anomalous vessel, minimizes respiratory embarrassment and aids in performance of the anastomosis. In the present case, a postoperative pulmonary angiogram revealed a patent left pulmonary artery, the second reported instance of such patency. The first successful repair of pulmonary artery sling was reported by Potts and colleagues in 1954. After a 24 year follow-up period their patient has normal exercise tolerance and no perfusion to the left lung is evident on ventilation-perfusion scan.

In 1954 Potts et al.[1] reported the first successful repair of an aberrent left pulmonary artery originating from the right and passing between the trachea and esophagus, causing obstruction of the right bronchus (pulmonary artery sling). Sade et al.[2] in 1975 reviewed the cases of 40 infants who had undergone surgical correction of this anomaly since Potts' original case. The overall mortality rate was 50 percent, and of the survivors studied again only one has a documented patent left pulmonary artery. This report describes the second successful repair and technical refinements to obtain patency of the anomalous pulmonary artery. Follow-up information on the first reported surgical case is also included.

Case Reports

Case 1: A 14 month old black boy was recently admitted to Michael Reese Hospital and Medical Center with wheezing and pneumonia. The child had had four previous admissions to an outlying hospital for asthma and recurrent pneumonitis. Results of routine laboratory studies were within normal limits. The chest X-ray film showed a right perihilar mass, and a lateral barium esophagogram revealed anterior indentation of the esophagus (Fig. 1). The pulmonary angiogram showed an anomalous left pulmonary artery coursing to the right and posterior to the trachea, continuing anterior to the esophagus and descending into the left hilum (Fig. 2). A ventilation-perfusion scan was normal.

Surgical repair was performed through a median sternotomy incision. The aberrant left pulmonary artery was identified as arising from the right pulmonary artery (Fig. 3). A left ligamentum arteriosum was divided. The anomalous vessel was mobilized to the left hilum, ligated at its origin and brought anterior to the trachea (Fig. 4). After the end of the vessel was spatulated lengthwise, a long arteriotomy on the main pulmonary artery was made. The posterior row of the anastomosis was completed with a running 6-0 polypropylene suture in Blalock fashion. The anterior row was completed with interrupted mattress sutures, resulting in a functional side to side anastomosis (Fig. 5). Blood flow was 1,000

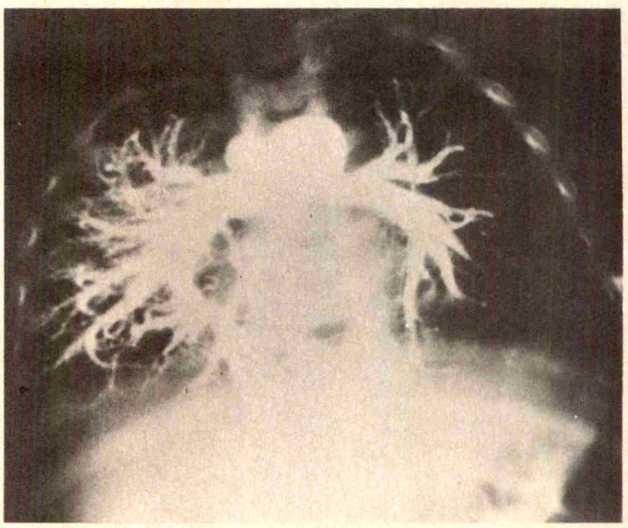

FIGURE 2. Case 1. Pulmonary angiogram showing the anomalous left pulmonary artery arising from the right pulmonary artery.

ml/min through the right pulmonary artery and 600 ml/min to the left lung, reflecting the small size of the left pulmonary artery. The child's postoperative course was uneventful, and he was discharged on the 10th day. A recent pulmonary angiogram shows a patent anastomosis (Fig. 6).

Case 2: In 1953 Potts et al.[1] first repaired an anomalous left pulmonary artery in a 5 month old infant. The child was dyspneic and cyanotic at birth. The chest roentgenogram and fluoroscopic examination revealed emphysema of the right lung and a mediastinal shift to the left. Bronchoscopic examination showed that the right mainstem bronchus was extrinsically compressed just below the upper lobe orifice. A barium esophagogram disclosed no abnormality. Because of repeated attacks of dyspnea and cyanosis associated with pulmonary infection, the child underwent surgical correction at age 5 months. The anomalous left pulmonary artery was exposed through the right fourth interspace and the aberrant vessel was divided and reanastomosed to the pulmonary artery in end to end fashion with a running suture anterior to the trachea. Occasional stridor developed in the early postoperative period, but the child was discharged on the 11th day. He has remained well and entirely asymptomatic for the ensuing 24 years. The patient had normal exercise tolerance on a recent treadmill test. A ventilation-perfusion study shows minimal perfusion to the left lung with normal ventilation, demonstrating a good long-term result and almost certain unilateral pulmonary blood flow (Fig. 7).

Discussion

In 1897 Glaevecke and Doehle[3] described the first case of anomalous origin of the left pulmonary artery. Since then, approximately 70 cases have been reported.[2,4,5] Forty-six patients were treated surgically; 23 (50 percent) were early survivors. The remaining 24 patients were managed medically; the mortality rate in this group was 90 percent.

Embryology: Normally the left pulmonary artery arises during the 5th week of intrauterine life. Gray et al.[6] showed that the embryonic left pulmonary artery projects as a branch from the ventral bud of the aortic sac to join an artery from the pulmonary plexus of the lung bud. These two vessels and the ventral left sixth arch or ventral bud of the aortic sac then become the left pulmonary artery, and the dorsal portion of the sixth arch becomes the ductus arteriosus.

Many anomalies can result from failure of the ventral pulmonary artery bud to develop or from reabsorption of the bud after it has developed. Once a pulmonary artery is no longer present, the lung may capture a vascular supply by connection with any nearby major artery. If connection is made to a systemic artery, the result is congenital unilateral absence of the pulmonary artery. The lung may capture its arterial supply by connection through the pulmonary plexus with derivatives of the sixth (pulmonary) aortic arch. If connection is established with the left sixth arch, normal development ensues. If connection of the left pulmonary plexus with the right sixth arch is established across the midline through capillaries caudal to the lung bud, the course of the left pulmonary artery is behind the developing tracheobronchial tree, thus creating a vascular sling.[7] The anomalous left pulmonary artery usually arises from the posterior aspect of the right pulmonary artery, passes over the right mainstem bronchus near its origin and runs between the trachea and esophagus, indenting the anterior aspect of the esophagus. The vessel courses inferiorly and enters the hilum at a slightly lower than normal site.

Associated anomalies: In more than 50 percent of cases of pulmonary artery sling,[2,4,8] anomalies involving the tracheobronchial tree occur. These are most commonly hypoplasia of the distal trachea or bronchus, frequently associated with complete cartilaginous rings. Occasionally the anomalous vessel is not in close proximity to the area of tracheobronchial compression, thus

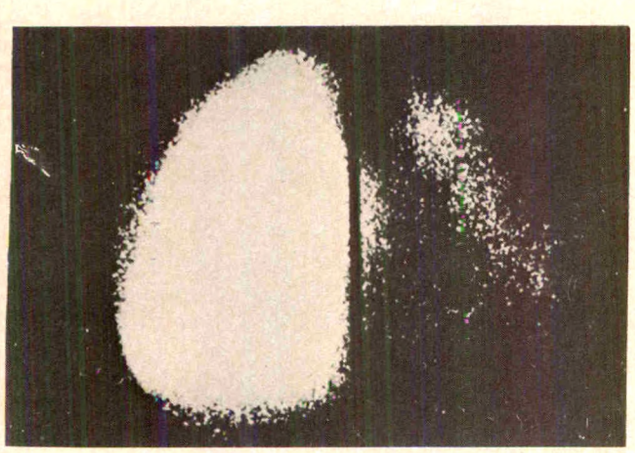

FIGURE 7. Case 2. Ventilation-perfusion scan (anterior view) in Potts' original case showing unilateral pulmonary blood flow. The patient is entirely asymptomatic 24 years after operation.

negating a cause and effect relation. Jacobson et al.[9] and Jue et al.[7] noted the right upper lobe bronchus arising from the trachea above the anomalous vessel.

Sade et al.[2] and Koopot et al.[8] reported a 50 percent incidence rate of cardiovascular anomalies in patients with pulmonary sling. These include aortic arch anomalies, tetralogy of Fallot, aortic stenosis, patent ductus arteriosus, ventricular septal defect, atrial septal defect and, most commonly, a left superior vena cava.

Clinical features and diagnosis: The most common symptoms are those of respiratory obstruction, including stridor and wheezing. Cyanosis and repeated pulmonary infections are also observed. The chest roentgenogram on frontal projection may show a right mediastinal mass; an indentation of the trachea or hyperexpansion of the right lung may be observed. The barium esophagogram shows anterior indentation of the esophagus. The left pulmonary hilum is sometimes noted to be lower than normal. Bronchoscopy and bronchography may reveal tracheal or bronchial compression. A pulmonary angiography showing the anomalous left pulmonary artery is diagnostic.

Our patient had a right mediastinal mass and overinflation of the right lung associated with respiratory distress. A barium swallow study showed anterior indentation of the esophagus. A pulmonary angiogram showed the anomalous vessel and a preoperative ventilation-perfusion scan was normal.

Surgical treatment: The surgical treatment of pulmonary artery sling has varied. The techniques utilized include division of the anomalous vessel and reanastomosis of the vessel to the proximal stump or the main pulmonary artery. In one instance the vessel was simply divided. Another approach is simple ligation of a patent ductus arteriosum or ligamentum and the third option is resection and reanastomosis of the bronchus. Despite a successful report (P. Mansfield, personal communication) of simple ligation of an anomalous pulmonary artery, this procedure in most cases would not alleviate the sling effect and results in a nonfunctioning left lung throughout the patient's life. Mustard et al.[10] reported an excellent result in a symptomatic child in whom only the patent ductus arteriosum was divided. In most instances this operation will not alleviate the compression effect of the anomalous vessel on the bronchus. Lochard et al.[11] described a case in which the right mainstem bronchus was successfully relocated. This procedure is technically difficult and may lead to bronchial stenosis.

Division of the anomalous vessel and reanastomosis to the pulmonary artery should relieve compressive symptoms and maintain normal lung function and therefore is the procedure of choice. Exposure of the aberrant left pulmonary artery has varied. Potts et al.[1] utilized a right thoracotomy and more recently other surgeons[2,4] have suggested left thoracotomy. In 1975 Koopot et al.[8] reported a successful repair through a median sternotomy, but they advocated a left anterolateral incision. Median sternotomy gives excellent exposure of the origin of the anomalous left pulmonary artery and allows complete mobilization of this vessel into the pulmonary hilum. Therefore, maximal length of the vessel is obtained and kinking of the distal vessel as it enters the hilum more inferiorly than normal is avoided.

In 1957 Hiller and MacLean[12] advocated a left pulmonary artery to main pulmonary artery anastomosis as opposed to a left end to end anastomosis. At present, left pulmonary to main pulmonary artery reconstruction is advocated because it prevents the kinking that occurs with end to end reanastomosis. The aberrant vessel can be spatulated longitudinally and a long functional side to side anastomosis performed on the left lateral aspect of the main pulmonary artery. The long posterior row can be made in Blalock fashion and the anterior row completed with interrupted sutures, thus allowing the anastomotic tissue to grow. Sternotomy aids in performance of this anastomosis and has the added benefit of minimal respiratory embarrassment. Right thoracotomy compromises the right lung while the left lung is nonperfused and left thoracotomy compromises the left lung throughout the procedure.

Surgical results: Grover et al.[4] reported the only documented case of a patent aberrant vessel after reimplantation, and many instances of occlusion have been documented.[1,2,12,13] Although Pool et al.[14] and Cournand et al.[15] suggested that pulmonary hypertension will develop in patients with unilateral obstruction of the pulmonary artery, but the occurrence of this complication appears unlikely. Wolfe et al.[16] suggested that there is a high risk of hemoptysis and recurrent pulmonary infection secondary to profuse bronchial circulation in patients with acquired hypoperfusion of the lung.

Eklof[18] and Pontius (personal communication) and their associates have unsuccessfully attempted reconstruction of occluded aberrant pulmonary arteries. Despite these reports it appears that occlusion of the left pulmonary artery in infancy is relatively benign, because all cases are asymptomatic. Certainly, if left pulmonary arterial occlusion occurs, attempted reconstruction is not advisable. In fact, the patient reported by Potts et al.[1] had normal exercise tolerance with only minimal perfusion to the left lung after a follow-up period exceeding 24 years.

With refinements in exposure and technique of repairing a pulmonary artery sling, the operative mortality rate (50 percent) will decrease and the rate of arterial patency (one other case) will increase. Finally, the severity of associated tracheobronchial and cardiac anomalies will continue to play a major role in the overall survival of these patients.

From Siemens-Elema—the people who pioneered with the first implanted pacemaker in 1958.

PACEMAKER DATA:

Here's what you may already have learned to appreciate about our ventricular-inhibited pulse generators.

- Stable basic rate during recommended service life, independent of battery resistance increase.
- 0.75 ms impulse duration for reduced current drain and increased service life.
- Small, thin and lightweight with soft convex-concave design.
- Protected against strong electromagnetic interference by selective input filters and titanium encapsulation.
- Separately encapsulated, highly reliable hybrid circuitry.
- Proved lithium-iodine power source.
- Two separate battery depletion indicators.
- Simple check of stimulation function.
- Easy end-of-life check.
- Built-in runaway protection.
- Withstands defibrillation energies to 400J (400Ws).
- Versatile plug-in connection.

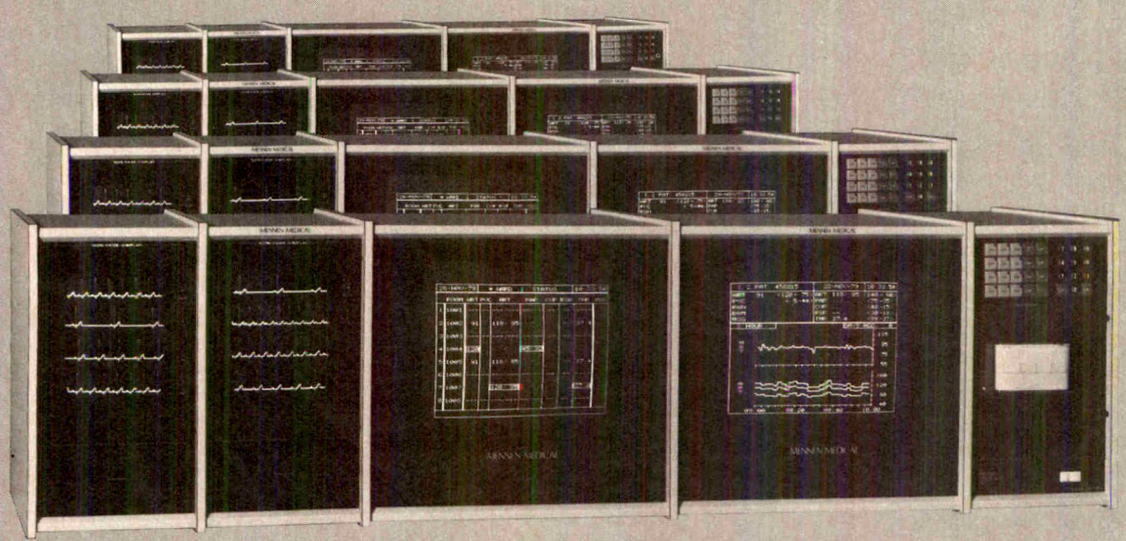
The Critical Care Monitoring System You're Searching For Has Arrived.



introducing the . . .

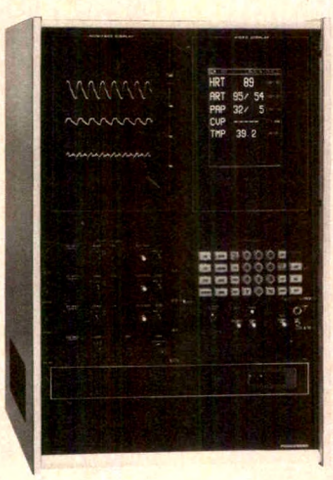
MENNEN SYSTEM 2000

The MENNEN SYSTEM 2000 provides total, continuous hemodynamic monitoring for up to sixteen patients. We've applied state-of-the-art microcomputer technology in designing a system that's cost-effective, reliable and easy to use.

SYSTEM 2000 acquires patient data from related bedside monitors and provides waveform and tabular displays, trending, alarm notification and chart recording. Each patient's vital signs are continuously displayed in a clear, concise tabular format. All parameters can be trended for up to 72 hours. Drug administration and treatments can be entered into the system to correlate displayed trends with patient response to medication.

Any parameter exceeding staff-selected alarm limits will cause the system to immediately record the corresponding patient's ECG waveform – fully documented with patient identification, time, date and vital signs at time of alarm. The system is controlled by a simple, special-purpose keypad for ease of operation. Options to the SYSTEM 2000 accommodate arrhythmia monitoring, ECG storage/recall and user programming as well as cardiac output and fluid measurements.

Complementing the MENNEN SYSTEM 2000 is SOLO – a bedside monitor with an integral microcomputer which provides dedicated surveillance of any critically ill patient. SOLO provides up to 72 hours of trending for all monitored parameters – including ECG/heart rate, arterial blood pressure, PAP, CVP, temperature and respiration rate. In addition, it can accommodate cardiac output, pulmonary wedge pressure and fluid measurements.



We also offer a complete line of conventional nurse stations, modular monitors and instruments.

Mennen Medical Inc.

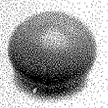
The potassium masquerade is over



Potassium with nothing to hide

There's no longer any need to try to hide the taste of potassium chloride—because KAON-CL TABS have no taste.
Thus your patients who can't or won't take liquid supplements have an acceptable alternative that enables them to get the potassium they need.

Wax-matrix tablets minimize likelihood of GI complications.
The special wax matrix used in KAON-CL TABS permits gradual release of potassium chloride in the GI tract. Because the potassium is slowly released, the possibility of high localized GI concentrations is limited. The reported frequency of GI lesions with wax-matrix tablets is less than one per 100,000 patient-years. There have been only two equivocal cases of GI bleeding reported with KAON-CL TABS to date and no reports of small bowel stenosis or ulceration. However, clinical experience is insufficient at this time to indicate that the incidence is other than the stated numerical ratio.

Logical, easily adjustable dosage. One tablet t.i.d. provides 20 mEq of potassium, the amount generally considered necessary for prevention of hypokalemia. Two tablets t.i.d. provide 40 mEq of potassium, usually adequate for the treatment of mild potassium depletion. Dosage should be adjusted to individual patient needs. In cases of more severe potassium depletion, 100 mEq daily or more may be required.

Patients stay on

KAON-CL TABS®
(potassium chloride) Controlled Release Tablets

For summary of prescribing information, please see following page.

WARREN-TEED LABORATORIES
DIVISION OF **ADRIA LABORATORIES INC.**
COLUMBUS, OHIO 43215

BRIEF SUMMARY
KAON-Cl TABS® (potassium chloride) Controlled Release Tablets
Description: Kaon-Cl Tabs is a sugar coated (not enteric-coated) tablet containing 500 mg potassium chloride (equivalent to 6.7 mEq potassium chloride) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.
Indications: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUIDS OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For the prevention of potassium depletion when the dietary intake is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure, hepatic cirrhosis with ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, and with certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium. Potassium supplementation, when indicated in such patients, should be with a liquid preparation.

All solid dosage forms of potassium chloride supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

Warnings: *Hyperkalemia*—In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics—Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions—Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Kaon-Cl Tabs (potassium chloride) is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient years. Kaon-Cl Tabs should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention or gastrointestinal bleeding occurs.

Metabolic Acidosis—Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

The most severe adverse effects are hyperkalemia (see Contraindications, Warnings and Overdosage) and gastrointestinal obstruction, bleeding or perforation (see Warnings).

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following:

1. Elimination of foods and medications containing potassium and potassium-sparing diuretics.
2. Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10-20 units of crystalline insulin per 1,000 ml.
3. Correction of acidosis, if present, with intravenous sodium bicarbonate.
4. Use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

Caution: Federal law prohibits dispensing without prescription.
How Supplied: Bottles of 100, 250 and 1000.

Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief Heart Institute, Chaim Sheba Medical Center, Tel-Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon — indeed, *every physician* — should have a good basic knowledge of The Pre-Excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is broght a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

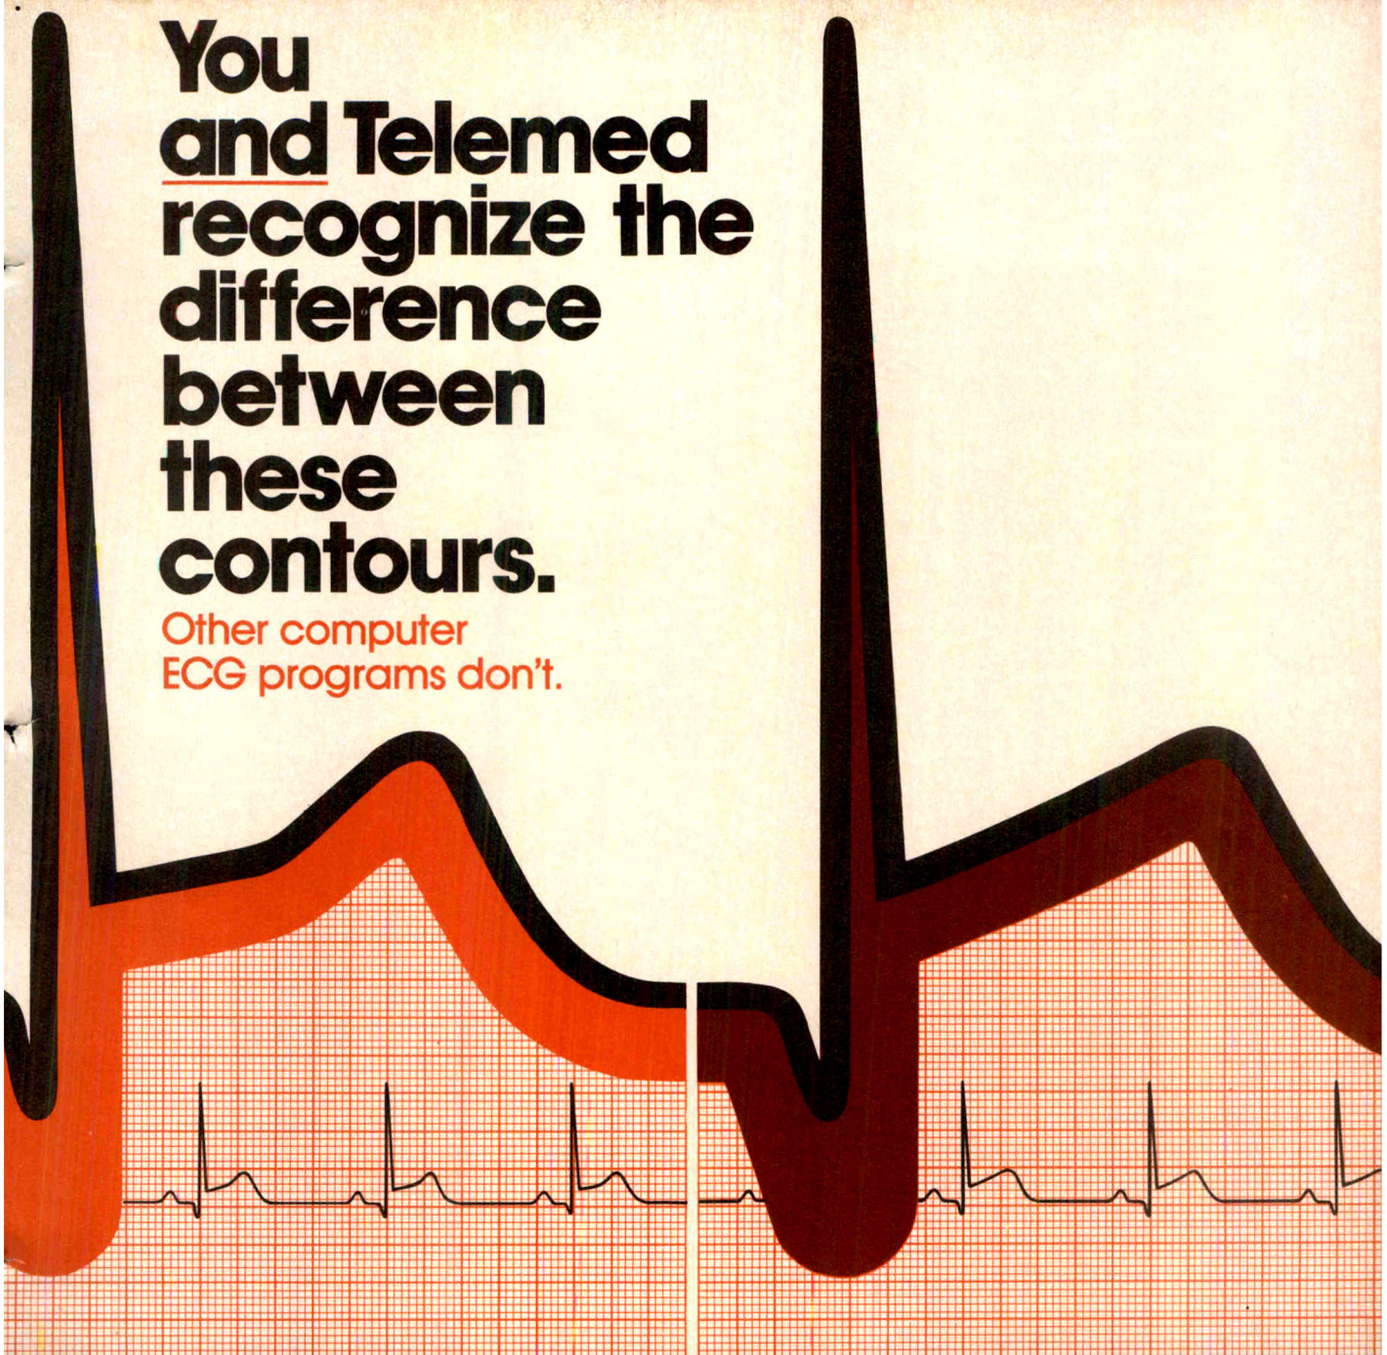
You and Telemed recognize the difference between these contours.

Other computer ECG programs don't.



Identical junctional ST segment elevations... different contour shapes. What's the significance? Both the electrocardiographer and the Telemed Program recognize it immediately. Other computer ECG programs don't consider wave form shape in their analyses.

Since the Telemed Program parallels the associative logic of the electrocardiographer, it also correlates patient age, sex, body build, clinical history and current drug regimen with the ECG trace and reports their related clinical significance.

These are two of the many reasons why no other computer ECG analysis program can match the clinical relevance and usefulness of the Telemed Program.

The Telemed Program enables the electrocardiographer to:

- Increase reading efficiency because it identifies abnormal ECG's.
- Expand his practice by saving him time and offering him 24 hour a day, 7 day a week back-up.
- Save valuable time because it can reduce or eliminate dictation.
- Simplify filing by providing him a permanent record for reference or serial comparison anytime it is needed.

For full details on how you can put the speed, relevance and economy of the advanced Telemed ECG Analysis Program to work for you, call or write Telemed today.

Tap the resources of the one ECG program that works like a cardiologist works—the Telemed Program.

She is assistant coach of the women's basketball team at Mount Aloysius College in Cresson, Pennsylvania, where she is studying to be an occupational therapist assistant. She is also a resident advisor in her dormitory and treasurer of the school's Occupational Therapy Club.

Like any college student, Connie enjoys visiting with her friends for late-night talk sessions. Classmates majoring in nursing frequently check Connie's pulse just to experience what they term the pacemaker "click-in." A member of an athletic family, twenty-year-old Connie still rough-houses with her siblings who don't consider her to be "fragile or different."

Obviously, Connie is a happy, healthy young woman. Her bradycardia is controlled by a CyberLith. Of course her personal lifestyle will change over the coming years. But the multi-programmable CyberLith will permit her physician to accommodate her changing physical requirements. We feel very certain that Connie will experience a lot of living in the future.

Connie's CyberLith is just one model in the growing family of specialized CyberLith pacemakers. Thin and lightweight, CyberLith pacemakers permit noninvasive adjustment of stimulation rate, pulse width, sensitivity level and pacing mode. And, the CyberLith has a longer history of reliability than any other programmable multi-parameter pacemaker line. CyberLith put Connie back on track. It could be the pacemaker of choice for your patients.

Intermedics Pulse Generators

INDICATIONS AND CONTRAINDICATIONS

The indications for cardiac pacemaking are increasing as pacemakers become more sophisticated and as advanced methods for patient management become more widespread. Generally accepted indications for long-term cardiac pacing include but are not limited to: (1) sick sinus syndrome; (2) chronic, symptomatic drug-resistant sinus arrhythmias, including sinus bradycardia, sinus arrest, and sinoatrial (S-A) block as seen in sick sinus syndrome; (3) chronic, symptomatic second-degree or third-degree A-V block; (4) recurrent Adams-Stokes syndrome; (5) bradycardia-tachycardia syndrome; (6) symptomatic bilateral bundle branch block; and (7) hypersensitive carotid sinus syndrome (carotid sinus syncope). In addition, certain patients presenting with intractable, recurrent, congestive heart failure; cerebral or renal insufficiency; or recurrent, drug-resistant tachyarrhythmias who have been shown to benefit from temporary cardiac pacing are considered candidates for permanent cardiac pacemaking.

The indications for permanent pacing in the presence of acute myocardial infarction have not yet been rigorously defined. Factors to be considered include the location of the myocardial infarct, the presence or absence of symptoms, ventricular rate, mechanism of the arrhythmias, and response to therapy. In general, symptomatic drug-resistant bradyarrhythmias which impair cardiac output are considered indications for pacing in patients with acute myocardial infarction, regardless of infarct location.

There are no known contraindications to the use of pacemakers as a medical method for control of heart rate. However, body rejection phenomena such as local tissue reaction or skin necrosis, muscle and nerve stimulation, embolism, and cardiac tamponade have been reported.

CAUTION: Federal (U.S.A.) law restricts this device to sale by or on the order of a physician.

NOTE: The CyberLith and the CyberLith Programmer are currently undergoing clinical evaluation.

KATO®
(potassium chloride for oral solution)
20 mEq (1.5 g. KCl)

Prescribing Information

DESCRIPTION:
Spray-dried tomato powder containing 20 mEq potassium (equivalent to 1.5 g. KCl) per 6 grams powder (one dose) with natural and synthetic flavors, spices and colors. Benzoic acid and potassium benzoate added as preservatives. When reconstituted as directed, makes a pleasantly flavored, low sodium tomato juice drink. Each daily dose (2 packets) contains less than 10 mg. sodium.

INDICATIONS:
The prevention or correction of potassium deficit, particularly when accompanied by hypochloremic alkalosis in conjunction with thiazide diuretic therapy, in digitalis intoxication, or as the result of long-term corticosteroid therapy, low dietary intake of potassium, or excessive vomiting or diarrhea.

CONTRAINDICATIONS:
Potassium is contraindicated in severe renal impairment involving oliguria, anuria or azotemia; in untreated Addison's disease, familial periodic paralysis, acute dehydration, heat cramps, hyperkalemia from any cause. Potassium chloride should not be employed in patients receiving potassium-sparing agents such as aldosterone antagonists and triamterene.

PRECAUTIONS:
KATO is a concentrate and should be taken only after reconstituting with water as directed. This preparation, like other potassium supplements, must be properly diluted to avoid the possibility of gastrointestinal irritation. Do not use in patients with low urinary output or renal decompensation. Administer with caution; it is impossible to assess accurately the daily dose required. Excessive dosage may result in potassium intoxication. Frequent checks of the clinical status of the patient, ECG and/or plasma potassium level should be made. High plasma concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease.

ADVERSE REACTIONS:
Vomiting, diarrhea, nausea, and abdominal discomfort may occur. Gross overdosage may produce signs and symptoms of potassium intoxication: mental confusion, listlessness, paresthesia of the extremities, weakness and heaviness of legs, flaccid paralysis, hyperkalemia, ECG abnormalities, fall in blood pressure, cardiac arrhythmias and heart block. The characteristic changes in the ECG are disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, tall peaked T waves, etc.

TOXICITY:
Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

TREATMENT OF HYPERKALEMIA:
1. Dextrose solution 10% or 25% containing 10 units of crystalline insulin per 20 g. dextrose, given I.V. in a dose of 300cc to 500cc in an hour. 2. Adsorption and exchange of potassium using sodium or ammonium cycle cation exchange resin, orally or as retention enema. 3. Hemodialysis or peritoneal dialysis. 4. Elimination of potassium-containing foods and medicaments. Warning: Digitalis toxicity can be precipitated by lowering the plasma potassium concentration too rapidly in digitalized patients.

ADMINISTRATION AND DOSAGE:
Mix with water to make a pleasant tomato juice drink. Each 6 gram unit dose packet provides 20 mEq of potassium. Usual adult dose—1 packet of KATO mixed with about 2 ounces of water twice daily—supplies 40 mEq potassium per day. Take with meals or follow with ½ glass of water. Larger doses may be required, but should be administered under close supervision because of the possibility of potassium intoxication.

HOW SUPPLIED:
Cartons of 30 and 120 6 gram unit dose packets, 20 mEq each.

LEA & FEBIGER

NEW! You'll want a copy of each of these new books!

Plan now to examine our many new books at The American College of Cardiology meeting in Houston, Texas, March 10 - 13, 1980.

INTERPRETATION OF COMPLEX ARRHYTHMIAS

By ALFRED PICK, M.D., *and* RICHARD LANGENDORF, M.D., *both of the Cardiovascular Institute of Michael Reese Hospital and Medical Center, and Pritzker School of Medicine, The University of Chicago, Chicago, Illinois.* This gem of a book is an outstanding contribution to the literature for experienced cardiologists—an entirely new book that differs from other texts in its aim, scope, format, and its specialization. It comprises the application of new knowledge to the unravelling, interpretation, and differential diagnosis of unusual and complex disorders of the cardiac rhythm encountered in *standard electrocardiographic leads. 586 pp. (11 x 8½), illus., 1979, $58.50.*

CARDIAC PACING: A Concise Guide to Clinical Practice

Edited and with contributions by PHILIP VARRIALE, M.D., *and* EMIL A. NACLERIO, M.D., *both of Cabrini Medical Center, New York, New York. (34 Contributors).* This book is a complete and totally practical review of the science of pacemakers, major developments and improvements in the field, the techniques and current clinical applications of cardiac pacing. It describes the present state of the art. Clinical principles and guidelines are stressed; established facts are emphasized and controversial issues analyzed. Provided are ample illustrations of pacing techniques, methods, new power sources, etc. *382 pp. (7 x 10), illus., 1979, $27.50.*

CLINICAL CARDIAC ELECTROPHYSIOLOGY: Techniques and Interpretations

By MARK E. JOSEPHSON, M.D., *University of Pennsylvania School of Medicine, Philadelphia; and* STUART F. SEIDES, M.D., *George Washington University School of Medicine, Washington, D.C.* The cardiologist is provided here with the means to fully understand the capabilities of the clinical cardiac electrophysiology laboratory. For those interested in performing the actual studies, methods of analyzing conduction defects, sinus node function, and tachyarrhythmias including those associated with pre-excitation syndromes are discussed together with their therapeutic implications. *318 pp. (7 x 10), numerous illus., 1979, $24.50.*

PROGRESS IN CARDIOLOGY, 8

Edited by PAUL N. YU, M.D., *University of Rochester School of Medicine and Dentistry, Rochester, New York; and* JOHN F. GOODWIN, M.D., *Royal Postgraduate Medical School, London, England. (23 Contributors).* This *Volume 8* is the latest in a well-known series of annual publications that present concise and informative articles related to cardiovascular medicine. The articles summarize recent advances and predict future trends in cardiology. The first seven chapters of this volume deal exclusively with newer concepts and developments in echocardiography. The second half of the book is devoted to chapters that range widely over other aspects of cardiovascular disease. *349 pp. (7 x 10), illus., 1979, $25.00.*

CARDIAC EMERGENCY CARE, 2nd ed.

Edited and with contributions by EDWARD K. CHUNG, M.D., *Jefferson Medical College of Thomas Jefferson University, Philadelphia, Pennsylvania. (22 Contributors).* Busy physicians will appreciate the new format and quick and easy access to information provided in this Second Edition. Three new chapters are included. *About 459 pp., illus., tables, 1980, $25.00.*

CARDIAC CATHETERIZATION AND ANGIOGRAPHY, 2nd ed.

Edited by WILLIAM GROSSMAN, M.D., *Peter Bent Brigham Hospital, Boston, Massachusetts. (22 Contributors).* Taking a highly pragmatic approach, this new edition provides an authoritative and completely up-to-date summary of the major techniques currently employed in cardiac catheterization and angiography. *About 400 pp. (7 x 10), illus., 1980, Ready Soon.*

HISTOPATHOLOGY OF CARDIAC ARRHYTHMIAS, 2nd ed.

By LINO ROSSI, Lib. Doc. Pathology *in the University of Milan, Milan, Italy.* This book presents an up-to-date and comprehensive account of histologic abnormalities of the heart's conduction and nervous system. It provides detailed and current information on histopathologic features of arrhythmias. *299 pp. (6 5/8 x 9½), 138 figures and 8 plates (1 in color), 1978, $54.00.*

Hypertension and Propranolol Therapy: Effect on Blood Pressure, Plasma Catecholamines and Platelet Aggregation

NICOLAS D. VLACHAKIS, MD, FACC
LOUIS ALEDORT, MD

New York, New York

The effects of propranolol on blood pressure, plasma catecholamine concentration and platelet aggregation were examined in 16 patients with uncomplicated primary hypertension. The patients were studied at rest, during isometric handgrip stress and 48 hours after sudden discontinuation of propranolol therapy. Plasma catecholamine concentration and platelet aggregation studies were also carried out in 11 age-matched normotensive and healthy subjects at rest.

Plasma catecholamine concentration and platelet aggregation were greater in the hypertensive than in the normotensive subjects, but the difference reached statistical significance for aggregation only. Exercise significantly increased catecholamines and platelet aggregability. The administration of propranolol (240 mg/day) produced a significant decrease in systolic and diastolic blood pressure and in aggregation (the percent of light transmission at 1 μM adenosine diphosphate, at rest) and a significant increase in catecholamine concentration. However, propranolol did not prevent the changes in all these variables with exercise.

The abrupt discontinuation of propranolol was not associated with any subjective or objective untoward cardiovascular effect or abnormal changes in plasma catecholamines. However, in some patients the platelet aggregation studies demonstrated a hyperaggregable state, which may be due to a state of supersensitivity of platelets to circulating catecholamines.

It has been reported[1,2] that patients with primary hypertension have increased plasma catecholamine concentration when compared with normotensive subjects and that patients with labile hypertension have a greater blood pressure and catecholamine response to stress than do normotensive control subjects.[3] Platelet adhesiveness is increased in patients with pheochromocytoma,[4] and several in vitro[5] and in vivo[6] studies showed that catecholamines bring about platelet aggregation. Many investigators find that propranolol is an effective and safe antihypertensive agent.[7–9] In vitro it may decrease platelet aggregation,[10] and in recent clinical trials it reversed to normal the abnormal platelet aggregation observed in patients with ischemic heart disease.[11]

In this study we examined the effects of propranolol on blood pressure, plasma catecholamines and platelet aggregation in patients with primary hypertension. We also studied the possibility of a rebound phenomenon in these variables after sudden discontinuation of propranolol.

From the Hypertension and Hematology Divisions of the Department of Medicine, Mount Sinai School of Medicine of the City University of New York, New York, New York. Manuscript received March 14, 1979; revised manuscript received August 6, 1979, accepted September 12, 1979.

Methods

Patients: The effect of propranolol on blood pressure, plasma catecholamine concentration and platelet aggregation was determined in 16 patients (12 men and 4 women) with uncomplicated primary hypertension at rest and during static exercise. The mean age (± standard error of the mean) was 54 ± 2 years. In 11 age-matched normotensive and healthy subjects plasma catecholamine concentration and platelet aggregation were studied at rest. Subjects and patients with a history of cigarette smoking, diabetes mellitus, lipid abnormalities, manifest atherosclerotic vascular disease, kidney or heart failure and thyroid dysfunction were excluded from the study. Informed consent was obtained from each subject and drugs of any sort were discontinued for at least 2 weeks before the study. Nine patients were new untreated hypertensive patients whereas two had been treated with hydrochlorothiazide alone and five had been receiving hydrochlorothiazide together with propranolol up to 3 weeks before the study.

Routine testing in the patients with hypertension consisted of physical examination and laboratory procedures including electrocardiogram, chest roentgenogram, rapid sequence pyelogram, complete blood count, routine urinalysis, 6 and 12 channel automated blood chemistry determinations and urinary catecholamine metabolite test. From the normal control volunteers blood was withdrawn for the complete blood count and multichannel automated blood chemistry determinations.

Platelet aggregation studies: After a 12 hour fasting period platelet aggregation studies were carried out during the morning hours in a quiet room with the subject at rest and during exercise. Before testing, each subject was instructed in the procedure and the technique of handgrip exercise; during the procedure no discussion with the subject was permitted. Each subject was asked to lie comfortably on a bed, and a 19 gauge siliconized needle was inserted, without use of a tourniquet, into an antecubital vein and a slow infusion of physiologic saline solution kept the needle open. After a 20 minute period of relaxation blood was withdrawn for determination of plasma catecholamines and platelet aggregation. Subsequently each hypertensive patient stood quietly for 10 minutes and then performed 3 minutes of isometric handgrip exercise (at two thirds of their maximal voluntary contraction) with use of a hand ergometer. At the end of this exercise blood was again obtained for determination of plasma catecholamines and platelet aggregation.

Platelet aggregation studies were performed using the turbidimetric method of Born[12] as modified by Mustard et al.[13] with adenosine diphosphate (ADP) as the aggregating agent. Blood was sampled by flow into plastic tubes containing 1/10 volume acid citrate (3.2 percent of concentration), and platelet-rich plasma was obtained by immediate centrifugation of the plasma at 150 *g* for 15 minutes at room temperature. The subsequent procedure was described in detail elsewhere.[14] We determined two indexes of platelet aggregability: (1) the percent of light transmission at 1 μM ADP and (2) the threshold (the minimal concentration of ADP) for biphasic aggregation.[14]

Propranolol therapy: After completion of the control period, all hypertensive patients were started on propranolol therapy at 80 mg/day, divided into four doses, and titrated against blood pressure response to a maximal dosage of 240 mg daily. Patients were followed up in the hypertension clinic every 2 weeks, when blood pressure, heart rate and body weight were measured. After 6 to 8 weeks of propranolol therapy the plasma catecholamines and platelet aggregation studies were repeated, exactly as in the control period, together with routine testing. All studies were performed 1 to 2 hours after ingestion of 80 mg of propranolol. Then each patient was asked to discontinue medication and to return to the laboratory 2 days later, where a complete history and physical examination were obtained and catecholamine and platelet aggregation studies, in the supine position only, were repeated as in the previous periods.

Plasma catecholamines: These were measured by a modification[14] of the radioenzymatic method of Passon and Peuler.[15] In this method, plasma norepinephrine and epinephrine are converted by the partially purified enzyme catechol-*O*-methyl-transferase and ^{3}H-adenosyl-methionine to ^{3}H-normetanephrine and ^{3}H-metanephrine, respectively. The sensitivity of the assay is less than 1 pg of plasma norepinephrine and epinephrine and requires 50 μliters or less of plasma.

Statistical analysis: Student's *t* test was used for comparisons between two groups and the paired *t* test for changes within the same group. Correlation coefficients were computed. Results are expressed as mean ± standard error of the mean.

Results

Clinical and laboratory characteristics: Table I includes some clinical data and the results of the re-

TABLE I

Some Clinical and Laboratory Data in the Hypertensive and Normotensive Subjects

Group	Age (yr)	Sex	LVH (n)	Optic Fundi (KWB) Grade	Recumbent Position SBP (mm Hg)	DBP (mm Hg)	HR (beats/min)	NE (pg/ml)	E (pg/ml)	Platelet Aggregation % of LT	Platelet Aggregation Threshold
Hypertensive patients (n = 16)	54 ± 2	12 M 4 F	4+	I (n = 10) II (n = 6)	160 ± 7	111 ± 3	79 ± 3	244 ± 12	39 ± 2	33 ± 2	1.8 ± 0.36
Normotensive subjects (n = 11)	50 ± 2	8 M 3F	0	0 (n = 9) I (n = 2)	116 ± 2	74 ± 2	75 ± 2	202 ± 18	35 ± 4	25 ± 3	2.9 ± 0.3

DBP = diastolic blood pressure; E = epinephrine; HR = heart rate; KWB = Keith-Wagener-Barker classification; LT = light transmission at 1 μm of ADP concentration; LVH = left ventricular hypertrophy on electrocardiography; NE = norepinephrine; n = number of patients; SBP = systolic blood pressure; threshold = minimal concentration of ADP to induce biphasic aggregation (μM); + = present.

cumbent studies of platelet aggregation and plasma catecholamines in the 16 hypertensive and 11 normotensive subjects. The blood pressure of the hypertensive group was significantly higher than that in the normotensive group, whereas mean values of plasma norepinephrine and epinephrine were essentially the same. The percent of light transmission at 1 μM ADP concentration was higher ($p < 0.05$), whereas the threshold of biphasic aggregation was lower ($p < 0.05$) in hypertensive than in normotensive subjects.

Effect of propranolol therapy on arterial pressure and heart rate in the hypertensive group: Propranolol significantly decreased systolic and diastolic resting blood pressures from 160 ± 7 to 141 ± 5 mm Hg ($p < 0.05$) and from 111 ± 3 to 97 ± 2 mm Hg ($p < 0.01$), respectively, but did not prevent or lessen the increase in these pressures during exercise. Although the exercise-induced increases in systolic and diastolic blood pressure during propranolol therapy (45 ± 6 and 33 ± 6 mm Hg, respectively), were similar to the 44 ± 3 and 31 ± 4 mm Hg increases during the control period, the absolute exercise levels in these pressures were significantly lower during propranolol therapy than in the control period ($p < 0.05$ for both). The abrupt discontinuation of propranolol was associated with a gradual elevation in blood pressure, and at 48 hours the systolic and diastolic blood pressures of 155 ± 3 and 109 ± 4 mm Hg, respectively, were slightly lower than the control levels.

Heart rate decreased significantly with propranolol from 79 ± 3 beats/min in the control period to 63 ± 3 ($p < 0.01$) at rest, and from 98 ± 3 to 71 ± 3 beats/min ($p < 0.001$) during exercise. Heart rate 48 hours after therapy 80 ± 3 beats/min was not significantly different from the control level.

Propranolol and plasma catecholamines: Propranolol increased both plasma norepinephrine and epinephrine from 244 ± 12 and 39 ± 2 pg/ml in the control period to 288 ± 16 ($p < 0.05$) and 55 ± 3 ($p < 0.02$), respectively, at rest and from 574 ± 34 and 102 ± 10 pg/ml in the control periods to 641 ± 40 and 135 ± 16 with exercise. Thus, exercise induced a significant elevation in both catecholamines and the extent of the increase was similar in the control and propranolol periods. Sudden discontinuation of propranolol was not associated with substantial changes in plasma catecholamines (265 ± 15 and 45 ± 3 pg/ml, respectively) when measurements were obtained 48 hours after therapy.

Propranolol and platelet aggregation: Table II gives results of platelet aggregation studies at rest and during exercise. Platelet aggregation was reduced by propranolol therapy when the patients were studied in the recumbent position at rest. The percent of light transmission at 1 μM ADP decreased from 33 ± 2 to 27 ± 1.5 ($p < 0.02$), and the threshold for biphasic aggregation increased from 1.8 ± 0.36 to 2.8 ± 0.72 μM of ADP (difference not significant). However, propranolol did not prevent the increase in platelet aggregation induced with exercise. Both before and during propranolol therapy exercise increased the percent of light transmission at 1 μM ADP significantly (+5.7 ± 1.6 [$p < 0.01$] before and +5 ± 1.3 [$p < 0.01$], during therapy) and decreased threshold for biphasic aggregation significantly (−0.55 ± 0.16 μM of ADP [$p < 0.01$] before and −0.25 ± 0.07 [$p < 0.01$], during therapy). The differences between the two periods were not significant.

The abrupt withdrawal of propranolol was associated with a significant rise in percent of light transmission ($p < 0.01$) and a significant decrease in threshold

TABLE II

Platelet Aggregation Studies in the Control Period, During Propranolol Therapy and 48 Hours After Propranolol Withdrawal in the Hypertensive Patients

($p < 0.05$) from the propranolol period, and in some patients results of platelet aggregation studies differed from those of the control period.

There was a positive correlation between age and plasma norepinephrine level ($r = 0.64$, $p < 0.01$) as well as with the percent of light transmission ($r = 0.56$, $p < 0.02$) at rest. Plasma norepinephrine was also correlated with the percent of light transmission ($r = 0.49$, $p < 0.05$) at rest.

Discussion

Plasma catecholamines and platelet aggregation in hypertension: In our study patients with uncomplicated primary hypertension demonstrated a greater platelet aggregability to adenosine diphosphate than did age-matched normotensive and healthy subjects ($p < 0.05$). The slightly higher mean plasma catecholamine concentration in hypertensive than in normotensive subjects was not statistically significant, and this finding is in accord with some,[16,17] but not all,[1,2] previous reports. It is generally assumed that circulating levels of catecholamines are maintained by catecholamines liberated from nerve terminals and are in proportion to the degree of sympathetic activity.[18] However, this assumption is not necessarily correct because an increase in catecholamine concentration could represent increased release, decreased uptake or a decreased clearance from plasma. Thus, primary hypertension may be associated with an abnormality of catecholamine metabolism in local but critical sites that may not be reflected by measurable changes in plasma catecholamines.[19]

Several in vitro[5] and in vivo[6] studies have demonstrated that catecholamines bring about platelet aggregation. In our study the increase in platelet aggregation in the hypertensive group, a phenomenon that has been reported by other investigators,[20,21] may be a secondary phenomenon unrelated to plasma catecholamines. It is possible that chronic elevation in blood pressure in itself[22] and turbulence of blood flow at certain areas may produce endothelial injury, which could lead to adherence and aggregation of platelets to the exposed connective tissue. Folts et al.[23] demonstrated increased platelet aggregability in dogs after induction of arterial stenosis.

Effect of propranolol therapy: There is evidence that the antihypertensive effect of propranolol is dose-related and that administration of propranolol as the sole antihypertensive agent, in oral doses of 80 to 160 mg/day, has a mild antihypertensive action.[24,25] In our study, administration of 240 mg/day of propranolol produced significant reductions in both systolic ($p < 0.05$) and diastolic blood pressures ($p < 0.01$) at rest; but did not prevent, as was expected,[26,27] the rise in blood pressure during exercise, although the absolute levels of blood pressure were lower during propranolol therapy than during the control period. Lamid and Wolff[28] failed also to show any significant effect on the change in blood pressure during isometric handgrip exercise in patients given therapeutic doses of hydrochlorothiazide, guanethidine, reserpine or hydralazine, whereas Shapiro[29] reported similar results in hypertensive patients subjected to the cold pressor test and psychologic stress.

In our study, as in previous reports,[27,30,31] propranolol therapy was associated with a significant rise in both plasma norepinephrine ($p < 0.05$) and epinephrine ($p < 0.02$). This elevation in plasma catecholamine levels is probably related to the inhibitory effect of propranolol on neuronal catecholamine binding ($uptake_1$) and possibly uptake into the platelets ($uptake_2$).[32,33]

Frishman et al.[11] reported abnormal platelet aggregation to ADP and epinephrine in patients with angina pectoris; this aggregation reversed to normal after propranolol therapy. In our study the administration of propranolol in patients with uncomplicated primary hypertension produced a significant decrease in platelet aggregation but did not prevent the increase in aggregation with exercise.

Effect of discontinuing propranolol on platelet aggregation: In this study the sudden discontinuation of propranolol was not associated with any subjective adverse reactions or rebound hypertension, although these responses have been reported with other antihypertensive agents.[34] Blood pressure gradually reached pretreatment levels in 48 hours in most of the patients, whereas plasma catecholamine concentration decreased slightly during this period. However, platelet aggregability increased significantly when the drug was discontinued. This increase in platelet aggregation may be attributed to catecholamines, although both plasma norepinephrine and epinephrine decreased rather than increased after sudden discontinuation of propranolol therapy. It is possible that long-term administration of propranolol may have decreased the pool of platelet receptors available to catecholamines. On rapid withdrawal of propranolol, an increased number of receptors might become available for occupancy by norepinephrine and epinephrine, thus leading to a state of supersensitivity, which accounts for the changes in platelet aggregability.[35] A similar hyperaggregable state in platelet function 48 hours after propranolol therapy was reported by Frishman et al.[36] in patients with angina pectoris.

Blood Pressure and Survival After Myocardial Infarction: The Framingham Study

WILLIAM B. KANNEL, MD, FACC*
PAUL SORLIE, MS†
WILLIAM P. CASTELLI, MD‡
DANIEL McGEE, PhD†

Framingham, Massachusetts

Blood pressures were routinely obtained biennially from 2,336 men in the Framingham cohort over a 20 year period of follow-up study. During that time 193 men had their first myocardial infarction. Blood pressure after myocardial infarction was unrelated to survival over the next 5 years, but the blood pressure status preceding the infarction was distinctly related to survival, with hypertensive patients having almost three times the mortality of normotensive patients. These results are explained by the two-fold greater risk of death incurred by hypertensive patients who had a substantial decrease in pressure after myocardial infarction compared with that of men who remained hypertensive. The greater the decrease in pressure after myocardial infarction the greater was the mortality. With exclusion of men who experienced a reduction of more than 10 mm Hg in pressure, men with hypertension after myocardial infarction had a five-fold greater risk of mortality than that of normotensive patients.

A decrease in pressure with interim myocardial infarction occurs frequently, even when the influence of age, treatment and regression toward the mean are taken into account. Men who experienced such reductions in pressure had a reduction in vital capacity (not statistically significant) and an increase in heart rate, thus suggesting that poorer myocardial function accounts for the greater mortality.

Effective secondary prevention in patients surviving a myocardial infarction requires some knowledge of the factors that influence their prognosis. Such factors are being discerned, but the evidence is still far from consistent.[1] It is agreed that the extent of damage to the myocardium and the severity of obstruction of the coronary arteries are important determinants of survival.[1] The influence of hypertension, a major established risk factor for initial myocardial infarction, remains in doubt.

In this report we examine the prognosis after myocardial infarction in relation to blood pressure before and after the event, taking into account the change in pressure with interim infarction. Comparisons are made with the prognosis after uncomplicated angina pectoris and the differences and similarities are noted.

Methods

The Framingham Heart Study: This study has followed up a cohort of 5,209 men and women for 20 years with biennial examinations at the Framingham Study Clinic. Each examination included an extensive cardiovascular history and physical examination, an electrocardiogram, various blood chemistry determinations and measurements of blood pressure, vital capacity and other physical variables. Morbidity and mortality were continuously monitored by hospital surveillance, contact with the Department of Vital Statistics for death certification and communication with family physicians and relatives. Less than 2 percent of the cohort has been completely lost to follow-up.

Systolic and diastolic blood pressure readings were taken from the left arm with a mercury sphygmomanometer while the subject was seated. Measurements were expressed in millimeters of mercury and were recorded to the nearest even number. Subjects were considered to have hypertension when two pressures on an examination were found to exceed 160/95 mm Hg. Those with pressures consistently below 140/90 mm Hg were designated normotensive, and the rest were judged to have borderline hypertension.

Patients with myocardial infarction: During the 20 year follow-up period, 193 men and 53 women had a recognized myocardial infarction and were eligible for prognostic follow-up study. Fifty-two additional episodes of infarction that occurred late in the study—that is, between examinations 10 and 11—were not included because of the short follow-up time available. A recognized myocardial infarction was one that satisfied the criteria (unequivocal electrocardiographic change or elevated serum enzyme levels) and produced symptoms severe enough for the victim to request medical assistance. Because of the small number of women with myocardial infarction, only the prognosis for men is considered in this report. Prognostic analysis was performed on the 193 men who had an infarction between 1950 and 1970. Their ages ranged from 33 to 76 years. Analyses that required survival and completion of the next examination (for example, hypertension both before and after myocardial infarction) used a sample of 135 men with myocardial infarction. The coronary events recorded (myocardial infarction or angina pectoris) could have occurred at any time in the 2 year period between examinations.

Angina pectoris was diagnosed on the basis of symptoms alone when two examiners agreed on the nature of the complaint. The symptom complex accepted as angina consisted of transient substernal distress, brought on by exertion or excitement, relieved by rest or nitroglycerin and not occurring while the patient was quiet and resting.

Survival analysis: To measure and test for the association between survival after a myocardial infarction and levels of a characteristic, the method of combining contingency tables at each level of follow-up was used. This procedure is described in detail by Hankey and Myers[2] and by Breslow.[3] For each level of the characteristic (for example, systolic blood pressure), the observed number of deaths and an expected number of deaths based on an hypothesis of no association were calculated. The ratio of observed to expected deaths is presented as a descriptive statistic of the excess mortality associated with the level of systolic pressure. The observed and expected number of deaths were aggregated over age-specific strata, thus giving age-adjusted ratios. A chi square statistic was calculated to test whether the regression of excess mortality on the levels of the characteristic is statistically significant from 0.

Results

Angina pectoris: In men with angina pectoris, a clear relation of blood pressure to subsequent mortality was evident. Subjects who had hypertension *after* angina became clinically manifest had four times the mortality of those who were entirely normotensive (Fig. 1). Even those with borderline hypertension after the onset of angina had a mortality double that of normotensive patients. Hypertension *before* the development of angina was also associated with excess 5 year mortality (seven-fold). A change in blood pressure after interim development of angina pectoris was not significantly related to mortality (Fig. 1).

Myocardial infarction: The picture was quite different for myocardial infarction. Blood pressure after recovery from an initial myocardial infarction was unrelated to subsequent survival for 5 years (Fig. 2). However, blood pressure *preceding* the myocardial infarction was distinctly related to survival, with hypertensive men having almost three times the mortality of normotensive men. This mortality does not include the early mortality in the 1st month after an infarction but does include all other deaths in the 5 years after infarction. These results suggest that the blood pressure after a myocardial infarction may be affected by the event itself, a hypothesis borne out by an examination of mortality in relation to *change* in blood pressure with an interim myocardial infarction. A hypertensive man who is no longer hypertensive after infarction is twice as likely to die within 5 years as a hypertensive man who

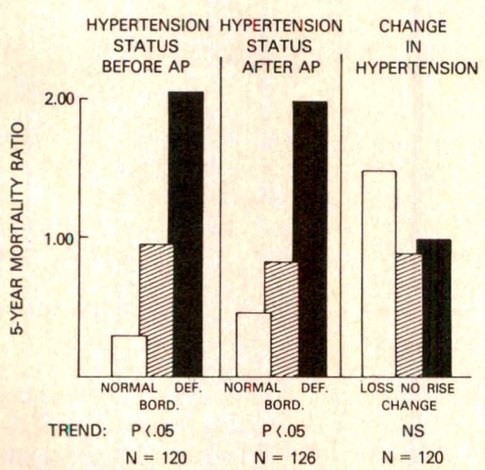

FIGURE 1. Mortality after uncomplicated angina pectoris (AP). BORD. = borderline hypertension; DEF. = definite hypertension; N = number of subjects; Normal = normal blood pressure; p = probability.

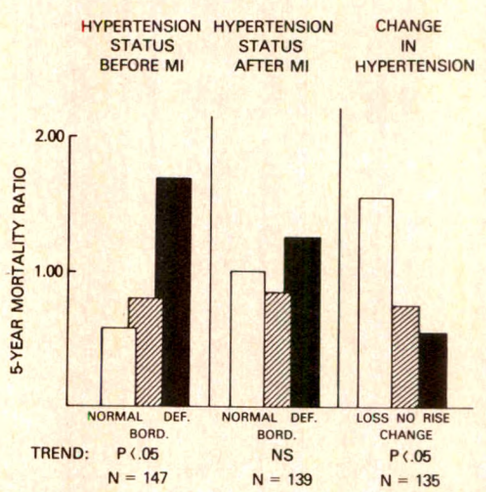

FIGURE 2. Mortality after recognized myocardial infarction (MI). Abbreviations as in Figure 1.

TABLE I

Mean Systolic Blood Pressure (SBP) Before and After a Recognized Myocardial Infarction (MI) (men, aged 33 to 76 years at infarction)

	n	Mean SBP	Standard Deviation of SBP
All Men With MI			
Before MI	135	143.9	21.5
After MI	135	133.8	22.0
Men With MI Excluding Those Taking Antihypertensive Drugs			
Before MI	112	139.7	18.5
After MI	112	132.5	20.1

shows no change in blood pressure status (Fig. 2). The greater the reduction in blood pressure after recovery from infarction, the greater was the observed mortality over the ensuing years. The association between a change in systolic blood pressure and death holds even when the antecedent level of pressure and antihypertensive treatment are taken into account.

When a man has a myocardial infarction, there is an average decrease in systolic blood pressure of 10.1 mm Hg between the examination performed before the event and the examination performed an average of 2 years after that examination and an average of 1 year after the infarction (Table I). This decrease compares with a slight average *increase* in systolic blood pressure of 1.6 mm Hg in men who did not sustain a myocardial infarction. The increase in systolic blood pressure of 1.6 mm Hg over 2 years tends to be uniform for all ages in the range of 40 to 70 years. When patients receiving antihypertensive drugs are omitted, the average decrease with interim myocardial infarction is 7.2 mm Hg. The decrease in pressure considered in this study is a sustained decrease and not the transient reduction often noted in the acute stage of myocardial infarction.

In part, the substantial reduction in systolic pressure after myocardial infarction, when a slight increase would be expected in the normal course of events, might be explained by the statistical phenomenon of regression toward the mean, because persons who have a myocardial infarction have pressures above average; that is, given a high initial value, subsequent values on reexamination tend to be closer to the mean for the entire study group and hence lower. An estimate of the reduction in systolic blood pressure due to regression to the mean can be made using the correlation between measures of systolic blood pressure at two examinations and the means and standard deviations of the group. The systolic blood pressure in the patients with a myocardial infarction would be expected, on the average, to decrease approximately 2 mm Hg because of regression to the mean.

Weight measured after a myocardial infarction also tended to be lower than that before the infarction. There was an average reduction of 2.66 kg in the 2 years spanning an infarction. The known association between change in weight and change in blood pressure is not large enough to account for the decrease (7.2 mm Hg) in systolic blood pressure (SBP). If one uses the regression equation $\Delta SBP = 1.58 + 0.375\ (\Delta\ wt)$, a loss of 2.66 kg ($\Delta$ weight is negative) accounts for a decrease in blood pressure of less than 1 mm Hg.

Hypertension before versus after myocardial infarction: An examination of the subjects with myocardial infarction according to their "hypertensive status" before and after the infarction revealed that 10 of 55 men with definite hypertension had a change in classification to borderline hypertension 2 years later, and an additional 23 had a change to normotensive status (Table II). This means that 60 percent of hypertensive men had normal or borderline hypertension after the infarction. Over a similar 2 year time span only about one third of hypertensive men in the Framingham cohort without a myocardial infarction were classified as normotensive or having borderline hypertension.

Thus, blood pressure *after* myocardial infarction appears to be a poor prognosticator of survival because the group with low pressure includes some subjects who have a decrease in pressure as a result of myocardial infarction. When men who experienced a substantial decrease in pressure (that is, greater than 10 mm Hg) are excluded, blood pressure status is related to mortality (Table III). This is also true when an adjustment is made for *change* in blood pressure throughout its range of increase or decrease.

Formal statistical analysis assessing the regression of mortality on change in systolic blood pressure and on the observed levels of pressure before the infarction indicates a statistically significant impact of change in blood pressure on mortality if one takes the initial blood pressure reading into account. Thus, the prognosis associated with a reduction in pressure is poor at all levels of initial pressure.

Myocardial state related to decrease in blood pressure: The higher the initial pressure the more likely it was to decrease after myocardial infarction (Table IV). Those who experienced a decrease in blood pressure tended to have a more rapid heart rate, which is related to risk of cardiac failure. These findings and the unchanged mortality when a decrease in pressure occurred

TABLE II

Number of Men With Myocardial Infarction (MI) Classified by Blood Pressure Status* Before and After Infarction (Framingham study: men, aged 30 to 62 years at entry)

Blood Pressure Status at Examination Before MI		Blood Pressure Status at Examination After MI		
Status	Men (n)	Normal	Borderline	High
Normal	41	35	2	4
Borderline	39	14	14	11
High	55	23	10	22

Normal = blood pressure less than 140/90 mm Hg; High = blood pressure equal to or greater than 160/95 mm Hg; Borderline = all others.

after uncomplicated angina suggest that myocardial damage explains the adverse effect of a reduction in pressure. Our data were too sparse to assess the relation of congestive heart failure to a decrease in blood pressure. The product of systolic pressure and heart rate after myocardial infarction was also unrelated to prognosis after myocardial infarction.

Subjects with unrecognized or silent myocardial infarction may be judged to have sustained a milder attack than those who are symptomatic. Such subjects had a significantly less pronounced reduction in blood pressure than that of subjects with an overt infarction (a reduction of only 2 mm Hg in systolic blood pressure was observed). This smaller reduction occurred although these subjects had slightly higher pressures and greater age, a finding that again suggests that myocardial damage is the most likely explanation for the decrease in blood pressure after an infarction.

Discussion

Previous studies on influence of hypertension on prognosis after myocardial infarction: Studies to date have not provided consistent results on the importance of hypertension as a determinant of survival once a myocardial infarction has occurred. Some studies[4–11] appear to indicate that it is an important predictor of subsequent mortality; others[12–23] appear to refute such a role. These inconsistencies probably stem from failure to take into account the change in pressure sometimes resulting from infarction and its prognostic import. Thus, Norris et al.[11] reported that chronic systemic hypertension did not influence mortality for several years after infarction, although on later follow-up it was related to survival, especially in those with an otherwise good prognosis. The early mortality was probably adversely influenced by those who had a decrease in blood pressure reflecting a badly damaged myocardium.

Most studies of blood pressure after infarction have had to rely on measurements obtained during hospitalization for the acute event[12–18,21–23] or only on a history of prior pressures. When such antecedent pressures were objectively and routinely obtained, a relation to prognosis after myocardial infarction has been demonstrated, as in the Framingham study.[8,9] The Göteborg study[24] also found a relation of antecedent blood pressure to short-term prognosis.

Rabkin et al.[4] specifically studied change in blood pressure with interim myocardial infarction. They found that a change was significantly related to prognosis, but in multivariate analysis the level to which the pressure changed was judged more important than the change itself.[4] Evan[25] also found that a decrease in pressure was associated with a poor short-term prognosis.

There are many reasons why a high pressure should be associated with a poor prognosis after a myocardial infarction. Blood pressure would continue to accelerate the process of coronary atherogenesis and place an increased work load on a myocardium with an already compromised coronary circulation. A decrease in pressure with interim infarction probably indicates deterioration of myocardial function as a result of infarction, which in turn explains the poor prognosis associated with infarction. Studies to document this hypothesis by direct investigation of myocardial function in relation to a reduction in blood pressure and infarct size seem indicated.

Implications of findings in Framingham study: Whatever the cause of the poor prognosis, the data imply that a high blood pressure after myocardial infarction is associated with an increased risk of early death and that a reduction in pressure is of ominous import, suggesting a severely damaged myocardium. Confusion about the role of blood pressure in prognosis after myocardial infarction derives from failure to separate subjects whose blood pressure is low as a result of a decrease in pressure due to severe myocardial damage from subjects who have always had a low level of pressure.

TABLE III

Mortality by Blood Pressure Status* After Myocardial Infarction (Framingham study: 20 year follow-up)

Blood Pressure Status After Myocardial Infarction	5 Year Mortality Ratios: All Subjects	5 Year Mortality Ratios: Excluding Persons With Pressure Reduction of 10 mm Hg or More	5 Year Mortality Ratios: Adjusted for Change in Systolic Blood Pressure†
Normal	0.98	0.25	0.87
Borderline	0.93	0.99	1.00
High	1.16	1.97	1.56
Significance of trend	NS	p = <0.05	p = <0.05

* Normal = blood pressure less than 140/90 mm Hg; High = blood pressure equal to or greater than 160/95 mm Hg; Borderline = all others.
† Adjusted for change in pressure with interim myocardial infarction by aggregating over change-specific strata of pressure.[2,3]
NS = not significant; p = probability.

TABLE IV

Correlation Between Change in Systolic Blood Pressure* After Myocardial Infarction and Selected Factors (Framingham study: 20 year follow-up)

Change in Systolic Pressure Versus:	r	p
Age	−0.10	NS
Initial systolic pressure	−0.44	< 0.05
Vital capacity/height change	+0.16	NS
Heart rate change	−0.25	< 0.05
Heart size change	−0.06	NS
Weight change	+0.22	< 0.05

* Change in systolic blood pressure. A decrease in pressure has a minus sign, a rise in pressure a plus sign.
NS = not significant; p = probability.

The data suggest the following: (1) Persons who sustain a substantial reduction in blood pressure after a myocardial infarction need investigation for incipient heart failure and might benefit from therapy for failure, although they may have no overt symptoms at the time. (2) Physicians should keep careful records of blood pressure so that if an infarction occurs there will be some baseline against which to compare postinfarction pressures. (3) Because of the relation between blood pressure after infarction and survival, it is possible that therapeutic control of elevated pressures might improve survival. A recent report by Stewart[26] on a mixed population sample implied that it is dangerous to lower pressures below 100 mm Hg diastolic. If this observation is correct, then it might be particularly dangerous to reduce further blood pressure that has already decreased markedly after an infarction although it has remained above normal. However, reducing the pressure might be beneficial if it reduces the cardiac work load without impairing myocardial perfusion. Only a trial that takes into account change in pressure with interim infarction could settle this issue.

Comparative Hemodynamic Effects of Converting Enzyme Inhibitor and Sodium Nitroprusside in Severe Heart Failure

THOMAS R. VROBEL, MD*
JAY N. COHN, MD, FACC

Minneapolis, Minnesota

In nine patients with severe congestive heart failure, the acute response to the infusion of a nonspecific vasodilator, sodium nitroprusside, was compared with the infusion of the converting enzyme inhibitor, teprotide (SQ 20, 881). The hemodynamic effects were similar. Nitroprusside and teprotide increased cardiac index 24 and 20 percent, respectively, reduced mean arterial pressure 11 and 14 percent and pulmonary wedge pressure 21 and 24 percent, and produced no significant change in heart rate (−0.5 and −0.7 percent). Arterial partial pressure of oxygen decreased in response to nitroprusside infusion from 75.8 ± 4.1 to 65.4 ± 3.2 mm Hg ($p < 0.05$) but did not change in response to teprotide infusion (77.0 ± 4.5 before and 76.3 ± 3.0 mm Hg after). Circulating norepinephrine levels were lowered in response to both agents in spite of the decrease in mean arterial pressure (nitroprusside 754 ± 126 to 580 ± 82 pg/ml, $p < 0.05$; teprotide 807 ± 136 to 518 ± 92 pg/ml, $p < 0.05$). Although the control plasma renin activity did not correlate closely with the hemodynamic response to either agent in this small series, this level did correlate directly with the dose of nitroprusside required to produce the desired hemodynamic response.

Therefore, converting enzyme inhibition produces an acute hemodynamic response in severe congestive heart failure comparable with that of sodium nitroprusside with less detrimental acute effect on pulmonary oxygen transport. Long-term oral therapy with converting enzyme inhibitor deserves evaluation in congestive heart failure.

Recent studies have shown that the converting enzyme inhibitor SQ 20,881 (teprotide) exerts a vasodilator effect and improves left ventricular performance in clinical[1,2] and experimental[3] congestive heart failure, in both hypertensive and nonhypertensive states. The vasodilator effect appeared to be related at least in part to activity of the renin-angiotensin system as assessed from plasma renin activity.[1] Thus, the hemodynamic effects of converting enzyme inhibitor might be expected to be most prominent on vascular sites most sensitive to angiotensin. However, converting enzyme inhibitor also enhances the activity of bradykinin and therefore its effect may also be due to mechanisms other than angiotensin inhibition.

Sodium nitroprusside, a nonspecific vasodilator with a balanced effect on arterial and venous smooth muscle,[4] has been widely used to treat severe congestive heart failure.[5] In this study we compared the acute effects of converting enzyme inhibitor and nitroprusside in a series of patients with severe congestive heart failure. In particular we compared the effects on hemodynamics, arterial blood gases and plasma catecholamine levels. We also attempted to assess the importance of the renin-angiotensin system as a determinant of the response to these two agents.

Methods

Patients: Nine patients admitted to the hospital with severe congestive heart failure who had been judged to have received optimal therapy with cardiac glycosides and diuretic drugs during hospitalization were studied. All patients had cardiomegaly at the time of study and all had pulmonary or venous congestion, or both, during the initial part of their hospitalization. At the time of study all patients were in New York Heart Association functional class III or IV[6] in spite of therapy. The cause of heart disease was either ischemic heart disease or cardiomyopathy. Diuretic drugs and vasodilators were withheld for at least 24 hours before study. The study protocol was approved by the University Committee on the Use of Human Subjects in Research. Informed consent was obtained from all subjects.

Procedures: All patients were studied in the fasting state and in the supine position. Right heart catheterization was performed by passing a no. 7 thermodilution Swan-Ganz flow-directed balloon-tipped catheter (Edwards Laboratories, Santa Ana, California) into the pulmonary artery from an antecubital vein. The brachial artery was cannulated with a short Teflon® catheter advanced over an 18 gauge thin-walled needle. Pressures were monitored with P23d Statham or Bell and Howell pressure transducers positioned at the mid axillary line and a Hewlett-Packard multichannel direct writing recorder. An electrocardiographic lead was monitored continuously during the study.

After the catheters were positioned, the patients were allowed to rest for 1 hour before baseline data were obtained. Right atrial pressure, pulmonary arterial free and occluded pressures and arterial pressure were recorded. Cardiac output was determined in triplicate with the thermodilution technique[7] using an Edwards 9510 thermodilution cardiac output computer. Repeated individual measurements by this technique vary by less than 15 percent and average values vary by

CI = cardiac index (liters/min per m^2); HR = heart rate (beats/min); MAP = mean arterial pressure (mm Hg); PAR = mean pulmonary arteriolar resistance (dynes sec cm^{-5}); PWP = mean pulmonary wedge pressure (mm Hg); RAP = mean right atrial pressure (mm Hg); SVR = mean systemic vascular resistance (dynes sec cm^{-5}).

less than 10 percent. Blood specimens were obtained for the measurement of plasma renin activity by the radioimmunoassay method of Sealey et al.[8] and plasma catecholamine levels by radioenzymatic assay (CAT-A-KIT,® Upjohn Company, Kalamazoo, Michigan). Duplicate measurements of norepinephrine by this method in our laboratory have a coefficient of variation of 8.3 percent. Arterial blood was obtained from the brachial artery cannula for determination of pH, partial pressure of carbon dioxide and oxygen saturation.

Protocol: After baseline measurements were made, an infusion of nitroprusside (Nipride®, Hoffmann-La Roche Incorporated, Nutley, New Jersey) was begun through a peripheral venous cannula starting at a dose of 10 μg/min with increases of 10 μg/min every 5 to 10 minutes. The infusion rate was increased until either pulmonary wedge pressure decreased by 40 percent below the control value or systolic arterial pressure decreased to less than 90 mm Hg. At this point all measurements made in the baseline period were repeated.

The patients were allowed to recover for 1 hour after the infusion of nitroprusside was discontinued. All baseline measurements were repeated. Teprotide (SQ 20, 881, The Squibb Institute, Princeton, New Jersey) was diluted in sterile water and injected intravenously over 1 minute at a dose of 0.25 mg/kg. Pressures were monitored for 30 minutes. If the hemodynamic end point described for nitroprusside had not been reached, additional doses were given every 30 minutes using 0.5 and 1 mg/kg and a maximum of 2 mg/kg. Thirty minutes after each dose all measurements were repeated.

Mean intravascular pressures were obtained by electronic integration and the following measurements were calculated: Systemic vascular resistance (SVR) = 80 $(\overline{MAP} - \overline{RAP})/CO$; pulmonary vascular resistance (PVR) = 80 $(\overline{PAP})/CO$; pulmonary arteriolar resistance (PAR) = 80 $(\overline{PAP} - \overline{PWP})/CO$, where $\overline{AP}$ = mean arterial pressure, CO = cardiac output, $\overline{PAP}$ = mean pulmonary arterial pressure, $\overline{PWP}$ = mean pulmonary wedge pressure, and $\overline{RAP}$ = mean right atrial pressure.

Statistical analysis was performed by using paired t tests and Pearson's coefficient of correlation. Data are presented as mean ± standard error of the mean.

Results

Hemodynamic responses: The hemodynamic results before and after treatment with nitroprusside and teprotide are shown in Table I. There was no significant difference between the hemodynamic values in the control periods before infusion of nitroprusside and before administration of teprotide. None of the patients were hypertensive; all had elevated pulmonary wedge pressure. Cardiac index was below the normal range in most patients, averaging 2.1 ± 0.2 liters/min per m^2 before nitroprusside and 2.0 ± 0.2 before converting enzyme inhibitor.

The maximal hemodynamic response to nitroprusside and to teprotide was similar (Table I, Fig. 1). Cardiac index increased significantly with both drugs (0.5 liters/min per m^2 or 24 percent with nitroprusside, $p < 0.001$, and 0.4 liters/min per m^2 or 20 percent with teprotide, $p < 0.01$). Heart rate was not changed by either agent. At peak effect, there was a significant and equivalent decrease in mean arterial pressure, systemic vascular resistance pulmonary wedge pressure, pulmonary arteriolar resistance and right atrial pressure. In this small group of patients there was no relation between baseline plasma renin activity and the response of any hemodynamic variable to infusion of either nitroprusside or converting enzyme inhibitor.

Renin activity: The baseline renin activity showed a significant correlation with the dose of nitroprusside necessary to attain the hemodynamic end point (dose of nitroprusside = 1.677 plasma renin activity + 61.11, r = 0.60) (Fig. 2). The amount of teprotide necessary to

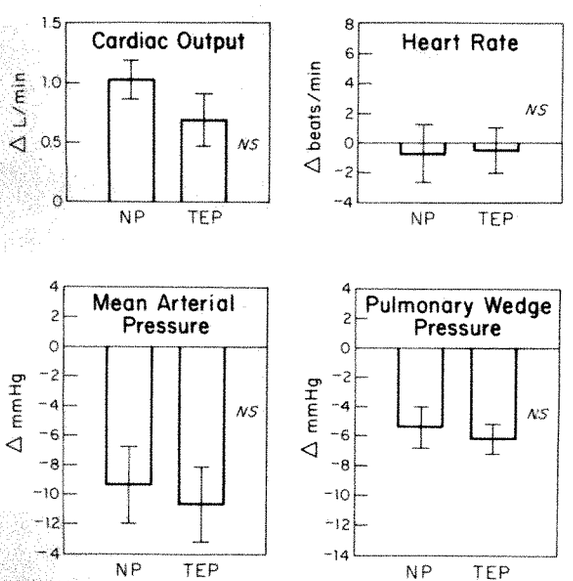

FIGURE 1. Change from hemodynamic values at rest produced by nitroprusside (NP) and teprotide (TEP) in nine patients with congestive heart failure. The response to the two agents was similar. NS = not significant.

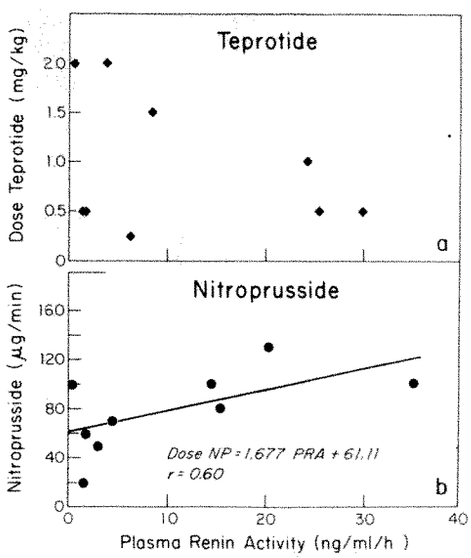

FIGURE 2. Effect of control plasma renin activity (PRA) on the dose of sodium nitroprusside (NP) and teprotide required to produce the desired hemodynamic response. The dose requirement for nitroprusside was directly related to the control level or plasma renin activity whereas that for teprotide tended to be lower when plasma activity was increased.

produce the hemodynamic end point did not relate closely to plasma renin activity. However, the two patients who required the maximal dose of converting enzyme inhibitor had a plasma renin activity of less than 5 ng/ml per h whereas the three patients with a plasma renin activity greater than 20 ng/ml per h all responded to a dose of 1 mg/kg or less (Fig. 2).

Plasma renin activity was 11.5 ± 4.0 ng/ml per h before teprotide and 10.6 ± 6.9 ng/ml per h before nitroprusside (difference not significant). At the time the hemodynamic measurements were made, plasma renin activity increased to 34.0 ± 15.6 ng/ml per h in response to teprotide ($p < 0.05$ compared with control value) but did not change in response to nitroprusside (10.5 ± 3.1 ng/ml per h).

Arterial partial pressure of oxygen (P_{O_2}) (Fig. 3): This value was not significantly different in the two control periods (75.8 ± 4.1 mm Hg before nitroprusside and 77.0 ± 4.5 before teprotide). Arterial P_{O_2} decreased to 65.4 ± 3.2 mm Hg with maximal nitroprusside infusion ($p < 0.01$ compared with control P_{O_2}) and did not change with the maximal dose of teprotide (76 ± 3.0 mm Hg). The difference between P_{O_2} at peak nitroprusside effect and peak teprotide effect was significant ($p < 0.025$). There was no change from the control value in arterial pH or P_{CO_2} with either agent.

Plasma norepinephrine levels (Fig. 4): The control levels were 754 ± 126 pg/ml before nitroprusside and 807 ± 136 before converting enzyme inhibitor (difference not significant). At peak nitroprusside response the plasma norepinephrine level decreased to 580 ± 82 pg/ml ($p < 0.05$ compared with control values) in spite of a 10 percent average decrease in mean arterial pressure. At peak converting enzyme inhibitor response, plasma norepinephrine level decreased to 518 ± 92 pg/ml ($p < 0.05$ compared with control values) in spite of a 14 percent average decrease in mean arterial pressure. There was no significant difference between the plasma norepinephrine levels at the hemodynamic end point after administration of nitroprusside and converting enzyme inhibitor.

Discussion

Converting enzyme inhibitor versus nitroprusside: Our data show that the acute administration of converting enzyme inhibitor to normotensive or mildly hypotensive patients with severe congestive heart failure produces essentially the same hemodynamic changes as those achieved by infusion of nitroprusside. Vasodilators may exert their effect either on the peripheral arterial or venous vasculature. In patients with heart failure arteriolar dilation leads to an increase in cardiac output where venous dilation contributes to a decrease in left ventricular filling pressure or pulmonary wedge pressure.[4,5]

In this study, as in previous studies, both nitroprusside and converting enzyme inhibitor produced effects on the arterial and venous vasculature, as manifested by the similar increases in cardiac output and reductions in pulmonary wedge pressure. Consequently, converting enzyme inhibitor therapy, similar to nitroprusside infusion, has the advantages of a balanced vasodilator response that has also been observed with the combination of hydralazine and isosorbide dinitrate[9,10] and with prazosin.[11]

Mechanism of action of converting enzyme inhibitor in congestive heart failure: The mechanism remains somewhat speculative. Because circulating angiotensin II levels decrease,[12,13] it is attractive to attribute the effect of converting enzyme inhibitor to blockade of conversion of angiotensin I to angiotensin II. Indeed, previous studies in congestive failure have shown a relation between pretreatment plasma renin activity and the decrease in systemic vascular resistance and in mean arterial blood pressure induced by infusion of converting enzyme inhibitor.[1,2] These data suggest that the renin-angiotensin system has a role in supporting systemic vascular resistance and blood pressure in some patients with congestive heart failure. In the present study involving only nine patients, a significant relation between baseline plasma renin activity and the response to converting enzyme inhibitor could not be

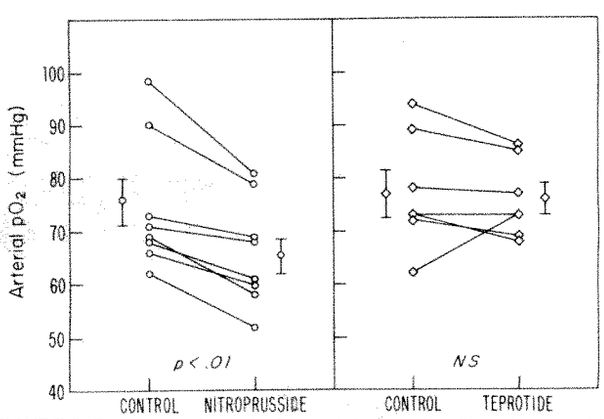

FIGURE 3. Response of arterial P_{O_2} to infusion of sodium nitroprusside and teprotide. Nitroprusside lowered arterial P_{O_2} whereas teprotide produced little effect on arterial P_{O_2}. NS = not significant; p = probability.

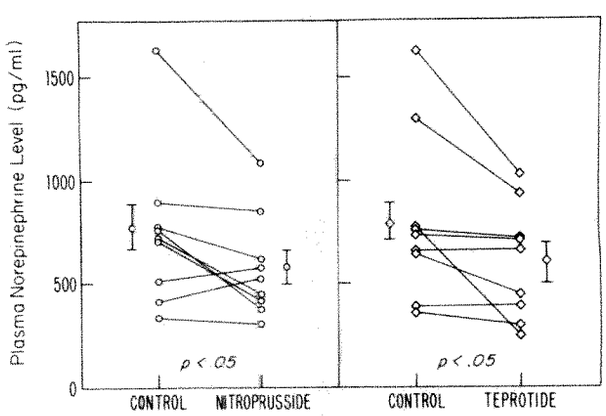

FIGURE 4. Response of plasma norepinephrine level to the infusion of sodium nitroprusside and teprotide. Both agents lowered plasma norepinephrine levels in spite of a reduction in mean arterial pressure. p = probability.

detected. Whether this finding relates to the small sample size, to a relatively small role for the renin-angiotensin system in the response to converting enzyme inhibitor or to inadequacy of plasma renin activity as a guide to activity of the renin-angiotensin system in these patients cannot be determined. Because converting enzyme inhibitor also inhibits the breakdown of bradykinin,[13] increased bradykinin levels could have contributed to the vasodilation.

Role of plasma renin activity: An unanticipated finding was that the dose of nitroprusside needed to produce the prescribed hemodynamic effect was related to the plasma renin activity level before treatment. This finding suggests that when angiotensin is an important factor in the vasoconstriction of heart failure a larger dose of a nonspecific vasodilator such as nitroprusside may be needed to produce vasodilation. A corollary would be that the patients with increased renin activity respond to a smaller dose of converting enzyme inhibitor. Although the required dose of teprotide tended to be larger if the level of plasma renin activity was low, this relation was weak. However, in our study teprotide was not titrated as was nitroprusside and, furthermore, the dose-response curve for converting enzyme inhibitor is very flat. Increased doses of this agent tend only to prolong the duration of effect rather than to augment peak effect.[2,14]

Role of pulmonary vasodilation versus pulmonary vasoconstriction: Converting enzyme inhibitor in this study produced no significant change in arterial P_{O_2} in patients with heart failure, whereas previous studies[15,16] showed that nitroprusside produced a significant decrease in arterial P_{O_2}. The hypoxemia during nitroprusside infusion has been attributed to pulmonary vasodilation as reflected by a decrease in pulmonary arteriolar resistance. This pulmonary vascular effect appears to result in an increased venous admixture by allowing increased perfusion to poorly ventilated alveoli.[16,17] Other agents such as phentolamine,[18] acetylcholine[19] and nitroglycerin[20] that also reduce pulmonary arteriolar resistance have been shown to decrease arterial P_{O_2}. In contrast, hydralazine has a lesser effect on pulmonary arteriolar resistance in patients with congestive heart failure and does not decrease arterial P_{O_2}.[16] On the basis of these observations the response to converting enzyme inhibitor appears paradoxic, because it decreased pulmonary arteriolar resistance but did not induce hypoxemia. Thus, the pulmonary vasodilator effect of converting enzyme inhibitor may be different from that of the nonspecific vasodilators. Perhaps the vasodilator effect of converting enzyme inhibitor predominates in well ventilated areas of the lung and leaves the hypoxia-mediated vasoconstriction uninhibited. Because angiotensin II is not a potent pulmonary vasoconstrictor,[21] the pulmonary vasodilator effect of converting enzyme inhibitor may result from a mechanism other than inhibition of angiotensin II generation.

Role of circulating norepinephrine: The mechanism of the decrease in circulating norepinephrine levels after treatment with nitroprusside and converting enzyme inhibitor is unknown. As has been shown previously in patients with congestive heart failure treated with various vasodilators. the reduction in arterial pressure does not induce the expected increase in heart rate or plasma catecholamine levels.[22] Although converting enzyme inhibitor, by reducing circulating levels of angiotensin II, might be expected to inhibit the sympathetic nervous system,[23–25] nitroprusside had a similar effect on catecholamines without affecting plasma renin activity. It is likely that the response to these two vasodilators is largely a nonspecific effect related to an increase in cardiac output or a reduction in pulmonary wedge pressure.

Implications: This study shows that the average acute hemodynamic response to converting enzyme inhibitor in severe congestive heart failure is similar to the hemodynamic response to nitroprusside, although individual variations in responsiveness to the two drugs may be in part related to plasma renin activity. Converting enzyme inhibitor appears to have less effect than nitroprusside on inducing a pulmonary ventilation-perfusion mismatch. Long-term studies with oral converting enzyme inhibitor are underway to evaluate further the therapeutic potential of this group of compounds.

Long-Term Therapy of Heart Failure With Prazosin: A Randomized Double Blind Trial

WILSON S. COLUCCI, MD
JOSHUA WYNNE, MD, FACC
B. LEONARD HOLMAN, MD, FACC
EUGENE BRAUNWALD, MD, FACC

Boston, Massachusetts

There is evidence that repeated administration of prazosin to patients with severe congestive heart failure results in tolerance to its initial salutary effects as a vasodilator. Therefore, we used a randomized, double blind protocol to evaluate the clinical effectiveness of 2 months of continuous prazosin therapy in 22 patients with severe congestive heart failure. After 2 months, the patients treated with prazosin showed significant improvement in mean New York Heart Association functional class (3.7 ± 0.2 to 2.3 ± 0.2, $p < 0.01$), treadmill exercise duration (123 ± 30 to 209 ± 40 sec, $p < 0.01$), echocardiographic ejection fraction (31.8 ± 3.2 to 37.3 ± 4.2 percent, $p < 0.01$), stroke excursion (1.02 ± 0.10 to 1.24 ± 0.14 cm, $p < 0.01$), mean velocity of circumferential fiber shortening (0.69 ± 0.07 to 0.80 ± 0.09 circumferences/sec, $p < 0.06$) and ejection fraction measured with radionuclide ventriculography (24.8 ± 2.2 to 32.1 ± 2.9 percent, $p < 0.001$). A comparable placebo-treated group showed no significant change in any index of functional or hemodynamic performance. The radionuclide ventriculographic ejection fraction fell to pretreatment levels 48 hours after the withdrawal of chronic prazosin therapy and rose to the long-term treatment level on readministration of the drug, thus confirming that the improvement observed after 2 months was due to prazosin. After 2 months there was clinical evidence of attenuation of the initial response to prazosin, although patients continued to show improvement over their pretreatment state. Prazosin-treated patients had an increase in plasma renin activity and required an increase in diuretic dose, suggesting that the renin-angiotensin system may contribute to the observed attenuation of drug effect. Long-term therapy with prazosin results in significant functional and hemodynamic improvement in patients with severe congestive heart failure.

The beneficial hemodynamic and clinical effects induced by the use of vasodilators have led to their increasing use in long-term treatment of congestive heart failure.[1–4] Unfortunately, most of these agents have been critically evaluated only during short-term administration to patients in the supine posture,[5–9] and to date there have been very few trials to determine the efficacy of long-term therapy.[10–15] Consequently, a justified plea has been made for caution in the extrapolation of results of acute studies to the chronic situation.[4]

Prazosin is an orally active alpha adrenergic antagonist that has been approved for the treatment of hypertension.[16] Early short-term evaluations of prazosin in patients with severe congestive heart failure demonstrated a balanced effect on both venous and arterial vessels, and hence an improvement in both pulmonary venous congestion and forward cardiac output.[9,17–19] Because the drug is readily absorbed and has a duration of action of approximately 6 hours when given orally, it appeared to be a logical candidate for the long-term treatment of heart failure.

Controversy has recently arisen regarding the long-term activity of prazosin in congestive heart failure. Packer et al.[20] noted a marked increase in cardiac index and a decrease in left ventricular filling pressure after the first oral dose (5 mg) of prazosin. However, when the drug was administered at 12 to 24 hour intervals this favorable initial response was significantly attenuated by the third dose, although it could be partially restored by increasing the dose to 10 mg. Two other reports compared the responses to the first and fifth doses of prazosin, and also noted a marked attenuation of the initial improvement in cardiac index in one study,[21] and in both pulmonary capillary wedge pressure and cardiac index in the other.[22] However, Aronow et al.[11] demonstrated that 6 weeks of prazosin therapy resulted in a significant improvement in clinical state, duration of treadmill exercise, echocardiographic ejection fraction and mean velocity of circumferential fiber shortening. Two preliminary reports indicate the continued efficacy of the drug after 5[14] and 10[15] weeks of therapy for congestive heart failure.

In an effort to resolve this controversy concerning the continued efficacy of prazosin in heart failure, we performed a 2 month randomized, double-blind trial in which the effects of prazosin were compared with those of placebo on the patients' clinical state, exercise duration and left ventricular performance as measured with radionuclide ventriculography and echocardiography. After completion of the 2 month study, the code was broken and, in several patients who had received prazosin, the drug was withheld for 48 hours; left ventricular function was reassessed with radionuclide ventriculography before and after a single administration of the dose of prazosin the patient had been receiving previously.

Methods

Patient population: Twenty-two patients with chronic left ventricular failure who were in New York Heart Association functional class III or IV[23] despite conventional therapy with digitalis and diuretic drugs (mean dose of furosemide 100 mg/day) were the subjects of this study (Table I). The mean age was 58.5 years (range 37 to 73 years). There were 17 men and 5 women. Thirteen patients had cardiomyopathy whereas 9 had ischemic heart disease. The mean duration of heart failure was 2.1 years (range 6 months to 7 years). All patients had cardiomegaly and evidence of pulmonary venous congestion on chest X-ray film.

TABLE I

Clinical Background of 10 Patients Treated With Prazosin and 12 Patients Treated With Placebo

Patient Data	Prazosin	Placebo
Number of patients	10	12
Age (yr)	59 ± 3*	58 ± 3*
Sex	7M, 3F	10M, 2F
Cause of heart failure		
Coronary artery disease	4	5
Cardiomyopathy	6	7
Functional class (NYHA)	3.7 ± 0.2*	3.5 ± 0.2*
Duration of heart failure (yr)	2.0 ± 0.5*	2.3 ± 0.5*

* Mean ± standard error of the mean.
NYHA = New York Heart Association classification.[23]

Eleven of the 22 patients underwent diagnostic cardiac catheterization during the baseline period. The cardiac index averaged 1.9 ± 0.2 (± standard error of the mean) liters/min per m^2, the mean capillary wedge pressure 29 ± 2 mm Hg, the mean right atrial pressure 13 ± 2 mm Hg and the mean systemic vascular resistance 1,940 ± 220 dynes/s per cm^{-5}. The patients with catheterization studies did not differ significantly from patients without such studies in clinical status (mean functional class 3.6 for both groups), radionuclide ejection fraction (22 ± 3 percent for patients with versus 27 ± 3 percent for those without catheterization), or end-diastolic diameter as assessed with echocardiography (7.0 ± 0.3 cm for patients with versus 6.8 ± 0.3 cm for patients without catheterization). Thus, although invasive hemodynamic studies were available in only half of the group, we believe that their findings are representative of the entire group.

Protocol: Patients were admitted to the General Clinical Research Center of the Peter Bent Brigham Hospital. After written informed consent had been obtained, they underwent a baseline evaluation that, in addition to the usual clinical and laboratory assessment, included measurement of plasma renin activity, treadmill exercise testing on 2 days, M mode echocardiography and radionuclide ventriculography. After the baseline evaluation was complete, each patient was randomly assigned to either treatment with prazosin (10 patients) or treatment with placebo (12 patients). During the first 8 weeks, treatment was given in double-blind fashion, and the placebo group received capsules that were indistinguishable from the drug.

The protocol medication was administered every 6 hours, and the dose was gradually increased over a 4 day period, starting in all cases with a dose of 1.0 mg at bedtime. During the titration period pulse and blood pressure were monitored before and 2 hours after the morning and evening doses. The end point of the first titration period was any one of the following: (1) an adequate clinical response (that is, distinct clinical lessening of heart failure), (2) a maximal dose of 16 mg/day of prazosin or a comparable number of placebo capsules, or (3) symptomatic orthostatic hypotension or other side effects. There were no significant side effects. The dose of digitalis and the dietary sodium intake were held constant for the duration of the study, whereas the dose of the diuretic drug was adjusted as clinically indicated; no other vasodilators were utilized. Patients were followed up in the outpatient department and after 4 weeks of treatment with drug or placebo were admitted for a second period of dose adjustment. The criteria for titration at this time were the same as for the first period except that the maximal permissible dose of drug was 24 mg/day.

After 8 weeks of treatment the patients were readmitted and evaluated as during the baseline period. The code was then broken and prazosin was withheld for 48 hours from six patients who had been receiving it, and a radionuclide ventriculogram was performed. A single dose of prazosin, identical to that the patient had been receiving, was then administered and the radionuclide ventriculogram repeated 2 1/2 hours later.

Measurements: *Echocardiograms* were performed with either an Ekoline-20 or an Irex Cardiac Ultrasound machine with use of 2.25 megahertz transducers and an Irex Continutrace-101 multichannel recorder. Patients were placed in the supine position or in a slight left lateral decubitus position. Ventricular dimensions were determined in the constant

respiratory phase of held mid expiration, with the transducer in the fourth intercostal space near the left sternal border. The T scan method was used to insure consistent and reproducible recordings,[24] which were made at the level of the posterior mitral valve supporting apparatus. Left ventricular end-diastolic diameter was measured at the peak of the R wave in the electrocardiogram, and left ventricular end-systolic diameter was taken as the smallest distance separating the left ventricular endocardial surfaces. Left ventricular stroke excursion was equal to the difference between end-diastolic and end-systolic diameters. Left ventricular volumes at end-diastole and end-systole were calculated by the method of Teichholtz et al.,[25] and the stroke volume was equal to their difference. Left ventricular ejection fraction was calculated as stroke volume divided by end-diastolic volume. Left ventricular ejection time was measured from the upstroke to the incisural notch of the indirect carotid pulse tracing. The mean rate of circumferential fiber shortening in circumferences/second was calculated as stroke excursion divided by the product of end-diastolic diameter and ejection time.

Left ventricular ejection fraction was determined from the gated equilibrium radionuclide ventriculogram utilizing previously described methods.[26] Red blood cells were labeled in vivo with 20 to 25 mCi of technetium-99m pertechnetate, and imaging was performed in the modified left anterior oblique position using a 30° slant hole straight bore collimator.[27] After operator identification of the left ventricular perimeter, a computer algorithm independently generated the background correction region and, thereby, a background-corrected time-activity curve.[28] The ejection fraction was calculated from end-diastolic and end-systolic frames using standard techniques.[29]

All treadmill tests were performed using a standard Bruce protocol.[30] The 12-lead electrocardiogram was continuously monitored. Heart rate (by electrocardiogram) and blood pressure (by arm cuff) were measured before exercise and every 3 minutes during exercise.

Diuretic drugs were withheld for the first 3 days of each admission and the patient was maintained on a diet of 10 mEq of sodium, 60 mEq of potassium and water as desired. When sodium balance was achieved (24 hour urinary sodium excretion 10 mEq/h or less), fasting blood was drawn in the supine position. Plasma renin activity was assayed as previously described.[31] After plasma renin had been measured, patients were placed on a 2 gram sodium diet and their prior diuretic regimen was resumed. Patients were weighed each morning before eating.

Data analysis: The data were analyzed using the paired *t* test except for those shown in Figure 6, which were analyzed by the two way analysis of variance, and the data in Figure 7, which were analyzed by the paired Wilcoxon test. Results are presented as the mean values ± standard error of the mean unless otherwise stated.

Results

Clinical status: All 10 patients treated with prazosin were living and completed the 2 month protocol (Fig. 1). Of the 12 patients treated with placebo, 7 completed the 2 month protocol, 2 died, 2 were withdrawn because of worsening congestive heart failure and 1 was withdrawn because of syncope due to high grade ventricular arrhythmia. The two deaths were due to myocardial infarction with cardiogenic shock in one patient, and a cerebrovascular accident in the other. The drug code had to be broken and treatment with prazosin begun in the two patients who were withdrawn because of worsening heart failure. One of these exhibited marked subjective and objective improvement, and his clinical condition has been stable for 9 months. The second patient had an increase in ejection fraction determined with radionuclide ventriculography (13 to 18 percent) but remained in severe heart failure despite treatment with 32 mg/day of prazosin, alone and in combination with hydralazine.

The mean functional class of patients treated with prazosin improved (3.7 ± 0.2 before treatment to 2.3 ± 0.2 at 2 months, $p < 0.01$), whereas there was no significant change in the placebo group (3.5 ± 0.2 before treatment, 3.3 ± 0.2 at 2 months; difference not significant [NS]) (Fig. 2). In patients who received the active drug exercise duration improved from 123 ± 30 to 209 ± 40 s ($p < 0.01$) (Fig. 3). The change in exercise duration was variable among the placebo-treated patients, but the average for the group as a whole did not change significantly. Heart rate at rest decreased slightly at 2 months in the treatment group (77 ± 4 to 73 ± 4 beats/min, $p = 0.09$), and was unchanged in the placebo-treated group (76 ± 4 to 76 ± 3 beats/min). Blood pressure at rest was unchanged in both groups at 2

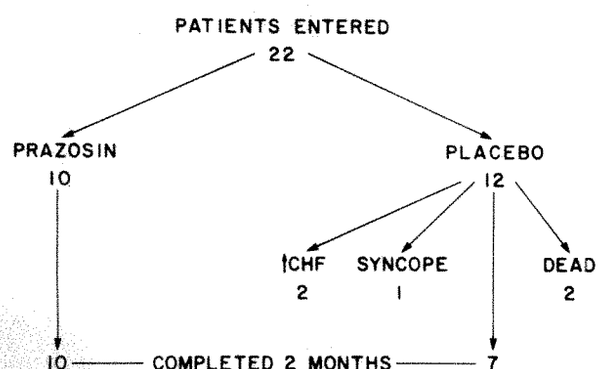

FIGURE 1. Summary of the clinical course of 22 patients during 2 months of randomized, double blind therapy with prazosin or placebo. ↑CHF = increased congestive heart failure.

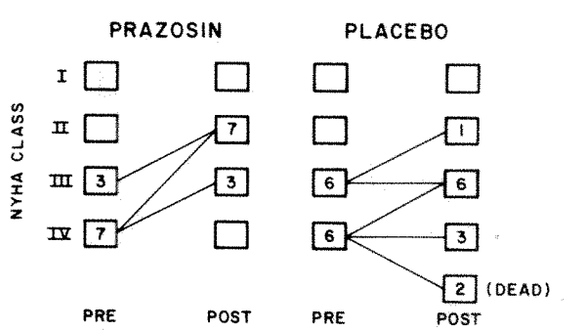

FIGURE 2. New York Heart Association (NYHA) functional class before (PRE) and after (POST) 2 months of double blind therapy with prazosin or placebo.

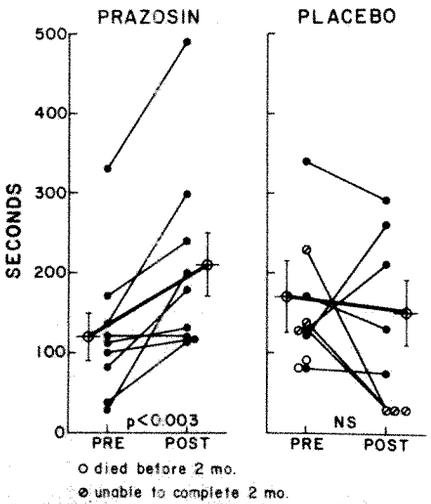

FIGURE 3. Treadmill exercise duration (seconds) on a standard Bruce protocol before (PRE) and after (POST) 2 months of double blind therapy with prazosin or placebo. NS = not significant; p = probability.

months. In both groups, blood pressure and heart rate-systolic pressure product (double product) at peak exercise were unchanged from baseline values at 2 months.

The prazosin-treated patients tended to accumulate peripheral edema and had an average increase in weight of 2.1 ± 0.6 kg ($p < 0.01$), whereas there was no evidence of further edema formation or change in weight (−0.8 ± 0.9 kg; NS) in the placebo-treated patients. These differences occurred although the dose of diuretic drug was increased in 9 of the 10 prazosin-treated patients but in only 1 of the 12 placebo-treated patients.

Echocardiogram (Fig. 4): Left ventricular end-diastolic diameter was unchanged in both groups, whereas end-systolic diameter decreased (from 5.8 ± 0.3 to 5.5 ± 0.3 cm; $p < 0.03$) in the treatment group but was unchanged in the placebo group (5.8 ± 0.4 to 5.7 ± 0.3 cm; NS). Left ventricular stroke excursion increased in the treatment group (1.02 ± 0.10 to 1.26 ± 0.14 cm; $p < 0.01$), but was unchanged in the placebo group (1.21 ± 0.10 to 1.19 ± 0.04 cm; NS). Ejection fraction increased in the treatment group (31.8 ± 3.2 to 37.3 ± 4.2 percent, $p < 0.01$) and was unchanged in the placebo group (33.4 ± 4.6 to 33.7 ± 3.8 percent, NS). The mean velocity of circumferential fiber shortening increased (0.69 ± 0.07 to 0.80 ± 0.09 circumferences/s; $p = 0.06$) in the treatment group but was unchanged (0.82 ± 0.13 to 0.78 ± 0.09 circumferences/s; NS) in the placebo group.

Radionuclide ventriculogram (Fig. 5): The ejection fraction determined with radionuclide angiography increased in all 10 patients treated with prazosin, the average for the group increasing from 24.8 ± 2.2 to 32.1 ± 2.9 percent at 2 months ($p < 0.001$). In the placebo-treated group there was a variable response, with no significant change in the group mean (26.4 ± 3.6 to 23.8 ± 3.4 percent; NS).

Withdrawal of long-term therapy (Fig. 6): After completion of the 2 month trial and breaking of the code, prazosin was withheld for 48 hours from six patients in the treatment group. The radionuclide ejection fraction of this group at baseline (that is, before the 2 month treatment period) averaged 23.1 ± 3.3 percent and increased to 31.0 ± 3.8 percent after 2 months ($p < 0.01$). After withdrawal of prazosin the ejection fraction fell to an average of 22.9 ± 3.0 percent, a value comparable with that observed before treatment was begun. Two and a half hours after the administration of what had been each patient's usual dose of prazosin, the mean ejection fraction had increased to 31.2 ± 4.2 percent ($p < 0.01$), a value almost identical to that observed during long-term treatment.

Plasma renin activity (Fig. 7): Eight patients treated with prazosin and five treated with placebo were evaluated both before and after 2 months of therapy. Supine plasma renin activity was significantly increased in the treatment group (3.1 ± 0.5 to 4.7 ± 1.2 ng/ml per h; $p < 0.05$) but was unchanged in the placebo-treated group.

Discussion

The acute beneficial effects of vasodilator therapy in severe congestive heart failure have been clearly demonstrated.[1–9] However, most studies evaluating the effectiveness of these agents have dealt only with the re-

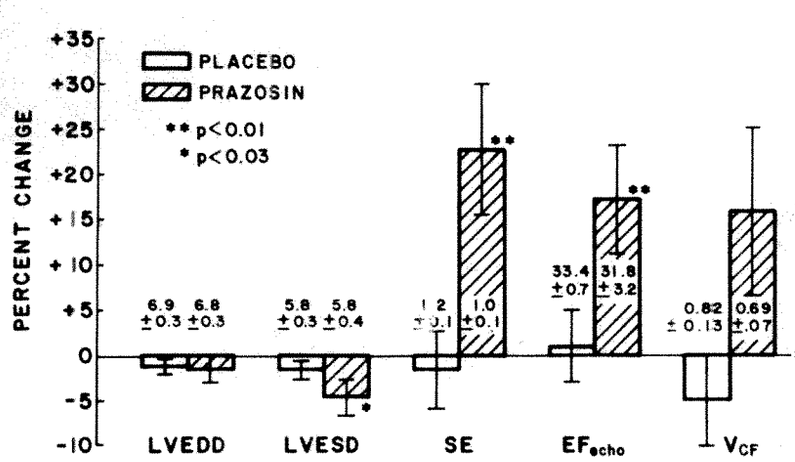

FIGURE 4. Echocardiographic assessment of the change in left ventricular function after 2 months of therapy with prazosin or placebo. Results are expressed as the mean percent change (standard error of the mean) compared with the pretreatment value (mean ± standard error of the mean indicated on each bar). EF_{echo} = ejection fraction (%); LVEDD = left ventricular end-diastolic diameter (cm); LVESD = left ventricular end-systolic diameter (cm); SE = stroke excursion (cm); V_{CF} = mean velocity of circumferential fiber shortening (circumferences/s).

sponse to initial doses. If it could be demonstrated that these acute salutary effects are sustained with maintenance oral therapy, then long-term vasodilator therapy can be assigned an important role in the management of heart failure and could potentially benefit a large number of patients. Although some studies have commented on the follow-up of treated patients, only a few have provided long-term repeat hemodynamic data,[10–15] and even fewer have been performed in a double blind manner.[11] Thus, there is very little information available regarding the long-term continued efficacy of vasodilator therapy in congestive heart failure.[4]

Prazosin: comparison with other vasodilators and alpha adrenergic blocking agents: Prazosin causes relaxation of vascular smooth muscle by competitive antagonism with agonists at the vascular (postsynaptic) alpha adrenergic receptor.[16,32] Several experimental studies suggest that prazosin does not cause a reflex tachycardia, increase in plasma renin activity or tolerance,[16,32,33] whereas direct smooth muscle relaxers such as hydralazine and classic alpha adrenergic blocking agents such as phenoxybenzamine cause reflex activation of the sympathetic nervous system with increased release of norepinephrine and renin,[32,34,35] increased sodium retention,[34] and attenuation of the vasodilatory effect.[34,35] Because presynaptic alpha adrenergic receptors inhibit neuronal release of norepinephrine,[36] their blockade by classic nonselective alpha adrenergic antagonists such as phenyoxybenzamine results in a marked increase in neuronal norepinephrine release.[32,37] There is experimental evidence that prazosin, in contrast to phenoxybenzamine, is several times more selective for postsynaptic alpha receptors than for presynaptic receptors,[16,32,38] and when compared with equidepressor doses of phenoxybenzamine, prazosin produces a significantly smaller increase in heart rate or plasma norepinephrine.[32,37] Thus, there is theoretical and experimental evidence to suggest that prazosin may be less prone to the major limitations of direct vasodilators and classic nonselective alpha blocking agents.

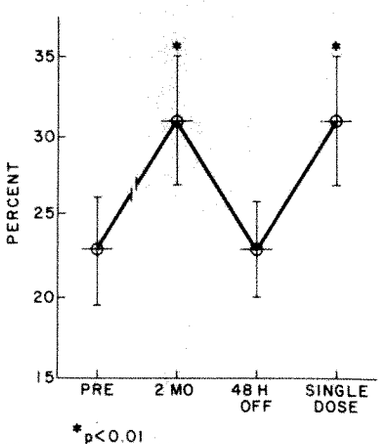

FIGURE 6. Left ventricular ejection fraction (percent) as assessed with radionuclide ventriculography in six patients before (PRE) and after (2 MO) 2 months of therapy with prazosin, 48 hours after withdrawal of prazosin therapy (48 H OFF) and 2.5 hours after the readministration of each patient's usual dose of prazosin (SINGLE DOSE).

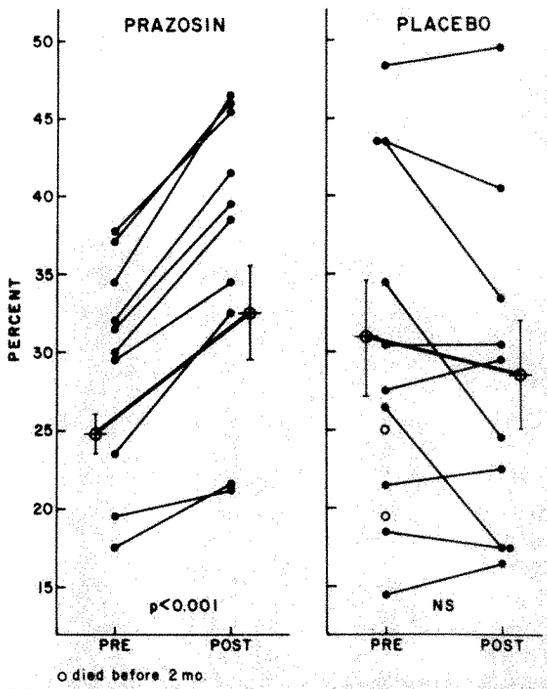

FIGURE 5. Left ventricular ejection fraction (percent) determined with gated equilibrium radionuclide ventriculography before (PRE) and after (POST) 2 months of therapy with prazosin or placebo. NS = not significant; p = probability.

Development of tolerance: Prazosin administered acutely produces a marked improvement in hemodynamic performance in heart failure.[9,17–19] Because the drug has few side effects, is well absorbed when administered orally and has a long duration of action, it appears to be an attractive agent for long-term therapy.

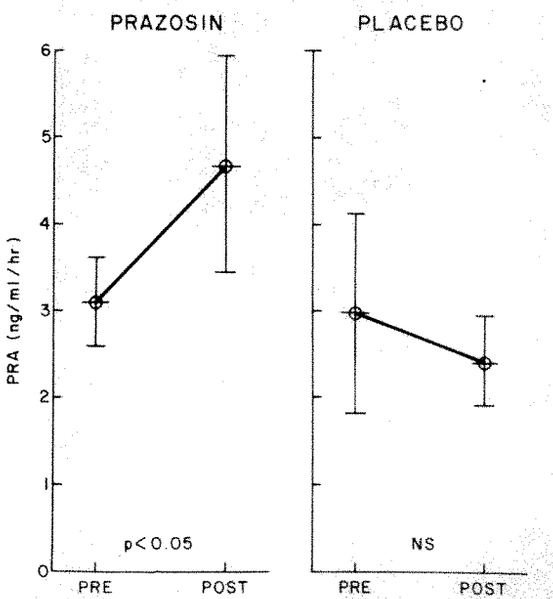

FIGURE 7. Supine plasma renin activity (PRA) before (PRE) and after (POST) 2 months of therapy with prazosin or placebo. Patients were in sodium balance on a 10 mEq Na diet with diuretic drugs withheld.

However, because of recent evidence that the initial response to prazosin is markedly attenuated over the course of only several doses,[20–22] the long-term effectiveness of the drug has been questioned. Before discarding a potentially valuable agent, we considered the possibility that tolerance may be a transient phenomenon, may be importantly related to the administration schedule and dose, or may be of an incomplete degree that does not preclude a useful long-term effect. Indeed, experience with prazosin in the treatment of hypertension has not revealed significant tolerance.[16,32,33,39,40] Of note is the observation that in hypertension the full therapeutic response may not be evident until 4 to 8 weeks after the initiation of therapy.[39,40]

Clinical signs of improvement: Our patients treated with prazosin for 2 months showed significant subjective, functional and hemodynamic improvement, in clear distinction to a comparable, randomly selected group treated with placebo in double blind fashion. The improvement in exercise duration in our patients was similar to that observed by Aronow et al.[11] after 6 weeks of prazosin therapy.[11] In their study, as in ours, the heart rate, systolic pressure and double product at peak exercise were unchanged with prazosin therapy, despite a marked increase in exercise duration. Rubin et al.[41] showed that the beneficial effects of prazosin on cardiac index, pulmonary capillary wedge pressure, and systemic vascular resistance are considerably more marked during exercise than at rest. One possible explanation of this finding is that during exercise the sympathetically mediated vascular response is exaggerated in patients with congestive heart failure[42] and that this vasoconstriction may be particularly responsive to a specific alpha adrenergic antagonist such as prazosin. It will be important in future trials of long-term prazosin therapy to include an assessment of exercise hemodynamics and to consider the relation of the response to prazosin to sympathetic tone at rest.

Effect on left ventricular function: Both echocardiography and radionuclide ventriculography demonstrated an improvement in left ventricular function during long-term prazosin therapy. The radionuclide ventriculogram appeared to be a more sensitive measure of changes in global left ventricular ejection fraction because it consistently revealed an increased ejection fraction with treatment, even in those patients with severe localized wall motion abnormalities that obscured the change measured with echocardiography. That the improvement in ejection fraction observed in the treatment group was a direct result of prazosin is confirmed by the observation that the ejection fraction fell to baseline levels 48 hours after withdrawal of prazosin and rose to long-term treatment levels after a single dose (Fig. 6).

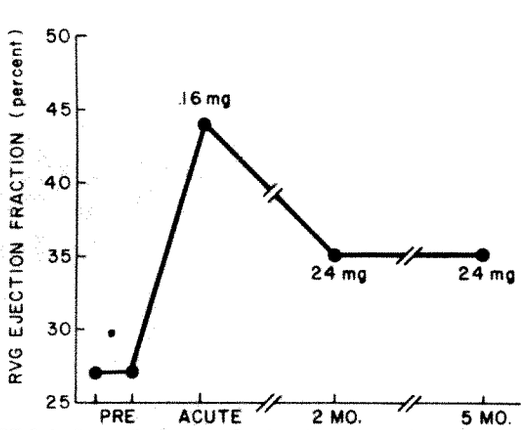

FIGURE 8. Left ventricular ejection fraction (percent) as assessed with radionuclide ventriculography (RVG) in one patient before treatment (PRE), during the initial prazosin titration period when the dose was 16 mg/day (ACUTE), and after 2 and 5 months of continuous prazosin therapy with a dose of 24 mg/day.

Attenuation of effects with chronic therapy: Despite the overall salutary effects of the drug over a 2 month period, our study does provide evidence that the marked hemodynamic response to initial doses of prazosin is significantly attenuated with the passage of time. Three findings support the conclusion that the long-term effect of prazosin is less than the effect of initial doses. First, patients often reported that their clinical improvement was most striking during the titration periods when the dose was initially adjusted. However, although the clinical effectiveness diminished, their condition never returned to the pretreatment state as long as treatment was continued. Second, Poliner et al.[43] reported a 93 percent increase in the ejection fraction measured with radionuclide angiography during the first several doses of prazosin. Although various factors may in part account for the more than two-fold greater response in their acute study than in our long-term trial, the magnitude of the disparity suggests that there may be a greater response to initial doses of prazosin. Finally, this suggestion is supported by the observation of one patient who was studied by radionuclide ventriculography during the 1st week of therapy and again after 2 and 5 months of long-term therapy (Fig. 8). In this patient ejection fraction was 27 percent on 2 days during the baseline period and rose by 62 percent (to 44 percent) after a 4 mg dose of prazosin during the initial titration week. The patient reported subjective improvement and was discharged on a regimen of 16 mg of prazosin/day. After 1 month, the dose of prazosin was increased to 24 mg/day and the dose of diuretic drug was increased because of accumulating peripheral edema, although the patient continued to feel improvement over the baseline condition. The patient's condition subsequently remained clinically stable and, when he was evaluated after 2 and 5 months of therapy, the ejection fraction was 34 percent on both occasions, 30 percent higher than before treatment. This latter finding is similar to the average 34 percent increase observed for the entire treatment group at 2 months. In three other patients who have been followed up for 6 months, the improvement in the radionuclide ejection fraction has been sustained at the level observed at 2 months.

The mechanism of developed tolerance to prazosin is unclear. Although our prazosin-treated patients had a clear improvement in functional class and hemody-

namic performance, they also tended to retain more sodium and required an increase in diuretic drugs in most cases. Because no significant change in weight was observed in the placebo group, an increase in the diuretic dose was not required except in one patient whose weight did increase. It is unlikely that the improved functional performance of patients in the prazosin group was a result of their increased diuretic dose, since they still had a positive fluid balance at the time of the 2 month reevaluation. However, it is likely that the increased fluid retention in the patients treated with prazosin attenuated the magnitude of the clinical response, and had their diuretic dose not been increased the response to prazosin might have been further obscured.

Increased plasma renin activity with prazosin: The plasma renin activity was significantly increased by long-term prazosin therapy and may have contributed to sodium retention by stimulating aldosterone secretion. The fact that sodium retention did not parallel hemodynamic status further suggests that a secondary sodium retaining system was activated. Renin may also contribute to drug tolerance through its stimulation of the production of the potent vasoconstrictor, angiotensin II. When suprapharmacologic doses (3 to 30 mg/kg per day) of prazosin are administered to spontaneously hypertensive rats, there is acute tolerance to the hypotensive effect by the 2nd day, and the development of tolerance is reduced by pretreatment with converting enzyme inhibitor or propranolol, thus suggesting that activation of the renin-angiotensin system is involved in the development of acute tolerance in that model.[44] It is unlikely that the increased plasma renin activity in our prazosin-treated patients was due to a change in sodium balance because sodium intake was strictly controlled at the time of renin measurement and the effect of the noted volume expansion would be to suppress renin secretion. Another potential mechanism of increased renin release would be an increase in sympathetic nervous system activity,[35] which would also directly reduce the effectiveness of a competitive alpha adrenergic antagonist such as prazosin. This possibility is supported by a preliminary report[45] indicating that plasma norepinephrine levels are increased during long-term prazosin therapy in congestive heart failure.

Implications: In patients with congestive heart failure prazosin appears to affect two major neuroendocrine mechanisms, the sympathetic nervous system and the renin-angiotensin system, both of which influence the peripheral vascular bed directly and indirectly. This observation raises the possibility that some of the controversy about prazosin's effectiveness may be due to differences in the manner in which the administration schedule, duration of study and dosage affect these two systems. Although further studies will be needed to define the mechanisms of tolerance, we conclude that tolerance to prazosin's hemodynamic effects occurs early in therapy, is most often partial and does not preclude a sustained, clinically useful effect in the treatment of chronic congestive heart failure.

ROQUE PIFARRÉ, MD, FACC

Hines, Illinois

The cases of 27 consecutive patients aged 40 to 78 years with ventricular septal rupture during acute myocardial infarction were reviewed. Myocardial infarction was inferior in 16 patients and anterior in 11. The time from myocardial infarction to rupture was less than 24 hours in 9 patients, 24 to 48 hours in 6 patients, 2 to 7 days in 11 patients, and 14 days in 1 patient. In 23 patients pressures (in mm Hg) were pulmonary arterial systolic 28 to 70 (mean 52), diastolic 9 to 34 (mean 23) and left ventricular end-diastolic 15 to 35 (mean 24). Cardiac index was 1.1 to 2.5 (mean 2.0) liters/min per m^2 and the ratio of pulmonary to systemic flow (Q_p/Q_s) 1.5 to 4.8 (mean 3.4). The number of coronary vessels with more than 50 percent obstruction was one in 8 patients, two in 11 patients and three or more in 8 patients. Of the eight patients with single vessel disease three had right, one had left circumflex, and four had left anterior descending coronary artery disease.

All seven patients treated without surgery died 1 to 13 days after ventricular septal rupture; all seven had inferior myocardial infarction, and none had previous transmural myocardial infarction. Of these seven patients, two were considered inoperable, one died during study, and four died abruptly while awaiting study. Eleven of 20 patients (55 percent) survived operation. The survival rate in seven patients operated on less than 2 days after ventricular septal rupture was 72 percent. Of 11 patients operated on 2 to 28 days after ventricular septal rupture 4 survived, whereas the 2 patients operated on later than 4 weeks after rupture survived. It is concluded that (1) early surgery in ventricular septal rupture has relatively low mortality; (2) delay of study and surgery is done at the expense of unacceptable and unpredictable mortality; and (3) ventricular septal rupture can occur with single vessel coronary artery disease.

Perforation of the interventricular septum, one of the most serious complications of acute myocardial infarction, was first reported by Latham,[1] in his Lectures of the Heart, published in 1847. In 1923, Brunn[2] described the antemortem diagnosis of this condition, but only 5 of the first 35 cases reported were actually diagnosed before death.[3] In 1934, Sager[4] presented the currently accepted diagnostic criteria for this condition. Since then septal rupture has been reported with increasing frequency and, although uncommon, is not rare.[5] Autopsy examination of 6,260 patients who died of acute myocardial infarction revealed septal rupture in 80, an incidence rate of 1.3 percent.[6] Septal rupture is less common than rupture of the ventricular free wall, with which it is sometimes associated.

The poor prognosis of patients whose interventricular septum perforates after myocardial infarction was documented. Sanders et al.[7] found that 54 percent of such patients died within 1 week of perforation and only 11 percent survived 2 months. The first surgical correction of this acquired defect was reported by Cooley et al.,[8] in 1956. Until re-

From the Departments of Surgery and Medicine, Loyola University Medical Center, Maywood, Illinois, and the Cardiopulmonary Surgery Section, Veterans Administration Hospital, Hines, Illinois. cently, the surgical repair of this condition was applied late, when the myocardial tissue is more ideal for repair, and in the small minority of patients who had survived the acute stage. Survival of the majority of patients with this complication is possible only if treatment is undertaken soon after the septal rupture occurs, because so few survive for late surgical management.

The clinical and hemodynamic findings in 27 patients seen at Loyola University Medical Center with ventricular septal rupture complicating an acute myocardial infarction, and the results of early surgical repair in 20 are presented in this study.

Clinical Features

Patients: From 1970 through 1978, 27 patients were clinically diagnosed as having ventricular septal rupture complicating acute myocardial infarction. There were 13 men and 14 women whose ages ranged from 40 to 78 years (mean 62 years).

Clinical diagnosis: In 23 patients the first clinical indication of septal rupture was the occurrence of a systolic murmur heard over the left sternal border. Cough and dyspnea were the first symptoms in the remaining four patients. A thrill was palpated over the precordium in 21 of the 27 patients. Clinical deterioration and a new murmur were part of the syndrome in all patients.

Clinical and electrocardiographic findings were diagnostic of an acute myocardial infarction in all patients. In 11 patients (41 percent) the location of the infarct was anterior, and in 16 patients (59 percent) it was inferior. The time interval between the myocardial infarction and the septal rupture ranged from less than 24 hours to 14 days. In 15 patients (55.5 percent) septal rupture occurred within the first 2 days; it occurred in only 1 patient after 7 days. Roentgenographic findings compatible with congestive heart failure or pulmonary edema, or both, were present in 24 patients.

Cardiac catheterization findings: Twenty-three patients underwent cardiac catheterization. In the group, pulmonary arterial pressure averaged 52/23 and left ventricular enddiastolic pressure 24 mm Hg. Cardiac index (assessed with the Fick or the thermodilution method) averaged 1.98 liters/min per m^2. The ratio of pulmonary to systemic flow (Q_p/Q_s) averaged 3.4. A left to right shunt, detected in each patient, ranged from 1.5:1 to 5.8:1.

Ten patients had a left ventricular aneurysm on ventriculography; six aneurysms were apical and four inferior. The ejection fraction averaged 32 percent (range 6 to 49 percent). Coronary arteriograms were obtained in each of the 23 patients studied with cardiac catheterization; in 4 patients who did not undergo catheterization the coronary anatomy was analyzed at necropsy. Single vessel disease was found in 8 patients (30 percent), two vessel disease in 11 patients (41 percent), and triple vessel disease in 8 (30 percent). Eighteen patients had an intraaortic balloon pump inserted before cardiac catheterization to achieve hemodynamic stability. All patients were in New York Heart Association functional class III or IV[9] at the time of cardiac catheterization.

Clinical Course

The number of diseased coronary vessels had no relation to the eventual outcome of our patients. Four of the eight patients with single vessel disease had a total occlusion of the left anterior descending coronary artery and anteroseptal infarction; one died. Four patients with single vessel disease had inferior infarction. The right coronary artery was occluded in three and a dominant circumflex artery was occluded in one. Four patients with single vessel disease and inferior infarction died.

Patients who did not undergo surgery: Seven of the 27 patients (26 percent) were not operated on, and all died. Death occurred from 1 to 13 days (mean 6.4 days) after rupture. All seven patients had an inferior infarction. Two patients had undergone catheterization but were deemed inoperable because of age and total organ failure. One patient died in the cardiac catheterization laboratory. Four patients died while waiting to undergo cardiac catheterization. Two of the latter died suddenly and unexpectedly. At necropsy both were found to have single vessel disease of the right coronary artery.

Surgically treated patients: Twenty of the 27 patients (74 percent) underwent surgical repair of the ruptured ventricular septum. The time between rupture and repair was less than 48 hours in seven patients, and five of these seven (71 percent) survived. Only one of the seven had an inferior infarction, and he survived. Eleven patients were operated on 2 days to 4 weeks after rupture of the septum and only 4 (36 percent) survived. Two patients operated on later than 4 weeks after rupture survived.

To expose the heart a median sternotomy incision was utilized. The ruptured septum was always approached through infarcted muscle. A primary repair with a patch was used in 14 patients after resection of the necrotic tissue. In six patients the sandwich technique with Teflon® strips were used. Infarctectomy or resection of a ventricular aneurysm, or both, was performed in 14 patients (70 percent). Six patients underwent one or more aortocoronary bypass grafts.

Eight of the 11 patients (73 percent) with anterior myocardial infarction survived the operation. Of nine patients with inferior infarcts only three survived (33 percent). Of the nonsurvivors, three died in the operating room, one died in the intensive care unit immediately after surgery, and the other patients died 1, 2, 14, 19 and 23 days, respectively, after operation. One nonsurvivor was reoperated on 1 week after initial closure to repair a persistent septal perforation, but he died of generalized organ failure 8 days after the second operation. At autopsy the septal repair in all nonsurvivors was found intact.

Follow-up: Eleven patients left the hospital after operation (survival rate 55 percent). All 11 were in New York Heart Association class I or II at the time of discharge. Three patients (28 percent) who were asymptomatic had a persistent murmur. Ten patients are alive after a mean of 17 months of follow-up. One patient died of hyperkalemia in another hospital, 26 months after operation, and no autopsy was performed. Of the entire group of 27 patients with postinfarction ventricular septal rupture, 11 (41 percent) survived at least 2 months. Patients with an anterior infarction had a significantly greater survival rate (8 of 11; 73 percent) than those with inferior infarction (3 of 16; 19 percent) ($p < 0.01$). There were no significant differences in survival

related to the number of obstructed coronary vessels or the magnitude of the left to right shunt.

Discussion

Site of coronary occlusion and infarction: The blood supply to the ventricular septum is dual, the anterior two thirds being supplied by branches of the left anterior descending coronary artery, and the posterior one third by branches of the posterior descending extension of the right or circumflex coronary artery, or both. Thus it might be expected that the majority of septal ruptures would occur in patients with anterior wall infarction. Although some authors[5] reported this to be the case, we and other investigators noted at least an equal frequency of inferior wall infarction in patients with septal rupture. The dual blood supply, with anastomosis in the septum between the two systems, might suggest that disease of both supplies would be necessary before the septum could be damaged sufficiently for perforation; however, 8 of our 27 patients (29 percent) had only one obstructed vessel, and in 4 patients the obstruction was limited to the dominant arterial supply of the posterior septum. There is no obvious reason why all of our patients who died without undergoing operation had infarction of the inferior wall, but it is apparent that inferior wall infarction with septal rupture is potentially lethal and that early surgery is indicated.[10]

Surgical indications: Surgical treatment of a ruptured ventricular septum after an acute myocardial infarction has generally been applied late, when the myocardial tissue is ideal for repair.[11–18] During the 1st years of our experience, we waited too long before intervening. With experience, it became obvious that the natural history of this condition is progressive deterioration and death if one delays intervention for any duration. Encouraged by several reports of successful early surgical treatment,[11,19–21] we instituted a policy of early and aggressive management.

Preoperative preparation: When ventricular septal rupture is suspected, the diagnosis can be established by demonstrating blood oxygen increase at the right ventricular level, from samples drawn through a Swan-Ganz catheter.[22] One must be certain that the distal orifice of the catheter is well back from the pulmonary wedge position. Complete knowledge of ventricular function, location of the perforation, presence or absence of mitral valve insufficiency and details of the coronary arterial anatomy are mandatory before operation. Therefore, cardiac catheterization is performed immediately after septal rupture is recognized, and surgery, if feasible, is undertaken without delay.

Patients who are in unstable condition have an intraaortic balloon inserted for counterpulsation support. The beneficial effects on left ventricular function obtained by reducing afterload and increasing aortic diastolic root pressure with this device have been demonstrated.[23–26] Of the 23 patients undergoing invasive studies, 18 had prior insertion of an intraaortic balloon, and clinical improvement was observed in most. Thus time was gained for adequate studies and surgical preparation. Although one of our patients died during this procedure, most patients have no serious complication with cardiac catheterization.

Factors determining surgical survival: Two primary factors that determine survival after surgical treatment of postinfarction ventricular septal rupture appear to be the time between rupture and the repair and the function of the residual myocardium.[10,20,27] The interval between the occurrence of the myocardial infarction and repair does not influence survival. Our results confirm that early operation can be performed quite successfully. Of seven patients operated on within 48 hours of rupture five (71 percent) survived. When operation was delayed to 48 hours and before 4 weeks after rupture only 4 of 11 patients survived (36 percent). Many of the latter operations were performed at a time when the general condition of the patient had deteriorated severely.

Regardless of the timing of surgery, the location of the infarction and the perforation has a bearing on the surgical outcome. Patients with anterior infarction have a better prognosis than those with inferior infarction.[28,29] In our series, 8 of 11 patients (73 percent) with anterior infarction survived operation, compared with only 3 of 9 patients (33 percent) with inferior infarction. This difference is explained in part by the proximity of the posterior septal rupture to the posterior papillary muscle. Involvement of the latter structure may result in mitral insufficiency and may make surgical repair technically more difficult. Because six of our seven patients operated on within 48 hours of rupture had anterior infarction, it is possible that the better survival in this group was secondary to the location of the infarction rather than the timing of the operation.

Surgical procedures: The type of surgical repair is determined by the quality of the tissue, the size of the septal defect and by its location. The best results follow resection of the infarcted myocardium and closure of the defect. Closure of the defect can best be accomplished with a Dacron® patch when tension is to be avoided or by a double Teflon felt sandwich technique when the defect is near the periphery of the septum.[8,19,30] It is necessary to approach the defect through the infarcted area, thus avoiding injury to the remaining uninvolved muscle. Because acute aneurysm of the free wall is frequently present with septal perforation,[31] resection of such an area is performed in an attempt to improve ventricular performance. We believe that aortocoronary bypass to all significantly obstructed vessels should be performed, when technically possible.

Late results: The condition of survivors of surgical repair of a perforated septum is greatly improved. In three patients a persistent murmur was heard, suggestive of a mild residual shunt, but late reoperation was not required in any survivors. The late survival rate of 55 percent of patients in the surgical group, all in functional class I and II at a mean follow-up time of 17 months, is a great improvement over the expected long-term late survival rate of only 10 percent with medical treatment of this lesion.

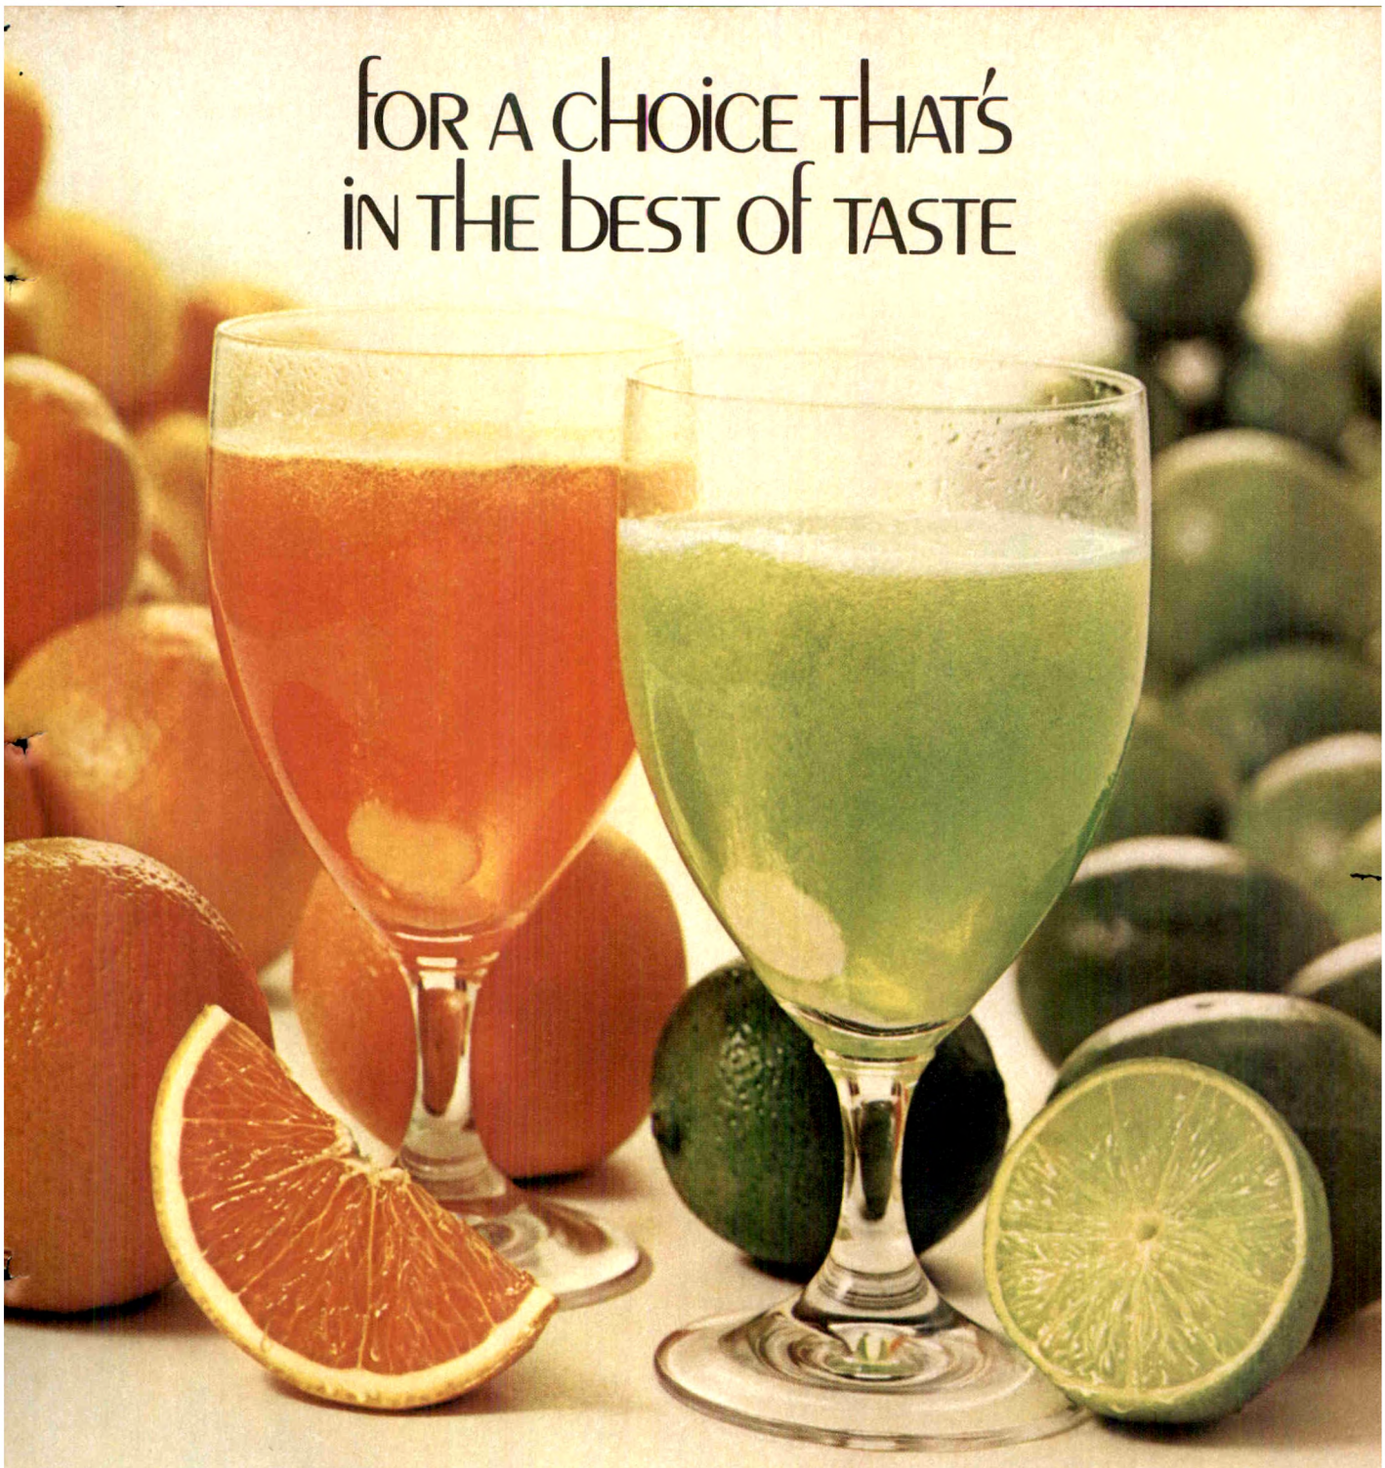
FOR A CHOICE THAT'S IN THE BEST OF TASTE



K-LYTE®

Each effervescent tablet in solution supplies 25 mEq potassium as bicarbonate and citrate

Orange and Lime Flavors
The best of taste for over a decade

K-LYTE® DS

Each effervescent tablet in solution supplies 50 mEq potassium as bicarbonate and citrate

Orange and Lime Flavors
Convenient once-a-day dosage

Prescribing Considerations

Indications: K-LYTE DS and K-LYTE are oral potassium supplements for therapy or prophylaxis of potassium deficiency. They are particularly useful when thiazide diuretics, corticosteroids, or severe vomiting and diarrhea cause excessive excretory potassium losses; and when dietary potassium is low. Carefully monitored, K-LYTE DS and K-LYTE may also be useful for potassium replacement where digitalis intoxication results in cardiac arrhythmias.

Contraindications: Impaired renal function with oliguria or azotemia; Addison's disease; hyperkalemia from any cause.

Warnings and Precautions: Since the amount of potassium deficiency may be difficult to determine accurately, supplements should be administered with caution, and dosages adjusted to the requirements of the individual patient. Potassium intoxication rarely occurs in patients with normal kidney function. Symptoms of potassium intoxication are variable. They include listlessness, mental confusion, and tingling of the extremities. Frequent checks of the clinical status of the patient, ECG, and serum potassium level are desirable. In established hypokalemia, attention should also be directed toward other potential electrolyte disturbances. Potassium supplements should be given cautiously to digitalized patients and such patients should be monitored by ECG for cardiac irregularities. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, **patients should be carefully directed to dissolve each dose completely in the stated amount of water.**

Adverse Reactions: Nausea, vomiting, diarrhea, and abdominal discomfort may occur with the use of potassium salts.

Dosage and Administration: Adults: 1 K-LYTE DS tablet (50 mEq potassium) completely dissolved in 6 to 8 ounces of cold or ice water, 1 to 2 times daily; 1 K-LYTE tablet (25 mEq potassium) completely dissolved in 3 to 4 ounces of cold or ice water, 2 to 4 times daily. **NOTE: It is suggested that K-LYTE DS and K-LYTE be taken with meals and sipped slowly over a 5 to 10 minute period.**

How Supplied: K-LYTE DS effervescent tablets (orange or lime flavors) are available in cartons of 30 and 100. K-LYTE effervescent tablets (orange or lime flavors) are available in cartons of 30 and 250. All tablets are individually foil wrapped.

We've been putting ideas to work at Telectronics for over eighteen years, years in which the future for patients requiring implanted pacemakers has grown steadily brighter.

The future. It's where we've always been.

Some of these Telectronics ideas have set universal standards in pacemaking: monolithic integrated circuitry and the hermetically sealed titanium case for example. Innovations like these represent measured steps, each carefully researched, tested and retested before being accepted for Telectronics pacemakers.

Our technology has been proven by the Slimline 16 and programmable 17 series. Now it's incorporated in the new 18 series to continue a record of reliability and experience that means confidence to physicians and patients all over the world, a world we are helping shape at manufacturing facilities in the United States, France and Australia.

At Telectronics, we'll continue looking ahead to a future with many exciting possibilities, and we're bringing them closer to you every day.

In Edema*
or Hypertension*

Potassium-Sparing

DYAZIDE® Makes Sense

Each capsule contains 50 mg. of Dyrenium®
(brand of triamterene) and 25 mg. of hydrochlorothiazide.

In Edema

In the patient receiving digitalis, or in other edematous patients who require extended diuretic maintenance therapy, it makes sense to prescribe 'Dyazide'. 'Dyazide' helps you preserve the patient's own endogenous potassium stores, limiting the potassium loss that could lead to digitalis toxicity, minimizing the occurrence of bothersome symptoms of potassium depletion that might interfere with patient adherence to the maintenance regimen.

In Hypertension

As the hydrochlorothiazide in 'Dyazide' lowers blood pressure, the triamterene component limits potassium loss. There's seldom a need to complicate the maintenance regimen with potassium-rich foods or multiple daily doses of potassium salts. In fact, they should not be given with 'Dyazide' except in the rare patient in whom hypokalemia develops or dietary potassium intake is markedly impaired. So when potassium loss interferes with patient adherence to the maintenance regimen, it makes sense to prescribe 'Dyazide'.

Serum K^+ and BUN Should Be Checked Periodically

particularly in the elderly, diabetics, and those with suspected or confirmed renal insufficiency (see Warnings). Elevated serum potassium levels can occur because of the K^+-sparing effect of triamterene, but they are rare in patients with normal renal function. If hyperkalemia develops, substitute a thiazide alone.

Easy to Recognize,
Hard to Forget

Patient-Pak™

100's

Before prescribing, see complete prescribing information in SK&F Co. literature or *PDR*. A brief summary follows:

* **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Watch for signs of impending coma in severe liver disease. If spironolactone is used concomitantly, determine serum K frequently; both can cause K^+ retention and elevated serum K^+. Two deaths have been reported with such concomitant therapy (in one, recommended dosage was exceeded, in the other serum electrolytes were not properly monitored). Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia have been reported with thiazides. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effect may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine. Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances. Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and, rarely, allergic pneumonitis have occurred with thiazides alone.

Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient Pak™ unit-of-use bottles of 100.

How to Keep Up with the Most Recent Advances in Your Specialty

in the Comfort of Your Home or Office

NOW—in book form—the famous UPDATE YOUR MEDICINE CONFERENCES

CORNELL MEDICAL UPDATE 1

208 PAGES
74 ILLUS.
KIVAR COVER

EDITED BY Lila A. Wallis, MD, FACP

This new book is designed for the busy physician who finds it difficult to keep up with the growing literature in his profession. Up until now the only way this could be done was to attend such conferences as the highly acclaimed Update Your Medicine sponsored by New York Hospital, Cornell Medical Center. These programs were developed to prepare doctors for Recertification despite heavy work loads.

AMA Physician's Recognition Award

CORNELL MEDICAL UPDATE I has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit is included with every copy.

Read it for 30 days—FREE
Use it to check any problems which come up in your practice throughout a full month. Then keep the book only if you want it for permanent reference. Otherwise simply return it and owe nothing. You have nothing to lose and a whole world of valuable life-saving knowledge to gain. Order right now!

The 16 Lectures are Presented in Compact Workbook Style for Quick Reading and Easy Comprehension:

1. Update Your Endocrinology I: Thyroid & Gonad
2. Update Your Endocrinology II: Hypothalamus and Anterior Pituitary
3. Update Your Cardiology
4. Update Your Gastroenterology: Chronic Active Hepatitis
5. Update Your Gastroenterology: GI Hormones
6. Nephrology: Renal Physiology and Diuretic Therapy
7. Recent Advances in Cancer Chemotherapy
8. Compendium of Antineoplastic Agents
9. Update Your Immunology: Hypersensitivity States
10. Update Your Immunology: Immunopharmacology of Asthma
11. Advances in Neurology
12. Update Your Radiology: Angiography of the GI Tract in Management of Acute Arterial Bleeding
13. Update Your Radiology: Sonography of the Abdomen
14. Recent Advances in Diabetes Mellitus and Hypoglycemia
15. Evaluation of the Program by the Reader
16. Evaluation of the Reader—for the AMA Physician's Recognition Award Credits

Yorke Medical Books AJC-2/80
666 Fifth Ave., New York, NY 10019

YES! Please send me a copy of CORNELL MEDICAL UPDATE I at $32.00. I may use the book for 30 days and if not completely satisfied, return it for full credit or refund.

Introducing the Ultimate Time Machine

Arrhythmia II

The New Dimension in Monitoring

Past, present, future in rapid edit recall, 24 hour trending or drug/vitals time correlation—Arrhythmia II, our time machine.

It required several years of clinical testing to develop a monitoring system that honestly meets the definition of the word "ultimate." It was worth it.

Super

If you're like most people, you've been using a Gould Statham P23ID blood-pressure transducer, Gould Statham Disposable Domes but somebody else's fast-flush device.

That's because we didn't make one.

Now we do.

But it's not just another flush device. It's a whole new idea. It's called the CritiFlo™ dome. It's a super new product that has all the features of a disposable diaphragm dome plus a continuous flow/fast-flush capability in one compact unit.

It minimizes bulk.

It minimizes bubble formation.

It reduces the number of connectors in the system, and thus set-up time.

It permits simple, two-fingered operation of the fast-flush mechanism.

It protects the transducer from over-pressure damage with a special pressure-relief valve.

Gould's new super domes for P23ID transducers are available separately or as part of ready-to-use blood pressure monitoring kits.

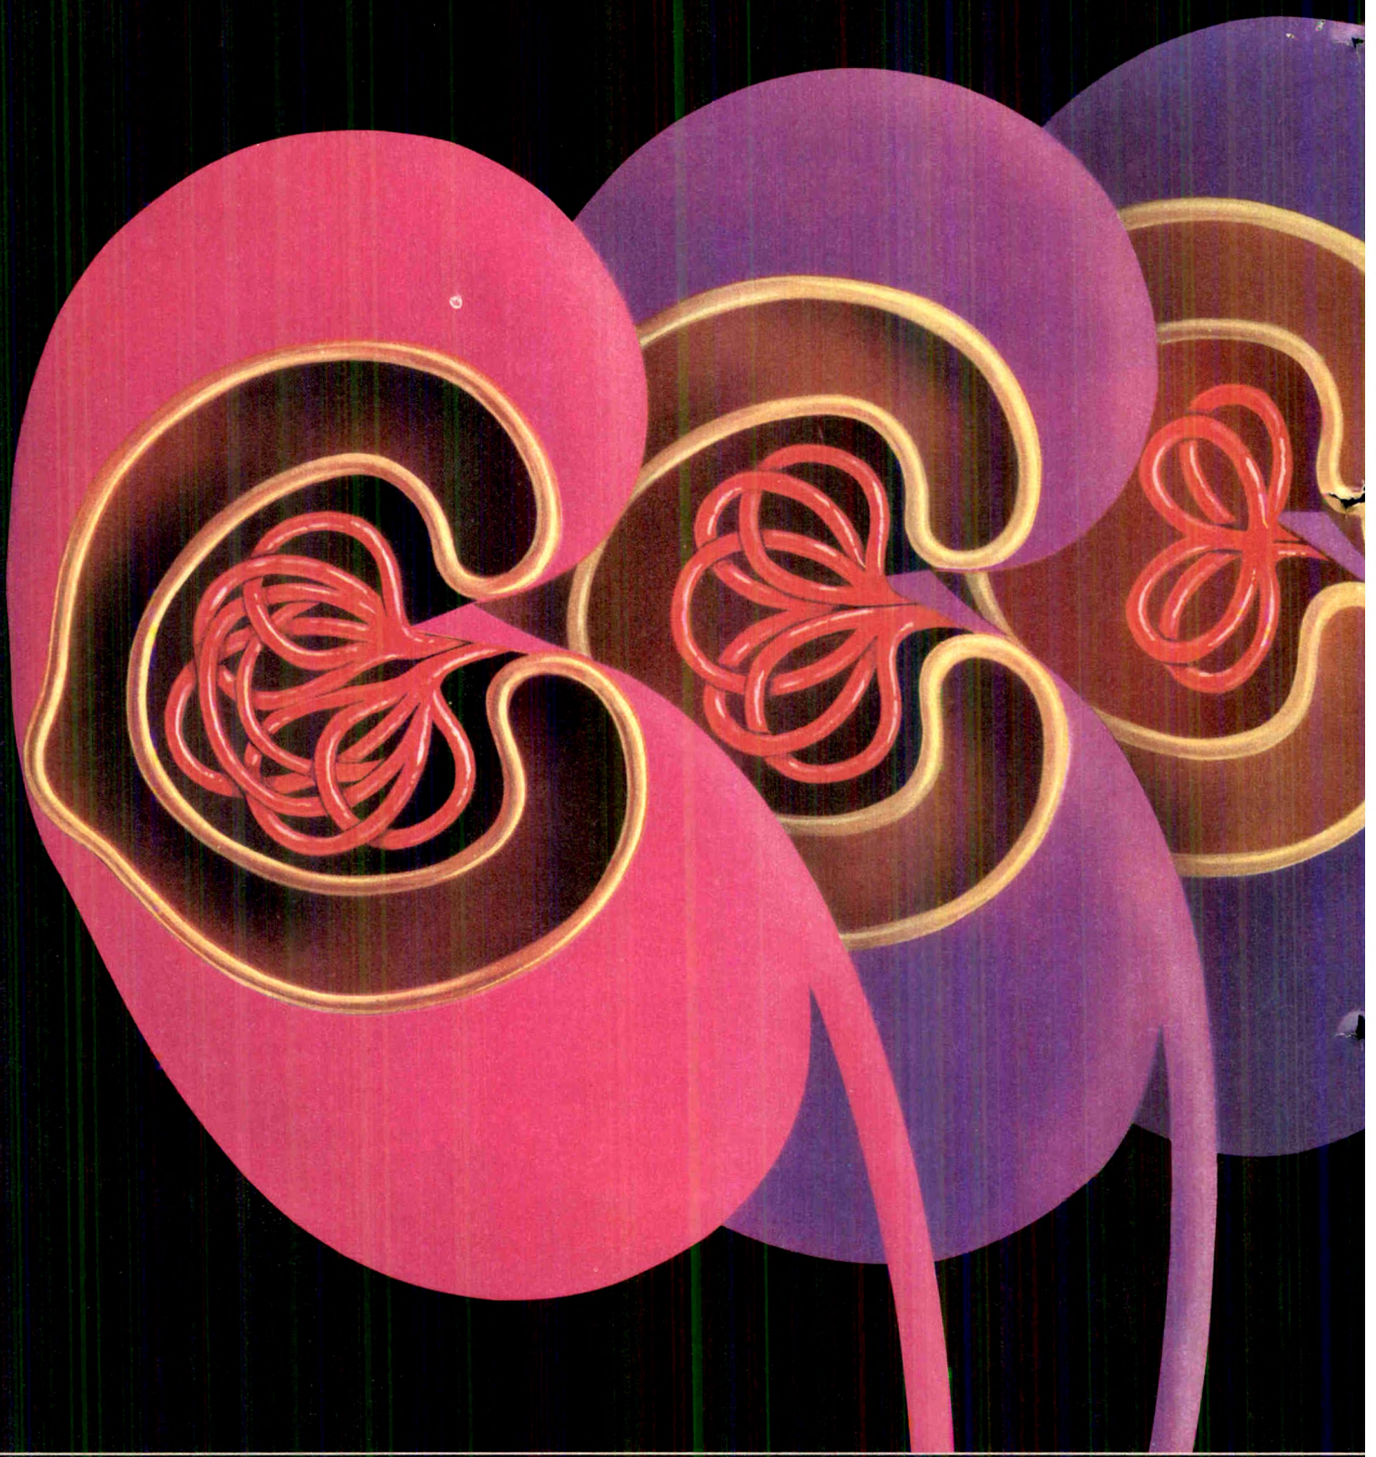
For more information, contact your Gould representative or Gould Inc., Medical Products Division, 2230 Statham Blvd., Oxnard, California 93030.

Or call (805) 487-8511 and ask for Medical Transducer Application Department.

GOULD

An Electrical/Electronics Company

Because kidney function declines



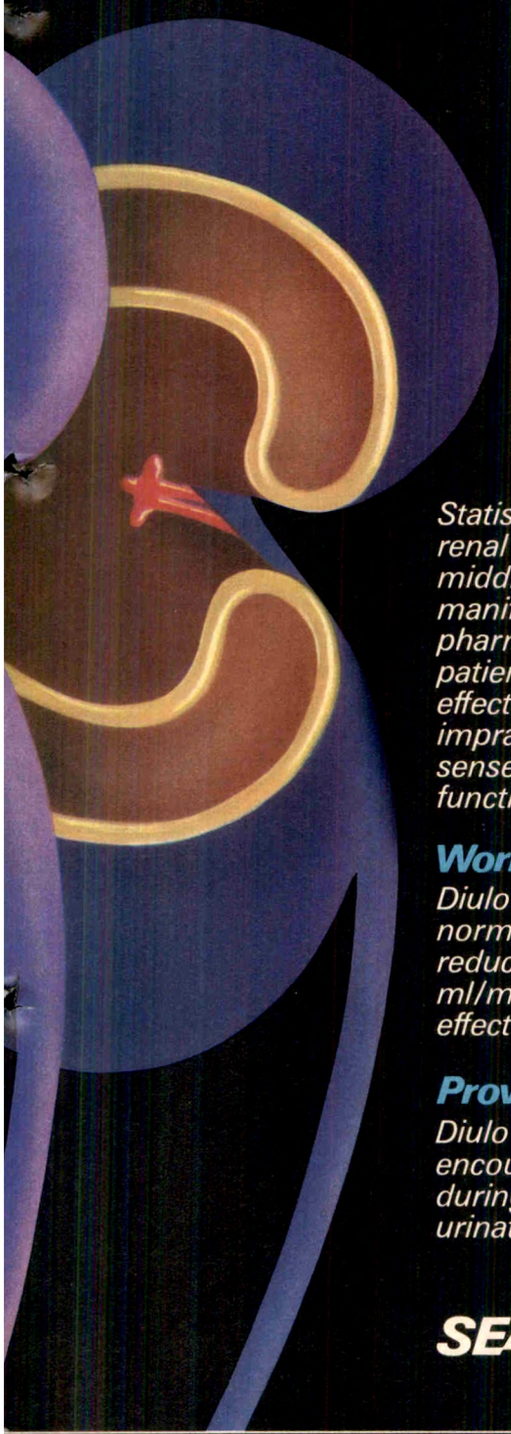
DIULO™ (metolazone) 2½-mg., 5-mg. and 10-mg. tablets *Before prescribing, see complete prescribing information. The following is a brief summary:* ***Indications:*** *Diulo (metolazone) is an antihypertensive diuretic indicated for the management of mild to moderate essential hypertension as sole therapeutic agent and in the more severe forms of hypertension in conjunction with other antihypertensive agents. Also, edema associated with heart failure and renal disease.* ***Contraindications:*** *Anuria, hepatic coma or precoma; allergy or sensitivity to metolazone.* ***Warnings:*** *In theory, cross-allergy may occur in patients allergic to sulfonamide-derived drugs, thiazides or quinethazone. Hypokalemia may occur, and is a particular*

Azotemia and hyperuricemia may be noted or precipitated. Considerable potentiation may occur when given concurrently with furosemide. When added to other antihypertensives, the dosage of the other agents should be reduced. Use with potassium-sparing diuretics may cause potassium retention and hyperkalemia. Administration to pregnant women or those of childbearing age requires that potential benefits be weighed against possible hazards to the fetus. Metolazone appears in the breast milk. Not recommended for pediatric use. ***Precautions:*** *Perform periodic examination of serum electrolytes, BUN, uric acid, and glucose. Observe patients for signs of fluid or electrolyte imbalance, hyponatremia, hypochloremic*

with age...

DIULO™

(METOLAZONE)



In hypertension...the only 24-hour acting diuretic that is effective even when kidney function is depressed

Statistics released by the National Institute on Aging show that renal function decreases with age – a decline most predictable in middle and old age, at just the time when hypertension often manifests itself. Thus, at some clinically unpredictable point, the pharmacology of a particular diuretic may no longer match your patient's pathophysiology; thus, therapy may become less effective. Because precise evaluation of renal function is often impracticable in the outpatient setting, it makes sound clinical sense to use a diuretic that continues to be effective as kidney function declines.

Works even when kidney function is depressed

Diulo works to lower blood pressure when kidney function is normal and may even produce diuresis and blood pressure reduction in patients with glomerular filtration rates below 20 ml/min. Through a unique secondary mode of action, it exerts an effect that differs from that of the thiazides or chlorthalidone.

Provides a 24-hour duration of action

Diulo permits a dosage regimen of one tablet a day, which encourages patient compliance. Furthermore, peak activity occurs during waking hours, minimizing the potential for nighttime urination.

SEARLE *Searle Laboratories*
Division of Searle Pharmaceuticals Inc.
Box 5110
Chicago, Illinois 60680

when there is excessive vomiting or diarrhea, or when parenteral fluids are administered. Patients treated with diuretics or corticosteroids are susceptible to potassium depletion. Caution should be observed when administering to patients with gout or hyperuricemia or those with severely impaired renal function. Insulin requirements may be affected in diabetics, and hyperglycemia and glycosuria may occur in latent diabetes. Chloride deficit and hypochloremic alkalosis may occur. Orthostatic hypotension may occur. Dilutional hyponatremia may occur. ***Adverse Reactions:*** *Constipation, nausea, vomiting, anorexia, diarrhea, bloating, epigastric distress, intrahepatic cholestatic jaundice, hepatitis, syncope, dizziness, drowsiness, vertigo, headache, orthostatic hypotension, excessive volume depletion, hemoconcentration, venous thrombosis, palpitation, chest pain, leukopenia, urticaria, other skin rashes, dryness of mouth, hypokalemia, hyponatremia, hypochloremia, hypochloremic alkalosis, hyperuricemia, hyperglycemia, glycosuria, raised BUN or creatinine, fatigue, muscle cramps or spasm, weakness, restlessness, chills, and acute gouty attacks.* ***Usual Initial Once-Daily Dosages:*** *Mild to moderate essential hypertension—2½ to 5 mg.; edema of cardiac failure—5 to 10 mg.; edema of renal disease—5 to 20 mg. Dosage adjustment is usually necessary during the course of therapy.* ***How Supplied:*** *Tablets, 2½, 5 and 10 mg.; in bottles of 100.*

For 30 years you've known us as

E FOR M ELECTRONICS FOR MEDICINE

Now, we are

E FOR M Honeywell

. . . and here's what this means to you:

- A more comprehensive product line that includes advanced echocardiographs, MEDDARS cath lab recorders and other fine medical products, all under the E for M/Honeywell name.
- Accelerated research and development, enriched by Honeywell technology, for the ongoing creation of new products to meet your ever-evolving needs.
- Expanding capabilities and greater resources than ever before!

But some things stay the same . . .

We will continue with the full E for M product line you've grown to rely on. Our free 2-year warranty stays as solid as ever. And our *really* personal sales and service philosophy is unchanged.

In most ways, then, we're still the same company. We've always done our best, worked our hardest to please you. But we'll have to double our efforts. Because now, we have 2 great names to live up to!

Ask E FOR M / Honeywell

Together, we'll show you a better way

See us at booths 452 and 556-563 at the American College of Cardiology Meeting in Houston, March 10-13

The clinical effects of early application of external pressure circulatory assistance (EPCA) in acute myocardial infarction were evaluated in a prospective, randomized trial involving 258 patients in 25 institutions. All patients had mild left ventricular failure and received circulatory assistance within the first 24 hours after the onset of symptoms. There were no significant differences between the treatment and control groups, consisting of 142 patients and 116 patients, respectively, with regard to age, sex, race, previous cardiac history, electrocardiographic location of myocardial infarction, Norris prognostic index, admission heart rate, blood pressure and chest roentgenogram, and time from onset of symptoms to hospital admission. There were also no differences between the treatment and control groups with regard to antiarrhythmic, positive inotropic, diuretic and vasodilator therapy. Hospital mortality was significantly decreased, compared with that of control patients, in the group receiving 4 or more hours of external pressure circulatory assistance within the first 24 hours after admission (mortality rate 6.5 percent [7 of 108] in treatment group versus 14.7 percent [17 of 116] in control group, $p < 0.05$). Circulatory assistance for 3 or more hours was also associated with a lower mortality rate in the subgroup (patients 46 or more years old) to which mortality in this study was confined (mortality rate 8.3 percent [9 of 109] in the treatment group versus 17.5 percent [17 of 97] in the control group, $p < 0.05$). For the combined group of patients with 3 or more and 4 or more hours of treatment, circulatory assistance was associated with significant lessening ($p < 0.05$ to < 0.01) of morbidity as manifested by recurrent chest pain, progression of cardiac failure, occurrence of ventricular fibrillation, change in heart size and clinical cardiac functional status at discharge. These data support further application and investigation of external pressure circulatory assistance in myocardial infarction.

As a result of advances in the management of cardiac arrhythmias in coronary care units, the major cause of mortality in patients hospitalized with acute myocardial infarction is cardiac pump dysfunction, manifested by severe left ventricular failure or cardiogenic shock.[1] This complication is directly related to loss of a critical mass of myocardium that is usually extensive, commonly involving 40 percent or more of the left ventricle.[2–4] Recent experimental and clinical studies[5,6] of myocardial infarction have demonstrated that therapeutic interventions that favorably alter the balance between myocardial oxygen supply and demand can reduce ischemic cardiac injury and limit infarct size. This approach thus has the potential of improving prognosis in acute myocardial infarction by preserving cardiac tissue and averting complications, such as pump failure, that are related to extent of myocardial damage.

Improvement in the relation between myocardial oxygen supply and demand can be achieved by increasing availability of oxygen or reducing

its requirement. Mechanical circulatory assistance elevates myocardial oxygen delivery by augmentation of arterial diastolic pressure, a major determinant of coronary blood flow, which assumes special importance in the maintenance of myocardial perfusion in the presence of obstructive narrowing of the coronary arteries.[7] Diastolic pressure augmentation can be effected by invasive techniques such as intraaortic balloon counterpulsation[8–14] or noninvasive external counterpulsation.[8,9,15,16] The latter approach has the advantages of wide applicability, ease of implementation and lack of associated trauma. Early intervention with mechanical circulatory assistance prior to the onset of severe cardiac dysfunction has been suggested[10–12] and recently applied[14] as a potential means of preserving myocardium, averting pump failure and reducing mortality in acute myocardial infarction. This report presents the results of a multicenter trial to evaluate the clinical effects of external pressure circulatory assist by a mechanical device (Cardiassist® External Counterpulsation System, Cardiassist Corporation, Hoffman Estates, Illinois) in patients with acute myocardial infarction complicated by mild left ventricular failure (Killip class II).[17]

Methods

Patients: Twenty-five cooperating institutions participated in the study, which was carried out over a 15 month period. The population evaluated consisted of 258 patients with acute myocardial infarction. The mean number of patients per institution was 9, and the range was one (two institutions) to 26 (one institution) patients per institution.

Diagnosis of myocardial infarction was by two of the three following criteria: classic history, characteristic electrocardiographic evolutionary changes and typical serum enzyme alterations. All patients fulfilled the following criteria, in addition to acute myocardial infarction, for admission to the study: mild left ventricular failure (Killip class II),[17] manifested by pulmonary rales over less than 50 percent of the lung fields; entrance into the study within 19 hours of onset of symptoms (with the goal of completion of at least 4 hours of circulatory assistance within the first 24 hours of myocardial infarction); absence of history of previously treated cardiac failure; and absence of clinical evidence of peripheral vascular disease and aortic valve insufficiency. All patients gave informed consent for entrance into the study. Allocation of patients to treatment and control groups was by random assignment as described in the Appendix.

Evaluation of left ventricular function: Left ventricular functional status on admission and during the subsequent hospital course was classified by clinical and roentgenographic criteria. Clinical classification was made according to the following criteria[17]: class I, absence of clinical complications, clear lung fields; class II, rales over less than 50 percent of the lung fields; class III, pulmonary edema with rales over 50 percent or more of the lung fields; and class IV, shock manifested by criteria for class III plus a systolic blood pressure of less than 90 mm Hg with signs of inadequate peripheral organ perfusion (diaphoresis, cyanosis, oliguria, altered mental status). Chest roentgenograms were interpreted and classified by a radiologist without knowledge of clinical classification: class I, normal lung fields; class II, redistribution of pulmonary blood flow to the upper lung fields and mild hilar congestion; class III, criteria for class II plus marked increase in prominence of pulmonary vessels of the outer lung fields; and class IV, criteria for class III plus presence of pleural effusion, and hilar congestion or cardiomegaly, or both.

Roentgenographic determination of heart size was performed on admission and on the day of, or 1 day before discharge. This evaluation[18] was based on the extent to which the transverse cardiac diameter exceeded that resulting in a cardiothoracic ratio of 0.5: normal, transverse cardiac diameter of up to 1.0 cm in excess of the latter criterion; questionable cardiac enlargement, increase in transverse cardiac diameter of more than 1.0 to 1.5 cm in excess of this criterion; definite cardiac enlargement, increase in transverse cardiac diameter of more than 1.5 cm in excess of this criterion. This analysis was included in the evaluation midway through the study and was therefore available in some patients.

External pressure circulatory assistance: Circulatory assistance was administered to the treatment group only. Each hour of treatment consisted of 50 minutes of circulatory assistance and 10 minutes of rest. There were no restrictions on any other available forms of therapy for patients in either the treatment or the control group.

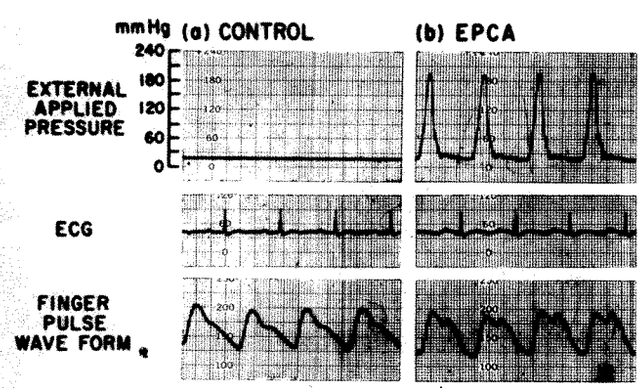

FIGURE 1. Top panel, actual external pressure applied during counterpulsation. **Middle panel,** electrocardiogram (ECG). **Bottom panel,** finger pulse waveform recorded from finger plethysmography depicting relative changes (uncalibrated). Data are recorded with patient in the external pressure circulatory assistance (EPCA) device before (**a**) and during (**b**) augmentation of diastolic pressure. The delays in transmission of central arterial pressure to the limbs and in transmission of peripheral externally applied pressure centrally account for the temporal relations between applied pressure and the finger pulse waveform. The water required to fill the leg unit accounts for the external pressure before activation of external pressure (**a**) and during the inactive phase of counterpulsation (**b**).

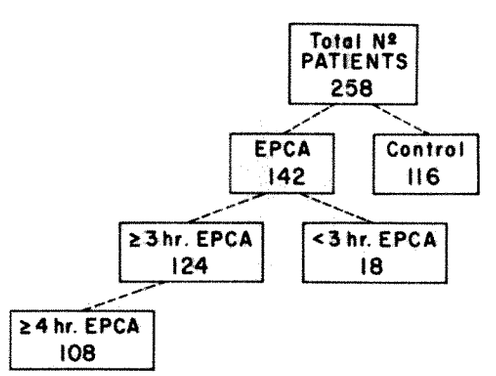

FIGURE 2. Number of patients in the control group and the groups with external pressure circulatory assistance. The number of hours indicates the total time of circulatory assistance in the first 24 hours after the onset of symptoms of myocardial infarction.

External pressure circulatory assistance was administered by a device that encloses the lower limbs from thigh to ankle in a hydraulically activated leg unit. External counterpulsation was delivered through the controlled application of positive external pressure by the leg unit. The device did not include a negative pressure phase. The timing, magnitude and duration of external pressure were each regulated to produce the desired diastolic augmentation. Diastolic augmentation was assessed by indirect recording of finger pulse waveform by a volume-sensing finger plethysmograph, with which each device is equipped (Fig. 1). Counterpulsation was effected by synchronization of mechanical activation with the electrocardiogram to produce positive pressure during diastole. The technique was applied to achieve maximal diastolic augmentation, which resulted in elevation of peak pressure during diastole to levels approximating systolic pressure (Fig. 1). External pressures ranged up to 250 mm Hg for a duration of up to 250 ms to produce satisfactory diastolic augmentation. The maximal duration of 250 ms was selected because prior experience indicated it to be the maximum necessary to produce the desired effect over a wide range of heart rates.

Evaluation of data: All data were recorded and maintained in individual patient books at each institution. A copy of the completed data record was forwarded to a central office where it was reviewed and evaluated by the project steering committee, consisting of the authors. All data were evaluated without knowledge of whether the patients were in the treatment or the control group.

Statistical analysis was performed by application of the chi square test to categorized variables and Student's two-tailed *t* test to continuous variables.

Results

Duration of treatment: Two hundred fifty-eight patients fulfilled the study criteria; 116 of the patients constituted the control group and 142 the treatment group. Of the latter patients, 108 received 4 or more hours of external pressure circulatory assistance (mean 5.0 hours, maximum 8.1 hours) completed within the first 24 hours after the onset of symptoms of myocardial infarction and 124 received the assistance for 3 or more hours (mean 4.7 hours, maximum 8.1 hours) within the first 24 hours (Fig. 2). Eighteen patients in the treatment group received less than 3 hours of treatment in the first 24 hours.

Time from onset of symptoms to completion of treatment: This interval was determined for the group receiving 4 or more hours of treatment. Completion of 4 or more hours of external pressure circulatory assistance was achieved within 12 hours of onset of symptoms in 31 patients (29 percent), within 18 hours in 45 patients (42 percent) and within 24 hours in 32 patients (29 percent). Therefore, treatment was completed within 18 hours of onset of symptoms in 71 percent of patients.

Hospital mortality: Mortality did not differ significantly ($p > 0.05$) from that of the control group for the total group of 142 patients who received external pressure circulatory assistance and for the group that received 3 or more hours of assistance in the first 24 hours (Table I). However, mortality was significantly less than that of the control group for those patients aged 46 or more years (the population in this study in which mortality occurred) who received 3 or more hours of circulatory assistance in the first 24 hours (8.3 versus 17.5 percent, $p < 0.05$) and for the entire group that received 4 or more hours of assistance in the first 24 hours (6.5 versus 14.7 percent, $p < 0.05$) (Table I). In addition, mortality from cardiac pump failure alone was significantly less than in the control patients for both the entire group that received 3 or more hours of circulatory assistance (5.7 versus 13.8 percent, $p < 0.04$) and the group that received 4 or more hours of treatment (4.6 versus 13.8 percent, $p < 0.02$) (Table II). There were no significant differences in proportion of deaths due to primary cardiac arrhythmias in the treated and control patients.

Specific subgroups of patients considered to be at increased risk were analyzed in regard to the effects of external pressure circulatory assistance on mortality. These subgroups consisted of patients with transmural myocardial infarction, anterior infarction, and a Norris index[19] greater than 6. (The Norris index is described in the Appendix.) For these analyses, the treatment

TABLE I

Mortality Rate in Control Group and Patients Treated With External Pressure Circulatory Assistance (EPCA)

	Total	Control Group	Treatment Group	p
All treated patients* vs. control group				
Patients (n)	258	116	142	
Deaths (n)	29	17	12

group consisted of patients receiving 3 or more hours of circulatory assistance. Mortality in treated patients with transmural myocardial infarction was 7.1 percent (8 of 113) compared with 15.4 percent (17 of 110) in the control group ($p < 0.05$). Although mortality tended to be lower in the treatment group with anterior infarction (8.5 percent, 5 of 59) than in the control group (16.4 percent, 11 of 67), this difference was not significant ($p > 0.05$). In patients with a Norris index greater than 6, the treated group had a significantly lower mortality rate, 9.6 percent (7 of 73) versus 22.7 percent (17 of 75), ($p < 0.04$).

Clinical characteristics and time from onset of symptoms to admission (Tables III, IV and V): There were no significant differences on admission with respect to the broad set of clinical characteristics assessed between the control group and the subgroup of patients aged 46 or more years with 3 or more hours of treatment, the entire group with 3 or more hours of treatment, or the entire group with 4 or more hours of treatment. In addition, the mean time from onset of symptoms to admission to the coronary care unit was similar in the treatment and control groups: 6.9 versus 7.2 hours ($p > 0.05$).

Cardiac complications: Morbidity, as defined by several cardiac complications, was significantly less in each of the total treatment groups completing 3 or 4 or more hours of external pressure circulatory assistance, respectively, within the first 24 hours after onset of symptoms of myocardial infarction than in the control

group (Table VI). Data regarding change in roentgenographically determined heart size were available for 57 percent (138 patients) of the study group because of inclusion of this factor after initiation of the study.

Other medical treatment: Analysis of pharmacologic therapy during the first 5 days of hospitalization demonstrated no significant differences ($p > 0.05$) between the groups receiving treatment (3 or more hours of treatment, age 46 or more years; total group with 3 or more hours of treatment and total group with 4 or more hours of treatment) and the control group with respect to proportion of patients receiving antiarrhythmic drugs, diuretic agents, digitalis, vasodilator drugs and propranolol and no differences with regard to analgesic or sedative therapy during the interval from 12 hours after admission through day 5. There was no relation between vasodilator therapy and the clinical outcome in either group. Data were not available for comparative analysis of therapy after day 5.

Complications of external pressure circulatory assistance: There were no complications directly attributable to this procedure. Discomfort of the lower limbs was a common complaint and some patients complained of a distressing feeling of confinement when in the device, but there was no injury or evidence of trauma from the procedure. Pulmonary embolism, which proved fatal, occurred in one patient in the treatment group, and in none of the control group.

Discussion

Validity of study: This trial of application of external pressure circulatory assistance during the first 24 hours after the onset of symptoms of myocardial infarction was associated with a reduction in hospital mortality and morbidity in certain large groups of patients with acute myocardial infarction complicated by mild cardiac failure. Several aspects of this study support a relation between this treatment and the favorable clinical outcome in the treated patients. The trial was controlled by application of randomization in the selection of the study groups. This method provides several important advantages in the design of a clinical trial and contributes considerably to the significance of the results.[20] Randomization affords an unbiased means of selecting the treatment and control groups and is the most practical approach to eliminating or reducing

CHF = cardiac heart failure; p = probability.

systematic differences in their characteristics. Further, this method is the most reliable means of limiting not only apparent bias in selection of study populations, but also those inapparent factors that could affect the outcome of an investigation of a therapeutic intervention. Adequacy of randomization of our patients was assessed by comparative statistical analysis of multiple risk factors related to prognosis in acute myocardial infarction. The results of the analyses are consistent with appropriate randomization, as reflected by comparable prevalence of these risk factors in the treatment and control groups on entry (Tables III to V).

With respect to the *unequal number of patients per institution,* we considered it mandatory to include all patients in this prospective trial in the analysis of data. Interestingly, the results of external pressure circulatory assistance were more favorable in institutions that contributed a higher number of patients than in those with fewer patients entered in the study. These differences were not significant however.

The validity of this study was supported by rigorous implementation of the protocol, randomization procedure, data acquisition and analytic methods. All patients included and excluded were reviewed and categorized at several levels of the investigation, as indicated in the Appendix, and all exclusions are accounted for. Of further importance is the representative nature of the control group in this study, in terms of hospital mortality among patients with Killip class II infarction[17], indicating that the observed differences in outcome between the treatment and control patients cannot be attributed to an atypically high mortality rate in the latter.

Role of duration of therapy in reducing mortality: The beneficial clinical effects of external pressure circulatory assistance were closely related to the duration of this therapy administered in the 24 hours after the clinical onset of acute myocardial infarction. Thus, whereas evidence of benefit in patients receiving less than 3 hours of treatment was lacking, morbidity related to infarction was reduced in the groups receiving 3 or more or 4 or more hours of treatment (Table VI). Moreover, mortality in relation to that of the control patients was reduced in only a specific subgroup of the patients treated for 3 or more hours, those aged 46 or more years, whereas it was decreased in the entire group treated for 4 or more hours (Table I). These findings demonstrate enhanced clinical benefit with greater duration of external pressure circulatory assistance, suggesting a direct relation of this therapeutic intervention to the differences in outcome in the treated and control patients. Although mortality in the treated and control patients differed significantly only in the two aforementioned groups, outcome was consistently favorable in all treated groups (Table I). Mortality related to cardiac pump failure alone was significantly less in the patients treated for 3 or more hours and those treated for 4 or more hours than in the control group (Table II). In this regard, it is reasonable that a beneficial effect on survival obtained from therapy with the potential to limit infarct size might be more directly reflected by a decrease in mortality due to pump failure than by a reduction in overall mortality.

Role of infarct size and pump failure: The most critical factor determining the clinical course of patients hospitalized with acute myocardial infarction is infarct size, because cardiac pump failure, the major cause of mortality in this setting, is the result of extensive cardiac damage.[2–4] The potential for limitation of infarct size has been demonstrated by interventions that improve the balance between myocardial oxygen supply and demand by decreasing oxygen consumption or increasing supply.[5,6] Mechanical augmentation of diastolic pressure has been utilized to achieve the latter effect.[6] In this regard, it has been suggested that mechanical circulatory assistance may have an important role in early application to control myocardial damage before hypotension and severe cardiac pump failure develop.[10–12] This concept has recently been applied with resultant evidence of limitation of myocardial injury in the subgroup of patients with anterior myocardial infarction and residual patency of the left anterior descending coronary artery.[14] External pressure circulatory assistance may provide a noninvasive means to achieve this effect.

Experimental data have demonstrated that therapy to limit ischemic myocardial injury is significantly influenced by the timing of the intervention after the onset of infarction. Thus, hyaluronidase has been associated with evidence of limitation of myocardial damage after experimental canine infarction when the agent was administered within 6 hours after coronary occlusion, whereas it had no demonstrable effect when given at 9 hours.[21] The beneficial clinical effects of external pressure counterpulsation in our patients were associated with application of treatment at a later time than that suggested as necessary by the aforementioned study. This discrepancy can be related at least in part to factors such as the inconsistency between the experimental model of myocardial infarction and the clinical entity and the multiplicity of factors that determine infarct size in man, such as the specific coronary artery involved and the site of obstruction, the presence or absence of collateral vessels and the state of myocardial oxygen demand. Nevertheless, the importance of early intervention in myocardial infarction to impede progressive ischemic damage is clear and it is noted that more than two thirds of our patients did complete treatment within 18 hours of the onset of symptoms.

Enhancement of myocardial perfusion: role of augmentation of diastolic blood pressure: Previous studies have suggested that external pressure counterpulsation may be beneficial in ischemic heart disease by improving myocardial perfusion. This improvement could involve an increase in total coronary blood flow or a favorable redistribution of myocardial blood flow. As indicated indirectly in this study and by previous direct measurements of intraarterial pressure,[15,16] external pressure counterpulsation produces considerable augmentation of diastolic blood pressure, a critical determinant of coronary blood flow, of particular importance in the presence of obstructive coronary artery

disease. Diastolic pressure augmentation possesses the major advantage of increasing arterial pressure during the period of minimal left ventricular intramural pressure, thereby producing a maximum gradient for coronary perfusion. Enhancement of myocardial perfusion by this procedure has been suggested by studies of the technique in experimental and clinical infarction demonstrating improvement in cardiac metabolism and efficiency,[22–25] a reduction in S-T segment injury pattern[26] and augmentation of regional contractile function.[27] The effect on total coronary blood flow has been inconsistent[16,21,22] although experimental studies suggest that external pressure counterpulsation may increase coronary collateral flow to ischemic myocardium.[28,29]

Complications of external pressure counterpulsation: Complications were limited to discomfort of the legs, which in a few patients may preclude this therapy. However, no local trauma or lesions were evident. One patient in the treatment group had a fatal pulmonary embolism. Although dislodging of thrombi in leg veins is a theoretic hazard with this procedure, we did not find an increased incidence of this complication with this approach.

Implications: The early results of external pressure counterpulsation in this multicenter trial of patients with acute myocardial infarction and mild (class II) cardiac failure are encouraging and support further application and evaluation of this approach in other subgroups of patients with acute myocardial infarction and other forms of ischemic heart disease. Further objective assessment of the effects of this treatment on myocardial ischemia and infarct size with current methods is also warranted.

Acknowledgment

We express our appreciation to Joseph V. Messer, MD, for his efforts during the conduct of this trial and gratefully acknowledge the encouragement and suggestions of Eugene Braunwald, MD, Leon Resnekov, MD and H.J.C. Swan, MD, during the design and performance of the study. We also thank Nubar Hagopian, BSEE, MBA, for technical assistance and Leslie Silvernail and Karen Gilmore for secretarial assistance.

APPENDIX

Randomization procedure: All patients were assigned to the treatment or control groups by random allocation made at a central, independent coordinating center. To promote representative distribution of patients in the treatment and control groups at all institutions, a separate set of random tables was prepared for each institution and was utilized exclusively for its patients throughout the study. On presentation of a patient, assignment to either the control or treatment group was obtained by direct telephone call to the coordinating center, which was available on a 24-hour basis.

Exclusion of ineligible patients: The 258 patients who met the study criteria were obtained from a total group of 326 patients on whom randomization and admission to the protocol were requested. Of this initial total, 68 patients (39 of 181 [21.5 percent] from the treatment group and 29 of 145 [20.0 percent] from the control group) were ineligible on the basis of study criteria and were therefore excluded. The ineligible group included 39 patients who did not fulfill the criteria for acute myocardial infarction, 10 patients who did not fulfill criteria for clinical class II status, 13 patients who were not admitted within the prescribed time limit, 3 patients with insufficient data and 3 patients who were excluded because of a noncardiac death. Exclusion of 40 of these patients was made by the principal investigator at each institution. The remaining 28 patients were excluded by decision of the steering committee because of absence of criteria for diagnosis of myocardial infarction (10 patients), nonfulfillment of the time requirements for admission (13 patients) and noncardiac death (3 patients [2 in the treatment and 1 in the control group]). In addition to the evaluation of all patients excluded from the study by the institutional principal investigator and the steering committee, a review and confirmation of the validity of exclusion was made by a physician unassociated with the study.

Mortality in the ineligible patients: Analysis of mortality in the 68 patients ineligible for inclusion in the study revealed eight deaths in the 39 patients who had been allocated to the treatment group and three deaths in the 29 patients assigned to the control group. Four of the eight deaths in the treatment group were in patients who, although randomized to this group, did not receive external pressure circulatory assistance because of their early exclusion by the respective institutional investigators on the basis of failure to meet inclusion criteria. The specific reasons for exclusion of the nonsurvivors were: absence of myocardial infarction (treatment group, two patients), failure to fulfill clinical class II criteria (treatment group, three; control group, one); failure to meet time requirements for entry (treatment group, one; control group, one) and noncardiac death (treatment group, two; control group, one). Exclusion of five of the nonsurvivors, three from the treatment group and two from the control group, was made by the steering committee on the basis of failure to meet the time requirements for entry (treatment group, one patient; control group, one patient) and noncardiac death (treatment group, two; control group, one). The remaining six nonsurvivors were excluded by the respective institutional investigators because of absence of myocardial infarction (treatment group, two) and failure to fulfill class II criteria (treatment group, three; control group, one).

Norris index: The Norris index[19] is a prognostic index that provides a probability level for hospital mortality in patients with acute myocardial infarction on the basis of six readily measurable clinical factors on admission: (1) age, (2) electrocardiographic location of infarction, (3) systolic blood pressure, (4) heart size, (5) lung fields on roentgenography, and (6) history of myocardial ischemia. Each factor is assigned a relative weight according to the specific data, the sum of the weights equaling the index score. Mortality associated with a score of 6 to 7 is 22 percent.

Fungal Infections of the Heart: Analysis of 51 Autopsy Cases

THOMAS J. WALSH, MD
GROVER M. HUTCHINS, MD
BERNADINE H. BULKLEY, MD, FACC
GEOFFREY MENDELSOHN, MD

Baltimore, Maryland

The clinical setting, predisposing factors and consequences of fungal involvement of the heart were examined in all patients with this condition who underwent autopsy at The Johns Hopkins Hospital from 1889 through 1977. The 51 patients with cardiac fungal infection were all observed since 1954; they ranged in age from 2 weeks to 80 years; 29 were male. Fungal endocarditis was present in 13 patients, myocarditis in 31, pericarditis in 4 and pancarditis in 3. In only one instance was cardiac fungal infection diagnosed during life. The infecting organisms were Candida in 34 patients, Aspergillus in 13, Cryptococcus in 3 and combined Candida and Aspergillus in 1. The conditions appearing to predispose to fungal infection were abdominal surgery in 20 patients, thoracic surgery in 7 and treatment with corticosteroids, antineoplastic agents or antibiotic drugs, alone or in combination, in 43 cases. Endocarditis was most commonly associated with central venous catheters or prosthetic valve surgery and was often caused by Aspergillus. Myocarditis and pancarditis usually occurred in a setting of gastrointestinal surgery, intense antibiotic therapy and systemic candidiasis. Death could be attributed to fungal infection in 36 patients and specifically to cardiac involvement in 8. Endocarditis was diagnosed once during life. Cardiac fungal infection, especially myocarditis, may be difficult to recognize clinically. It is associated with extensive therapeutic interventions and may in itself produce a fatal outcome.

Cardiac infection by fungi was rarely reported in the past. In 1915 Hurley[1] described a patient with Blastomyces dermatitidis in the right atrium. In the first completely documented case of candidal endocarditis, reported in 1940,[2] the patient was a heroin addict. A patient with postvalvulotomy endocarditis due to Candida albicans was described in 1956.[3] Aspergillar mural endocarditis in a child was described in 1947.[4] Aspergillar valve endocarditis was first reported in 1950 in a patient with rheumatic heart disease who received large doses of penicillin for a leg wound.[5] Systemic fungal infections have since been identified with increasing frequency. Cardiac involvement may be difficult to diagnose clinically, is frequently fatal and may first be discovered at autopsy. In this study we systematically examined the clinical setting, predisposing conditions, pathologic findings and consequences of endocarditis, myocarditis and pericarditis in 51 patients with postmortem examination.

Case Material

The cases of all patients who underwent autopsy patients at The Johns Hopkins Hospital from 1889 through 1977 were reviewed for histologically confirmed fungal infection of the heart. There were 51 patients with such confirmation; the first identified case occurred in 1954. Among these patients the incidence, clinical setting, signs contributing to early diagnosis, the consequences and pathologic features of cardiac fungal infection were studied. The clinical records, autopsy reports, histologic sections, surgical pathology material and the available preserved hearts of all patients were examined.

From the Department of Pathology and the Cardiovascular Division of the Department of Medicine of The Johns Hopkins Medical Institutions, Baltimore, Maryland. This study was supported by Grant P50-HL-17655-05 from The National Institutes of Health, Bethesda, Maryland. Manuscript received January 16, 1979; revised manuscript received September 4, 1979, accepted September 5, 1979.

Patients were included in the study only if their heart demonstrated unequivocal morphologic evidence of fungal organisms in cardiac tissue. Because identification of organisms was made on morphologic grounds (Fig. 1), the mention of Candida, Aspergillus or Cryptococcus in this study must be understood as "organisms morphologically consistent with" one of these genera. However, histologic identification was confirmed with premortem cultures from 24 patients and with postmortem cultures from 8 other patients.

Results

The 51 patients formed three distinct clinicopathologic groups (Table I). Thirteen patients had fungal endocarditis, occurring usually in a setting of previous cardiac surgery or prolonged maintenance of an infected central venous catheter. Thirty-four patients had fungal myocarditis, usually associated with abdominal surgery or with prolonged administration of multiple antibiotic drugs. Included in this group are three patients with pancarditis with involvement of all three layers of the heart that arose from a hematogenous dissemination comparable with that producing the myocarditis only. Only four patients had fungal pericarditis which was associated with cytotoxic therapy, corticosteroids, leukemia and pericardiectomy, respectively.

Endocarditis (Fig. 2 and 3): *Clinical features:* Among the 13 patients with fungal endocarditis, the initial clinical manifestations were fever in 13, leukocytosis with a "left shift" in 8 and a new murmur with a palpable spleen in 3. Roth spots, Osler nodes and splinter hemorrhages were not described. Four patients

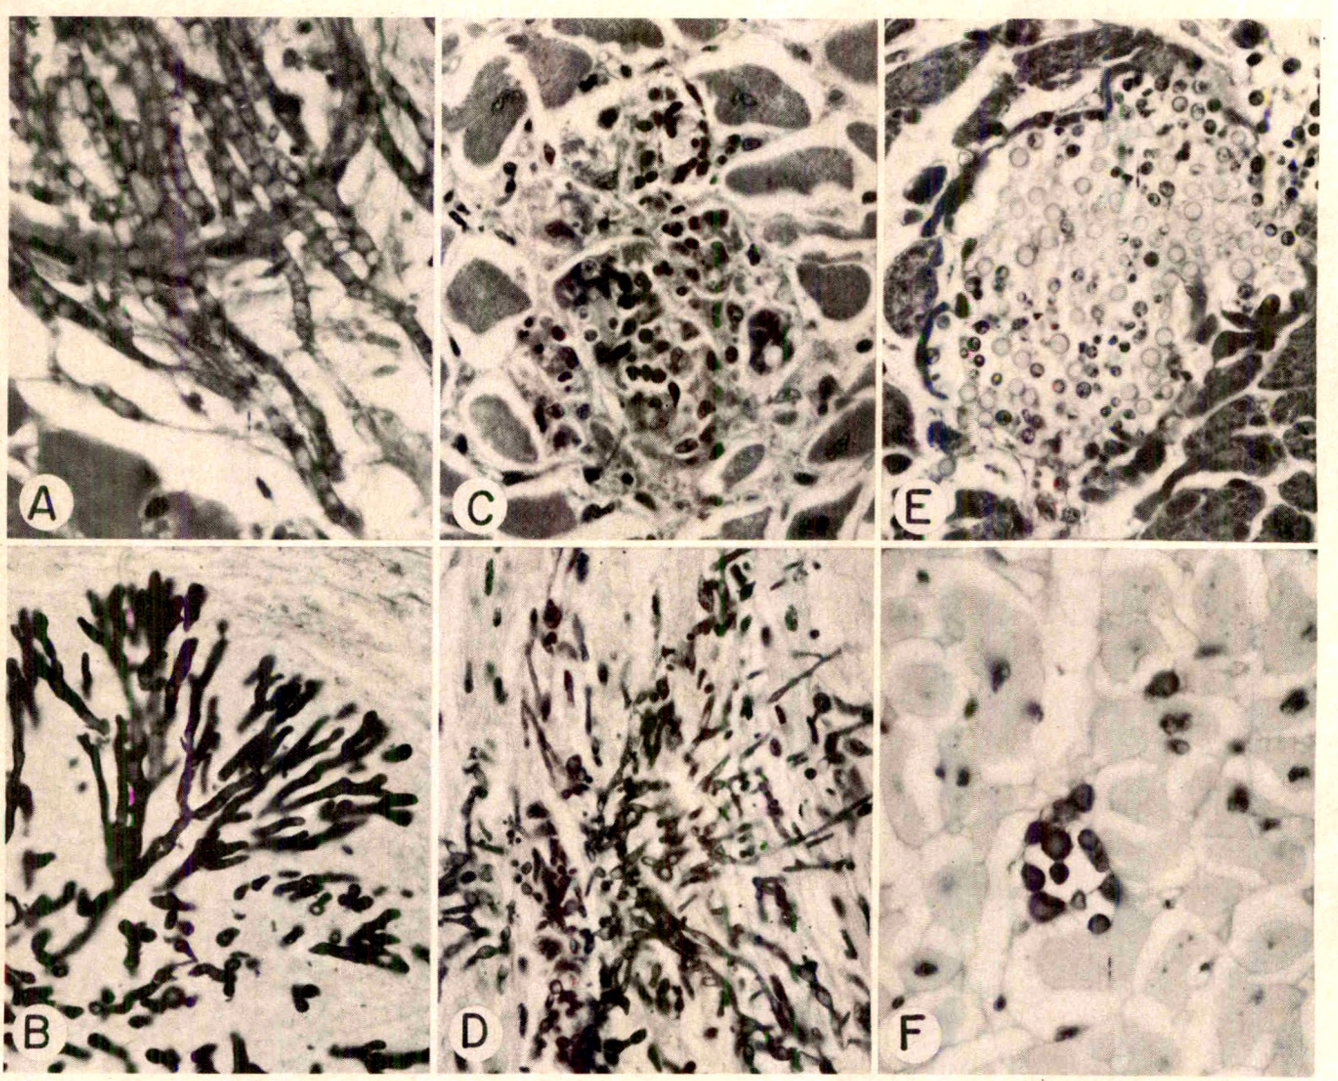

FIGURE 1. Morphology of fungi. **A**, Aspergillus growing through myocardium and penetrating a vessel wall. Note septa within the hyphae. **B**, Aspergillus colony growing in the epicardium. The organisms show extensive branching. **C**, myocardial microabscess containing spore and hyphal forms of Candida. The fungi may be difficult to distinguish from the inflammatory cells. **D**, Candida growing in the myocardium of a patient who had received immunosuppressive therapy. The inflammatory cell response is slight but the muscle cells invaded by organisms are necrotic. **E**, cryptococcal organisms producing a small focus of myocardial destruction apparently by mechanically pushing the muscle cells aside. There is very little inflammatory cell reaction. **F**, Cryptococcus blastospores showing the characteristic positive reaction to mucicarmine. (Hematoxylin-eosin [**A, C, E**], methenamine silver [**B**], periodic acid-Schiff stain [**D**] and mucicarmine stain [**F**]; all ×500, reduced by 6 percent.)

(31 percent) had clinically evident systemic embolism as an early sign of fungal endocarditis. Three had abrupt onset of neurologic changes: hemiparesis in two and oculomotor palsy in the third. The fourth patient presented with sudden femoral and mesenteric arterial occlusion by Candida-laden emboli 3 months after hospital discharge after implantation of a prosthetic aortic valve. Septic emboli arose from vegetations on the prosthetic valve. Femoral arterial embolectomy established the diagnosis of candidal embolus and led to valve resection. Cardiac fungal infection was diagnosed during life only in this patient.

Five (38 percent) of the 13 with fungal endocarditis underwent thoracic surgery compared with only 1 (3 percent) of the 34 patients with myocarditis. Similarly, only 2 patients (15 percent) with endocarditis underwent abdominal surgery in contrast to 16 patients (47 percent) with myocarditis. Candidal thrombosis of central venous catheters was observed in three patients (23 percent). After removal of the infected catheters, candidemia continued, with persistence of fungi in endocardial thrombi. Mitral commissurotomy for rheumatic valve disease in one patient was complicated by candidal endocarditis, valve obstruction by vegetations, and pulmonary edema. Clinically occult mycotic emboli occluded major arteries.

Pathology: Prosthetic valve implantation in three patients, mycotic thrombosis of central venous catheters in four, old bacterial endocarditis in one patient and rheumatic mitral stenosis in another were the major endocardial lesions preceding fungal endocarditis. Fungal vegetations complicated prosthetic valves in three ways: (1) obstruction causing intractable pulmonary edema, (2) multiple emboli, and (3) rupture of the aortic root. Fungal thrombosis of central catheters ranged from right atrial mural endocarditis to massive obstruction of tricuspid and pulmonic valve orifices by continuous Candida-laden thrombus.[6] Among the remaining four patients with fungal endocarditis, there was no identifiable predisposing endocardial lesion. Instead these patients had fungal mural endocarditis and systemic mycosis.

Myocarditis (Fig. 4): *Clinical features:* Thirty-one of the 34 patients had pathologically defined fungal myocarditis without endocardial or pericardial involvement. Unlike patients with fungal endocarditis, those with myocarditis had no embolic events. The earliest clinical sign of fungal myocarditis was a positive blood culture. The most frequently associated therapeutic intervention related to fungal myocarditis was gastrointestinal surgery, which was performed in 47 percent of these patients compared with only 2 of 13 patients (15 percent) with fungal endocarditis. Other therapeutic interventions related to myocarditis were prolonged antibiotic therapy, administration of multiple antibiotic drugs and corticosteroids. More than 70 percent received a prolonged course of antibiotic therapy. Antibiotic agents typically were instituted for gram-negative bacteremia. Among 11 patients with either bacterial peritonitis or local intraabdominal abscess, 10 had fungal myocarditis.

Pathology: Myocardial abscesses ranged from microabscesses containing few organisms to grossly confluent regions of necrotic myocardium, inflammatory cells and invasive fungi. The abscesses were grossly visible at autopsy in 10 (29 percent) of the 34 hearts, principally as white to hemorrhagic well circumscribed defects in the myocardium ranging from 1 to 5 mm in diameter.

The intensity of inflammatory response varied inversely with the number of fungal organisms present in the myocardial lesions. The paucity or absence of

polymorphonuclear leukocytes and the simultaneous unchecked proliferation of organisms was related to clinical use of immunosuppressive agents, whereas an intense focal myocardial necrosis with many polymorphonuclear leukocytes and scarcity of organisms appeared in those patients who did not receive cytotoxic agents (Fig. 4, C and D).

Pancarditis: Three of the 34 patients with myocarditis had fungal pancarditis: coincident involvement of endocardium, myocardium and pericardium. Abdominal surgery, gram-negative sepsis and use of multiple antibiotic agents or immunosuppressive therapy for leukemia were the clinical settings of fungal pancarditis. There were no predisposing endocardial or pericardial defects in the patients with pancarditis. All 3 hearts were infected with aspergillar thromboemboli. Aspergillus occluded and invaded the myocardial vessels.

There were two patterns of lesions in pancarditis. The more destructive type was a transmural erosion through contiguous regions of endocardium, myocardium and pericardium. The second type was a diffuse embolic pancarditis; endocardial and pericardial lesions consisted of smaller but more widespread nodular fungal vegetations that were often contiguous with underlying myocardial abscesses.

Pericarditis (Fig. 5): Only 4 of the 51 patients had isolated pericarditis. Underlying conditions included pericardiectomy, leukemia, cytotoxic therapy, prolonged and multiple antibiotic therapy, corticosteroids and DiGeorge's syndrome. The severity ranged from the subclinical to an unremitting aspergillar pericarditis progressing through a friction rub, diffuse S-T segment elevation, pulsus paradoxus, hypotension and death. A 1 liter fibrinous and purulent pericardial effusion was

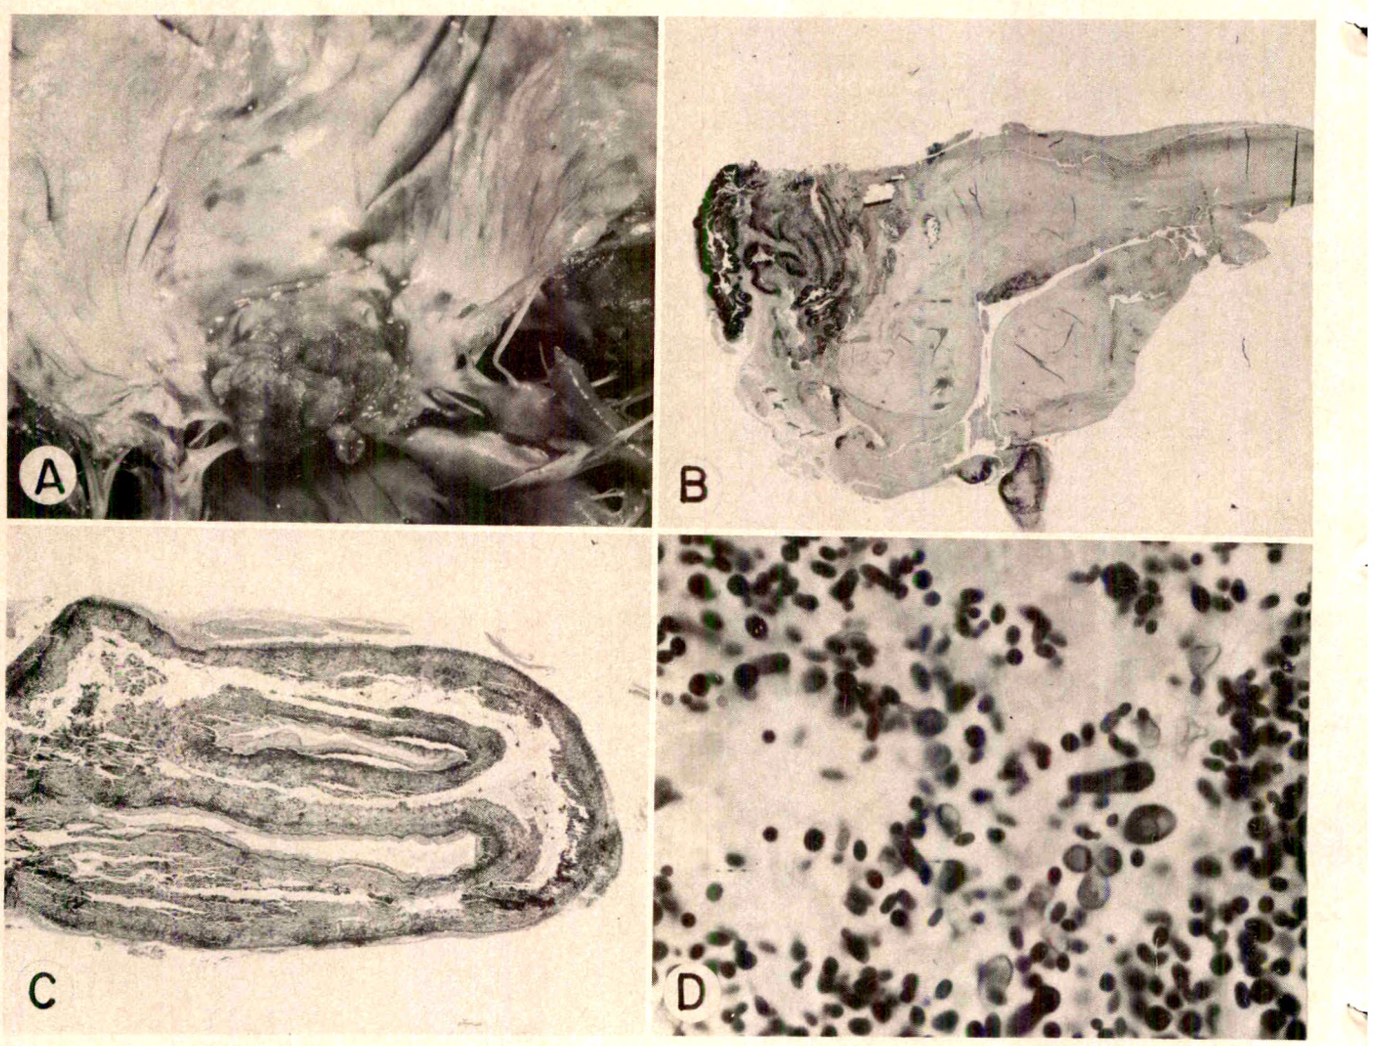

FIGURE 2. Candida endocarditis superimposed on rheumatic mitral stenosis and complicated by systemic embolization. **A**, a large verrucous lesion is present on the atrial aspect of the anterior mitral leaflet. **B**, the mitral leaflet is markedly thickened as a consequence of the rheumatic heart disease. The large mass of fungi stains darkly in the superimposed endocarditic lesion. **C**, embolus surgically removed from the internal iliac artery; the clot consists mainly of fungi and resembles the material still present on the mitral valve. **D**, candidal organisms present in the embolus. (Periodic acid-Schiff stain × 5 [**B**], ×10 [**C**] and ×500 [**D**].)

found at postmortem examination in one of the four patients.

Pathologic lesions ranged from insignificant visceral pericardial nodules to a purulent and fibrinous pericarditis.

Organisms: Candida was the most frequently observed organism in each of the three major clinicopathologic groups. When species were determined, at least 15 cardiac infections were due to Candida albicans and 2 to Candida tropicalis. Aspergillus was the second most frequent fungus to involve the heart. Aspergillus caused approximately 50 percent of all cases of endocarditis, whereas Candida caused 71 percent of cases of myocarditis. Cryptococcus caused myocarditis in 3 cases.

Diagnosis: Definitive premortem diagnosis of cardiac fungal infection was established in only one patient. A diagnosis of systemic mycosis leading to antifungal therapy was established in 22 percent. Positive blood cultures were documented in 42 percent. The earliest identification of Candida was established by blood culture in 10 patients (20 percent). Nine other patients (18 percent) had positive cultures of urine, peritoneal fluid, intravenous catheters, wounds, cerebrospinal fluid or emboli 1 to 3 weeks before cultures of blood were positive. Aspergillus was never cultured from blood during life, whereas Candida was cultured from 54 percent of patients with candidal cardiac infections.

Autopsy evidence revealed the following as apparent sources of infection (Table II): prosthetic valves, central venous catheters and mitral commissurotomy in patients with fungal endocarditis. Fungal pneumonitis, esophagitis, enterocolitis and urinary tract infections were apparent sources of infection in patients with myocarditis with or without pancarditis.

Treatment: Amphotericin B was administered to 11 patients (22 percent), two of whom also received 5-fluorocytosine. Impaired renal function prompted discontinuation of amphotericin B in 4 of the 11 patients. Only one patient underwent resection of an infected valve.

Causes of death: The nonfungal associated diseases of 15 patients (29 percent) immediately contributed to their death (Table III). These included bacterial sepsis, profuse gastrointestinal hemorrhage and acute renal failure with terminal arrhythmias. A total of 36 patients died with fungal infection as the principal factor contributing to their death; 8 of these died as the result of direct cardiac fungal involvement.

Discussion

Fungal infections of the heart, heretofore considered uncommon, have occurred with increasing frequency during the last two decades.[7–10] In our hospital the incidence has increased from 1 case per 1,000 autopsies in the period from 1954 to 1961 to 4 cases per 1,000 from 1962 through 1977. Endocarditis, myocarditis and pericarditis may result from involvement of the heart by fungus; they are virtually always associated with multiple therapeutic interventions. Fungal endocarditis was especially related to cardiac surgery and preexisting valvular heart disease. Fungal myocarditis was most

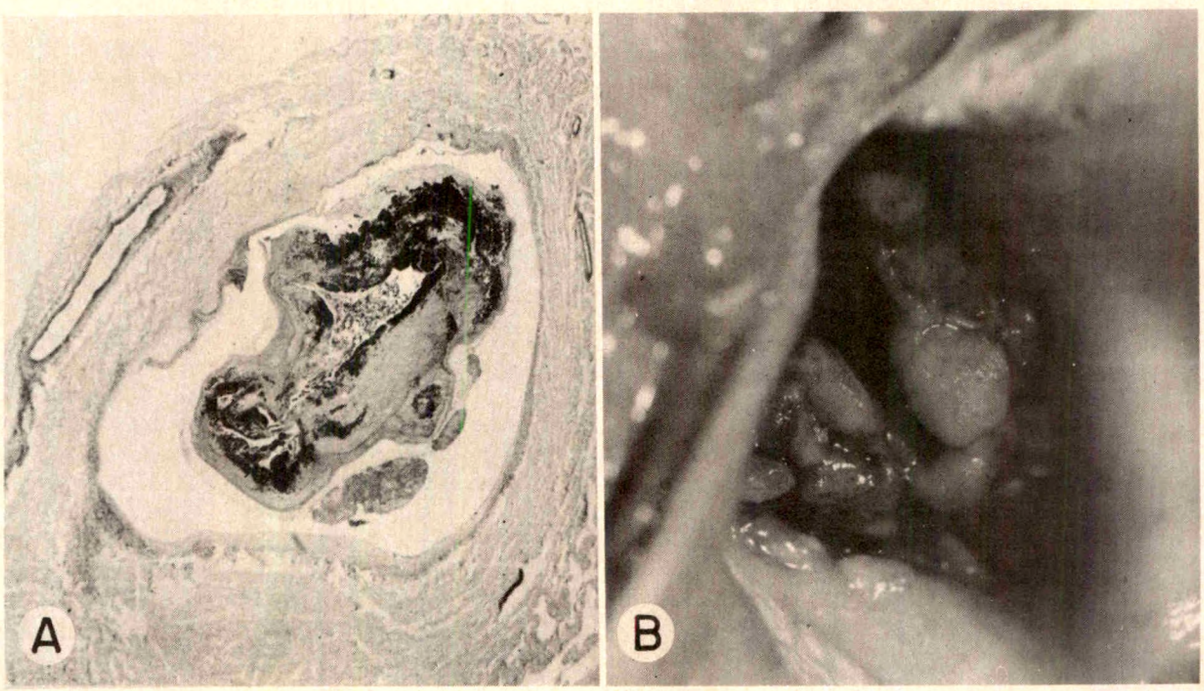

FIGURE 3. Fungal endocarditis. **A**, cross section of the right atrium near its junction with the superior vena cava containing a thrombus consisting largely of masses of dark-staining Candida. The central venous catheter, which had been in place during life, has been removed from the center of the thrombus (periodic acid-Schiff stain ×15). **B**, aspergillar endocarditis on a prosthetic aortic valve viewed from the aortic aspect. The valve had been in place for 3 weeks and death occurred from rupture of the aortotomy site, which was also infected by Aspergillus.

frequently associated with gastrointestinal surgery, prolonged multiple antibiotic therapy and corticosteroid therapy. Pancarditis developed as a progression of myocarditis to involve endocardium and pericardium. Pericarditis occurred infrequently and was related to pericardiotomy, immunosuppression therapy and treatment with multiple antibiotic drugs.

Endocarditis

Clinical manifestations: The classic manifestations of bacterial endocarditis often were not seen in fungal endocarditis. Fever, anemia and leukocytosis occurred in 50 percent of patients and a new murmur developed in less than 25 percent. Osler nodes, Roth spots or splinter hemorrhages were not described in our patients whereas an earlier study[7] reported their frequent appearance. Absence of these signs should not reduce suspicion of fungal infection in the patient at risk.

Embolic manifestations were important clinical features in one third of the patients with endocarditis: acute onset of a central neurologic deficit (hemiparesis, oculomotor palsy, for example), a fungus-laden macu-

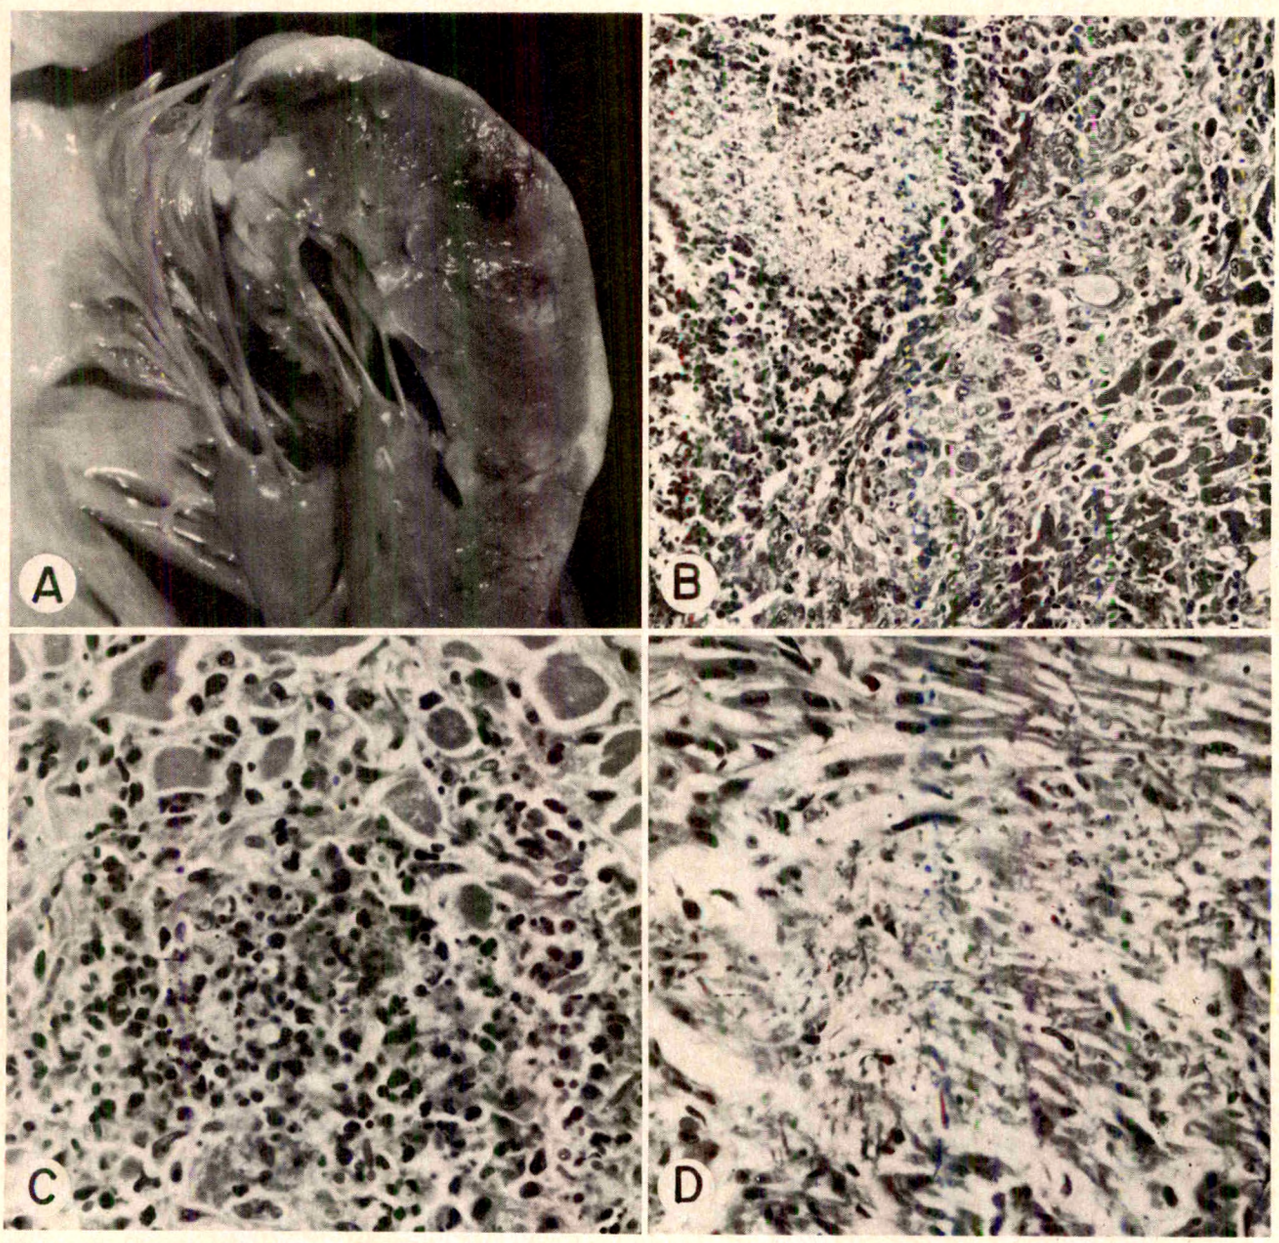

FIGURE 4. Fungal myocarditis. **A**, several large fungal abscesses are seen on the cut surface of the left ventricular myocardium. **B**, a purulent and granulomatous myocardial abscess which appears to have been present for at least 10 to 14 days. A clump of Candida is present at the upper left. **C**, a typical Candida microabscess with an admixture of organisms and acute inflammatory cells. **D**, focus of myocardial Candida infection in a patient with severe leukopenia. Spores and hyphae are growing in and destroying cardiac muscle cells. There is almost no inflammatory cell response. (Hematoxylin-eosin ×250 [**B**], ×500 [**C**] and ×125 [**D**].)

TABLE II

Apparent Sources of Infectious Organisms in 51 Patients

	Endocarditis	Myocarditis/ Pancarditis	Pericarditis	Total

lopapular rash in nonintertrigenous regions, abrupt major arterial occlusion and fungal endophthalmitis. Among four patients whose eyes were examined postmortem, three had fungal chorioretinitis that would have been ophthalmologically visible during life. The typical discrete retinal lesion described elsewhere[11,12] may be diagnosed early in the course of endocarditis before the onset of more catastrophic events.

Acute major arterial occlusion—a characteristic of fungal endocarditis[8,13]—may occur abruptly long after hospital discharge. One patient presented with mycotic femoral and mesenteric arterial emboli 3 months after

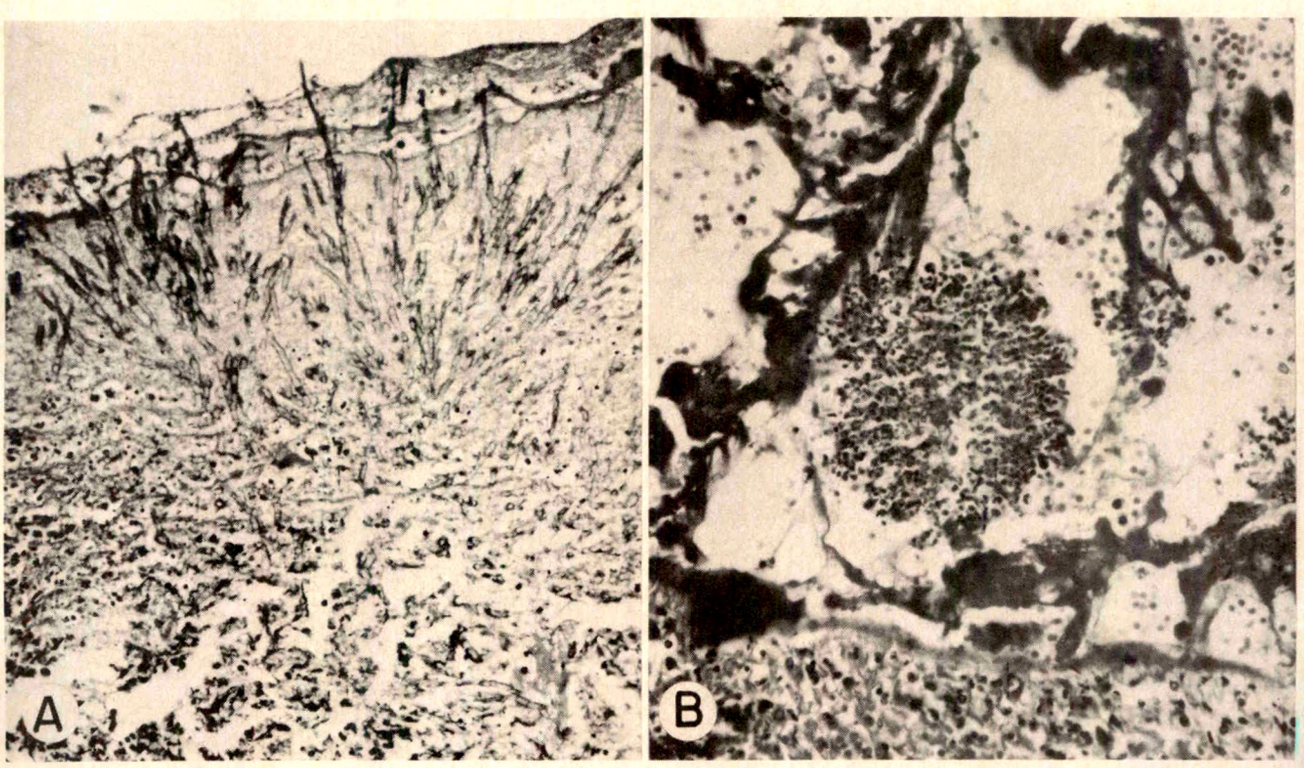

FIGURE 5. A, aspergillar pericarditis in a patient who had undergone immunosuppressive therapy. **B,** colonies of Candida albicans growing in a fibrinopurulent pericarditis. The infection developed after pericardiotomy in an infant with DiGeorge syndrome. (Hematoxylin-eosin ×250 [**A** and **B**].)

hospital discharge after prosthetic valve implantation. Fungal endocarditis occurred in settings ranging from one of positive fungal blood cultures, embolic phenomena, murmurs and intractable congestive cardiac failure to one of an indolent infection in which the patient succumbed to an undetected disseminated mycosis.

Fungal blood cultures in aspergillar endocarditis are virtually always negative regardless of extent of dissemination and size of vegetations.[14,15] Candida, however, is frequently cultured during a candidal endocarditis, although the diagnostic significance of candidemia has been disputed[16,17] as representing colonization and not invasive mycosis. A positive admission blood culture for Candida albicans in a woman with fever, rheumatic mitral disease, mitral commissurotomy and congestive heart failure was dismissed as a contaminant: Candidal vegetations compromising the mitral valve were discovered after death (Fig. 2). This patient and four similar patients who died with systemic candidiasis document the hazard of dismissing a positive fungal blood culture.

An important sign of candidal endocarditis is persistence of Candida in blood cultures after removal of a central venous catheter that has an infected tip. The source of persistent dissemination may be a Candida-laden thrombus adherent to the endocardium.[18] The data on hospital-acquired fungemia have recently been reviewed.[19]

Diagnosis: Diagnostic methods that identify fungal endocarditis earlier in the clinical course are necessary. In our series, cultures of urine, wounds, skin lesions and cerebrospinal fluid often grew Candida earlier than did blood cultures. Only one third of patients with endocarditis had positive blood cultures. Aspergillus was never cultured from blood.

Echocardiography may reveal an exophytic valve vegetation of fungal endocarditis, allowing for prompt medical and surgical therapy.[20,21] Vegetations on mitral and aortic valves in fungal endocarditis have been echocardiographically diagnosed and followed by early therapeutic initiatives.[20,22]

Serologic determinations of precipitin antibodies against the cytoplasmic constituents and cell wall of candidal organisms may facilitate early diagnosis of active infection.[23] Murray et al.,[24] in a prospective study, identified by serologic determinations six patients who had candidal endocarditis after cardiac surgery. Precipitin antibodies are most rapidly diagnosed by immunoelectrophoresis. Efficacy of antifungal therapy corresponds to declining titers. However, immunosuppressive therapy or a disease that severely compromises the immune response may prevent an appreciable precipitin antibody response.[25] Diagnosis of systemic candidiasis may be improved with crossed immunoelectrophoresis.[26]

Aspergillar versus candidal endocarditis: The large incidence of aspergillar endocarditis among our patients is an unusual finding in contrast with that in previous series of cases of fungal endocarditis.[8,27] Candida is most commonly responsible for fungal endocarditis in narcotic addicts,[10,28] who may constitute a large proportion of the patients studied. There were no narcotic addicts among our patients.

Fungal infections have been responsible for 13 to 20 percent of all opportunistic endocarditis following open cardiac surgery.[29] Whereas Candida is the most frequent cause of fungal endocarditis after open heart surgery,[23,30] Aspergillus and Candida were equally present in our patients with open heart surgery. Environmental factors play a role. Aerosolized aspergilli from contaminated operating room ventilating systems were identified as a source of postoperative aspergillar endocarditis in another study.[31] The higher proportion of aspergillar endocarditis is also ascribed to patients who had mural endocarditis.[32] These patients were severely debilitated or had received immunosuppressive therapy and were without predisposing endocardial lesions. Aspergillar pneumonia was a probable portal of entry.

Thus, there are two populations at risk for fungal endocarditis: those patients just described, who are debilitated but without an initial endocardial lesion, and those patients whose endocardium has been damaged. Patients with an altered immune defense and aspergillosis are at risk for endocarditis even without an antecedent lesion. Similar involvement of the endocardium has been described in cancer patients with cardiac candidiasis.[33,34]

Aspergillus was more invasive than Candida in our series. Aspergillus endocarditis involved contiguous myocardium more frequently than did candidal endocarditis. Aspergillus eroded through the aorta in a patient with an infected prosthetic aortic valve. It caused transmural erosion of the mitral valve ring and produced each of the three cases of pancarditis. The invasiveness and myocardial necrosis adjacent to mycelia may be due in part to the organism's elaboration of oxalic acid, which is toxic to tissue.[35]

Myocarditis

The importance of myocarditis has been emphasized only recently.[36,37] Among patients with disseminated candidiasis, the frequency of myocarditis may exceed 60 percent.[36,38] Franklin et al.[36] described new conduction disturbances, supraventricular arrhythmias and QRS changes in the electrocardiogram. These changes are not specific for fungal myocarditis.[39] Candidal myocarditis has caused complete heart block at the His bundle.[40] Myocarditis may progress to involve the endocardium or pericardium.

Several patients in our large series of myocarditis had extensive confluent abscesses even though myocarditis is said not to be diffuse[37] and of little clinical significance.[33] Two patients with widespread confluent candidal myocarditis had a relentless course of intractable congestive heart failure without other apparent cause. Myocarditis often occurs in the setting of fungal sepsis and may be very difficult to diagnose before death.[41]

The predisposing clinical setting in myocarditis of abdominal surgery, intensive antibiotic therapy and

corticosteroid therapy contrasts with that of thoracic surgery, valve disease and infected central venous catheters in endocarditis. Candida was the overwhelming cause of myocarditis, whereas Aspergillus was an important cause of endocarditis and serious complications. Myocarditis did not cause the embolic complications or new murmurs of endocarditis. Contiguous myocardial abscesses extended into the pericardial space as the principal mechanism for pericarditis in this series.

Pericarditis

The pericardial space was infected either by erosion of a contiguous myocardial abscess or by direct contamination during or after thoracotomy. The infrequency of fungal pericarditis within a series of cardiac mycoses has been observed.[33,36,41] Lesions ranged from small pericardial nodules to widespread purulent pericarditis. Postthoracotomy purulent pericarditis, whose cause is usually bacterial, has presented with increased frequency.[42] Severe fungal pericarditis may occur with no history of thoracic surgery (Table I). Aspergillar pericarditis resulted in fatal cardiac tamponade in a pancytopenic woman. Signs of pericarditis in the immune-compromised patient may be due to underlying cardiac fungal infection.

Treatment

Therapeutic results of cardiac fungal infection remain dismal. Patients undergoing treatment for fungal endocarditis have had a survival rate of less than 20 percent.[8] Early diagnosis is difficult but crucial to successful treatment. Delay or failure in establishing the diagnosis, embolization causing extracardiac foci of infection, invasion of myocardium,[32] poor penetration of amphotericin B into vegetations[43] and severity of underlying disease[37] contribute to the bleak prognosis. Early surgical intervention,[44–46] especially in patients with prosthetic valves,[47,48] and concomitant medical therapy[45,49] are advocated for fungal endocarditis. The toxicity and administration of amphotericin B have been well reviewed.[37,50,51] Synergism between amphotericin B and 5-fluorocytosine has been demonstrated; this combination is recommended in serious candidal infections.[37] Treatment of the underlying disease is imperative. A minimal follow-up period of 2 years in successfully treated patients is strongly encouraged.[52]

BRIEF SUMMARY

Kaon® Elixir (potassium gluconate) Grape or Lemon-Lime Flavors Sugar-Free

Description: Each 15 ml (tablespoonful) supplies 20 mEq of elemental potas (as potassium gluconate, 4.68 g) with saccharin and aromatics. Alcohol 5%.

Indications: Kaon Elixir is indicated for the treatment of potassium depletio patients with hypokalemia and for the treatment of digitalis intoxication. Kao Elixir is also indicated for the prevention of potassium depletion when the die intake of potassium is inadequate for this purpose. The prophylactic administra of potassium ion may be indicated in patients receiving digitalis and diuretics fo treatment of congestive heart failure; hepatic cirrhosis with ascites; patients with hypertension on long-term diuretic therapy; patients on corticosteroid therapy; hyperaldosteronism states with normal renal function; the nephrotic syndrome; and certain diarrheal states.

Contraindications: Potassium supplements are contraindicated in patients with hyp kalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Ch renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-spa diuretic (e.g. spironolactone, triamterene).

Warnings: Do not administer full strength. Kaon Elixir may cause gastrointestinal irritation if adn tered undiluted. For details regarding adequate dilution, see Dosage and Administration.

In patients with impaired mechanisms for excreting potassium, the administration of potassium salts produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g. spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

In hypokalemic states, especially in patients on a low-salt diet, hypochloremic alkalosis is a possibility that may require chloride as well as potassium supplementation. In these circumstances, potassium replacement with potassium chloride (e.g. Kaochlor 10% Liquid, W-T) may be more advantageous than with other potassium salts. However, Kaon can be supplemented with chloride. Ammonium chloride is an excellent source of chloride ion (18.7 mEq per gram) but it should not be used in patients with hepatic cirrhosis where ammonium salts are contraindicated.

Adverse Reactions: Nausea, vomiting, diarrhea, and abdominal discomfort have been reported. The symptoms and signs of potassium intoxication include paresthesias of the extremities, flaccid paralysis, listlessness, mental confusion, weakness and heaviness of the legs, fall in blood pressure, cardiac arrhythmias, and heart block.

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle paralysis and cardiovascular collapse from cardiac arrest.

How Supplied: Pints and gallons in Grape and Lemon-Lime flavors; 15 ml Stat-Pak® and 4 fl. oz. in Grape flavor only.

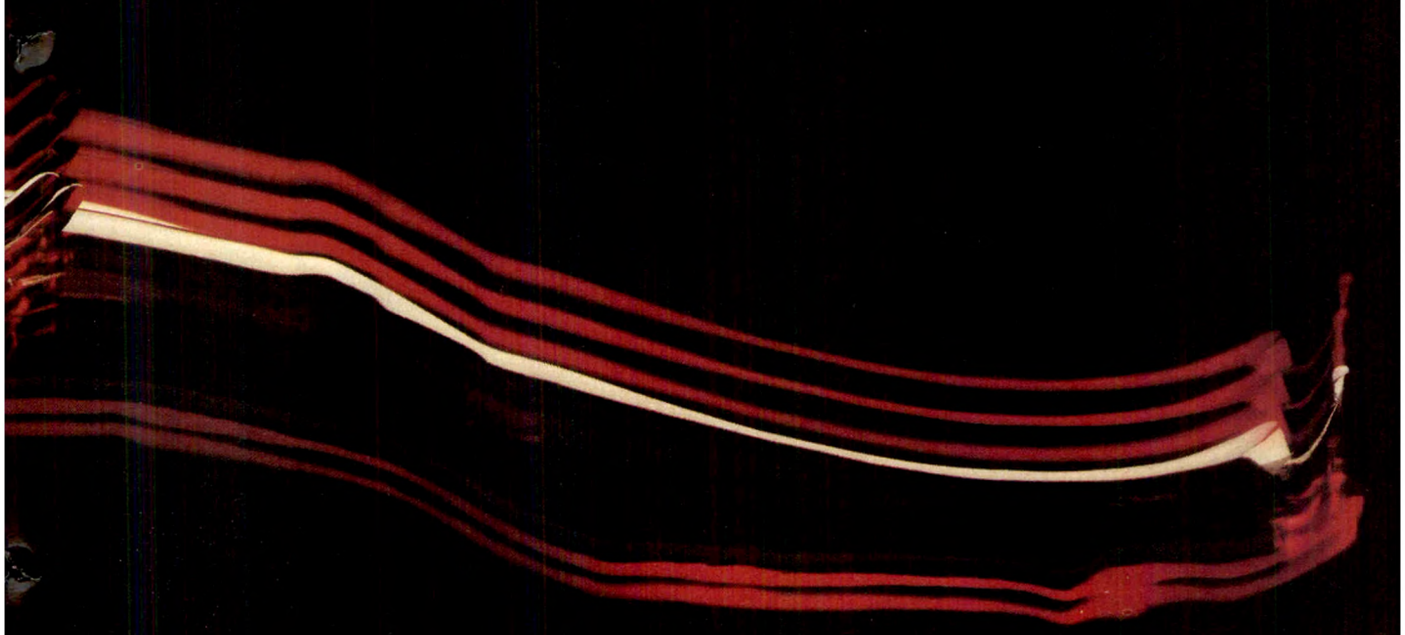
BRETYLOL®
(bretylium tosylate)

Unique antifibrillatory-antiarrhythmic effect
Unique mechanism of action
Unique safety: no cardiac depression



Bretylol® (bretylium tosylate), the unique new antifibrillatory-antiarrhythmic, provides lifesaving effects in the suppression of life-threatening ventricular arrhythmias unresponsive to lidocaine.

See last page of this advertisement for prescribing information.

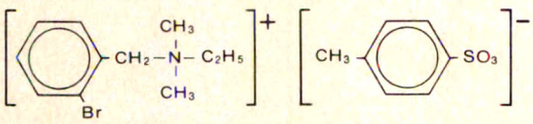
BRETYLOL® bretylium tosylate

BRETYLOL INJECTION

FOR INTRAMUSCULAR OR INTRAVENOUS USE

DESCRIPTION

BRETYLOL (bretylium tosylate) is o-Bromobenzyl ethyldimethylammonium p-toluene sulfonate. The chemical structure is:



$C_{18}H_{24}BrNO_3S$ Mol. Wt. 414.39

BRETYLOL is a white, crystalline powder with an extremely bitter taste. It is freely soluble in water and alcohol. Each ml of sterile, pyrogen-free solution contains 50 mg bretylium tosylate in Water for Injection, USP. The pH is adjusted, when necessary, with dilute hydrochloric acid or sodium hydroxide. BRETYLOL contains no preservative.

CLINICAL PHARMACOLOGY

BRETYLOL (bretylium tosylate) is a bromobenzyl quaternary ammonium compound which selectively accumulates in sympathetic ganglia and their postganglionic adrenergic neurons where it inhibits norepinephrine release by depressing adrenergic nerve terminal excitability.

BRETYLOL also suppresses ventricular fibrillation and ventricular arrhythmias. The mechanisms of the antifibrillatory and antiarrhythmic actions of BRETYLOL are not established. In efforts to define these mechanisms, the following electrophysiologic actions of BRETYLOL have been demonstrated in animal experiments:

1. Increase in ventricular fibrillation threshold.

2. Increase in action potential duration and effective refractory period without changes in heart rate.

3. Little effect on the rate of rise or amplitude of the cardiac action potential (Phase 0) or in resting membrane potential (Phase 4) in normal myocardium. However, when cell injury slows the rate of rise, decreases amplitude, and lowers resting membrane potential, BRETYLOL restores these parameters toward normal.

4. Increase in impulse formation and spontaneous firing rate of pacemaker tissue as well as increased ventricular induction velocity.

The restoration of injured myocardial cell electrophysiology toward normal, as well as the increase of the action potential duration and effective refractory period without changing their ratio to each other, may be important factors in suppressing re-entry of aberrant impulses and decreasing induced dispersion of local excitable states.

BRETYLOL induces a chemical sympathectomy-like state which resembles a surgical sympathectomy. Catecholamine stores are not depleted by BRETYLOL, but catecholamine effects on the myocardium and on peripheral vascular resistance are often seen shortly after administration because BRETYLOL causes an early release of norepinephrine from the adrenergic postganglionic nerve terminals. Subsequently, BRETYLOL blocks the release of norepinephrine in response to neuron stimulation. Peripheral adrenergic blockade regularly causes orthostatic hypotension but has less effect on supine blood pressure. The relationship of adrenergic blockade to the antifibrillatory and antiarrhythmic actions of BRETYLOL is not clear. In a study in patients with frequent ventricular premature beats, peak plasma concentration of BRETYLOL and peak hypotensive effects were seen within one hour of intramuscular administration, presumably reflecting adrenergic neuronal blockade. However, suppression of premature ventricular beats was not maximal until 6-9 hours after dosing, when mean plasma concentration had declined to less than one-half of peak level. This suggests a slower mechanism, other than neuronal blockade, was involved in suppression of the arrhythmia. On the other hand, antifibrillatory effects can be seen within minutes of an intravenous injection, suggesting that the effect on the myocardium may occur quite rapidly.

BRETYLOL has a positive inotropic effect on the myocardium, but it is not yet certain whether this effect is direct or is mediated by catecholamine release.

BRETYLOL is eliminated intact by the kidneys. No metabolites have been identified following administration of BRETYLOL in man and laboratory animals. In man, approximately 70 to 80% of a ^{14}C-labelled intramuscular dose is excreted in the urine during the first 24 hours, with an additional 10% excreted over the next three days.

In various studies of BRETYLOL excretion, estimates of the terminal half-life have varied from about 5 to about 10 hours, with an even wider range in individual subjects (4 to 17 hours). Whether this represents true intrapatient variability or limitations of methodology remains to be determined.

Effect on Heart Rate: There is sometimes an initial small increase in heart rate when BRETYLOL is administered, but this is an inconsistent and transient occurrence.

Hemodynamic Effects: Following intravenous administration of 5 mg/kg of BRETYLOL to patients with acute myocardial infarction, there was a mild increase in arterial pressure, followed by a modest decrease, remaining within normal limits throughout. Pulmonary artery pressures, pulmonary capillary wedge pressure, right atrial pressure, cardiac index, stroke volume index, and stroke work index were not significantly changed. These hemodynamic effects were not correlated with antiarrhythmic activity.

Onset of Action: Suppression of ventricular fibrillation is rapid, usually occurring within minutes following intravenous administration. Suppression of ventricular tachycardia and other ventricular arrhythmias develops more slowly, usually 20 minutes to 2 hours after parenteral administration.

INDICATIONS

BRETYLOL is indicated in the treatment of life-threatening ventricular arrhythmias, principally ventricular fibrillation and ventricular tachycardia, that have failed to respond to adequate doses of a first-line antiarrhythmic agent, such as lidocaine or procainamide. At this time, BRETYLOL should not be considered a first-line antiarrhythmic agent.

Use of BRETYLOL should be limited to intensive care units, coronary care units or other facilities where equipment and personnel for constant monitoring of cardiac arrhythmias and blood pressure are available.

Following injection of BRETYLOL there may be a delay of 20 minutes to 2 hours in the onset of antiarrhythmic action, although it appears to act within minutes in ventricular fibrillation. The delay in effect appears to be longer after intramuscular than after intravenous injection.

CONTRAINDICATIONS

There are no contraindications to use in treatment of ventricular fibrillation or life-threatening refractory ventricular arrhythmias.

WARNINGS

1. Hypotension: Administration of BRETYLOL regularly results in postural hypotension, subjectively recognized by dizziness, light-headedness, vertigo or faintness. Some degree of hypotension is present in about 50% of patients while they are supine. Hypotension may occur at doses lower than those needed to suppress arrhythmias.

Patients should be kept in the supine position until tolerance to the hypotensive effect of BRETYLOL develops. Tolerance occurs unpredictably but may be present after several days.

Hypotension with supine systolic pressure greater than 75 mm Hg need not be treated unless there are associated symptoms. If supine systolic pressure falls below 75 mm Hg, an infusion of dopamine or norepinephrine may be used to raise blood pressure. When catecholamines are administered, a dilute solution should be employed and blood pressure monitored closely because the pressor effects of the catecholamines are enhanced by BRETYLOL. Volume expansion with blood or plasma and correction of dehydration should be carried out where appropriate.

2. Transient Hypertension and Increased Frequency of Arrhythmias: Due to the initial release of norepinephrine from adrenergic postganglionic nerve terminals by BRETYLOL, transient hypertension or increased frequency of premature ventricular contractions and other arrhythmias may occur in some patients.

3. Caution During Use with Digitalis Glycosides: The initial release of norepinephrine caused by BRETYLOL may aggravate digitalis toxicity. When a life-threatening cardiac arrhythmia occurs in a digitalized patient, BRETYLOL should be used only if the etiology of the arrhythmia does not appear to be digitalis toxicity and other antiarrhythmic drugs are not effective. Simultaneous initiation of therapy with digitalis glycosides and BRETYLOL should be avoided.

4. Patients with Fixed Cardiac Output: In patients with fixed cardiac output (i.e., severe aortic stenosis or severe pulmonary hypertension) BRETYLOL should be avoided since severe hypotension may result from a fall in peripheral resistance without a compensatory increase in cardiac output. If survival is threatened by the arrhythmia, BRETYLOL may be used but vasoconstrictive catecholamines should be given promptly if severe hypotension occurs.

USE IN PREGNANCY

The safety of BRETYLOL in human pregnancy has not been established. However, as the drug is intended for use only in life-threatening situations, it may be used in pregnant women when its benefits outweigh the potential risk to the fetus.

USE IN CHILDREN

The safety and efficacy of this drug in children has not been established. BRETYLOL has been administered to a limited number of pediatric patients, but such use has been inadequate to define fully proper dosage and limitations for use.

PRECAUTIONS

1. Dilution for Intravenous Use: BRETYLOL should be diluted (one part BRETYLOL with four parts of Dextrose Injection, USP or Sodium Chloride Injection, USP) prior to intravenous use. Rapid intravenous administration may cause severe nausea and vomiting. Therefore, the diluted solution should be infused over a period greater than 8 minutes. In treating existing ventricular fibrillation BRETYLOL should be given as rapidly as possible and may be given without dilution.

2. Use Various Sites for Intramuscular Injection: When injected intramuscularly, not more than 5 ml should be given in a site, and injection sites should be varied since repeated intramuscular injection into the same site may cause atrophy and necrosis of muscle tissue, fibrosis, vascular degeneration and inflammatory changes.

3. Reduce Dosage in Impaired Renal Function: Since BRETYLOL is excreted principally via the kidney, dosage should be reduced in patients with impaired renal function.

ADVERSE REACTIONS

Hypotension and postural hypotension have been the most frequently reported adverse reactions (see Warnings section). Nausea and vomiting occurred in about three percent of patients, primarily when BRETYLOL was administered rapidly by the intravenous route (see Precautions section). Vertigo, dizziness, light-headedness and syncope, which sometimes accompanied postural hypotension, were reported in about 7 patients in 1000.

Bradycardia, increased frequency of premature ventricular contractions, transitory hypertension, initial increase in arrhythmias (see Warnings section), precipitation of anginal attacks, and sensation of substernal pressure have also been reported in a small number of patients, i.e., approximately 1-2 patients in 1000.

Renal dysfunction, diarrhea, abdominal pain, hiccups, erythematous macular rash, flushing, hyperthermia, confusion, paranoid psychosis, emotional lability, lethargy, generalized tenderness, anxiety, shortness of breath, diaphoresis, nasal stuffiness and mild conjunctivitis, have been reported in about 1 patient in 1000. The relationship of BRETYLOL administration to these reactions has not been clearly established.

DOSAGE AND ADMINISTRATION

BRETYLOL is to be used clinically only for treatment of life-threatening ventricular arrhythmias under constant electrocardiographic monitoring. Since there is a delay in onset of its antiarrhythmic action, BRETYLOL is not to be considered or used as a replacement for rapidly-acting antiarrhythmic agents currently in use. The clinical use of BRETYLOL is for short-term use only. Patients should either be kept supine during the course of BRETYLOL therapy or be closely observed for postural hypotension. The optimal dose schedule for parenteral administration of BRETYLOL has not been determined. There is comparatively little experience with dosages greater than 30 mg/kg/day, although such doses have been used without apparent adverse effects. The following schedule is suggested:

A. For Immediately Life-threatening Ventricular Arrhythmia, as in Ventricular Fibrillation: Administer undiluted BRETYLOL at a dosage of 5 mg/kg of body weight by rapid intravenous injection. Other usual cardiopulmonary resuscitative procedures, including electrical cardioversion, should be employed prior to and following the injection in accordance with good medical practice. If ventricular fibrillation persists, the dosage may be increased to 10 mg/kg and repeated at 15 to 30 minute intervals until a total dose of not more than 30 mg/kg of body weight has been given. For maintenance dosage, see below.

B. Other Ventricular Arrhythmias:

1. Intravenous Use: *BRETYLOL must be diluted as follows before intravenous administration:* Using aseptic technique, dilute contents of one BRETYLOL ampul (10 ml containing 500 mg bretylium tosylate) to a minimum of 50 ml with Dextrose Injection, USP or Sodium Chloride Injection, USP.

Administer the diluted solution at a dosage of 5 to 10 mg BRETYLOL per kg of body weight by intravenous infusion over a period greater than 8 minutes. More rapid infusion may cause nausea and vomiting. A second dose may be given in 1 to 2 hours if the arrhythmia persists.

2. For Intramuscular Injection: *(Do not dilute BRETYLOL prior to intramuscular injection.)* Inject 5 to 10 mg BRETYLOL per kg of body weight. Dosage may be repeated in 1 to 2 hours if the arrhythmia persists. Thereafter maintain with same dosage every 6 to 8 hours.

Intramuscular injection should not be made directly into or near a major nerve, and the site of injection should be varied on repeated injection.

C. Maintenance Dosage: The diluted BRETYLOL solution may be administered by intermittent bolus infusion or by constant infusion.

1. Intermittent Infusion: Infuse the diluted solution at a dosage of 5 to 10 mg BRETYLOL per kg body weight, over a period greater than 8 minutes, every 6 hours. More rapid infusion may cause nausea and vomiting.

2. Constant Infusion: Infuse the diluted solution at a dosage of 1 to 2 mg BRETYLOL per minute.

Dosage of BRETYLOL should be reduced and discontinued in 3 to 5 days under electrocardiographic monitoring. Other appropriate antiarrhythmic agents should be substituted, if indicated.

HOW SUPPLIED

NDC 0094-0012-10: 10 ml ampul containing 500 mg bretylium tosylate in Water for Injection, USP. pH adjusted, when necessary, with dilute hydrochloric acid or sodium hydroxide. Sterile, pyrogen-free.

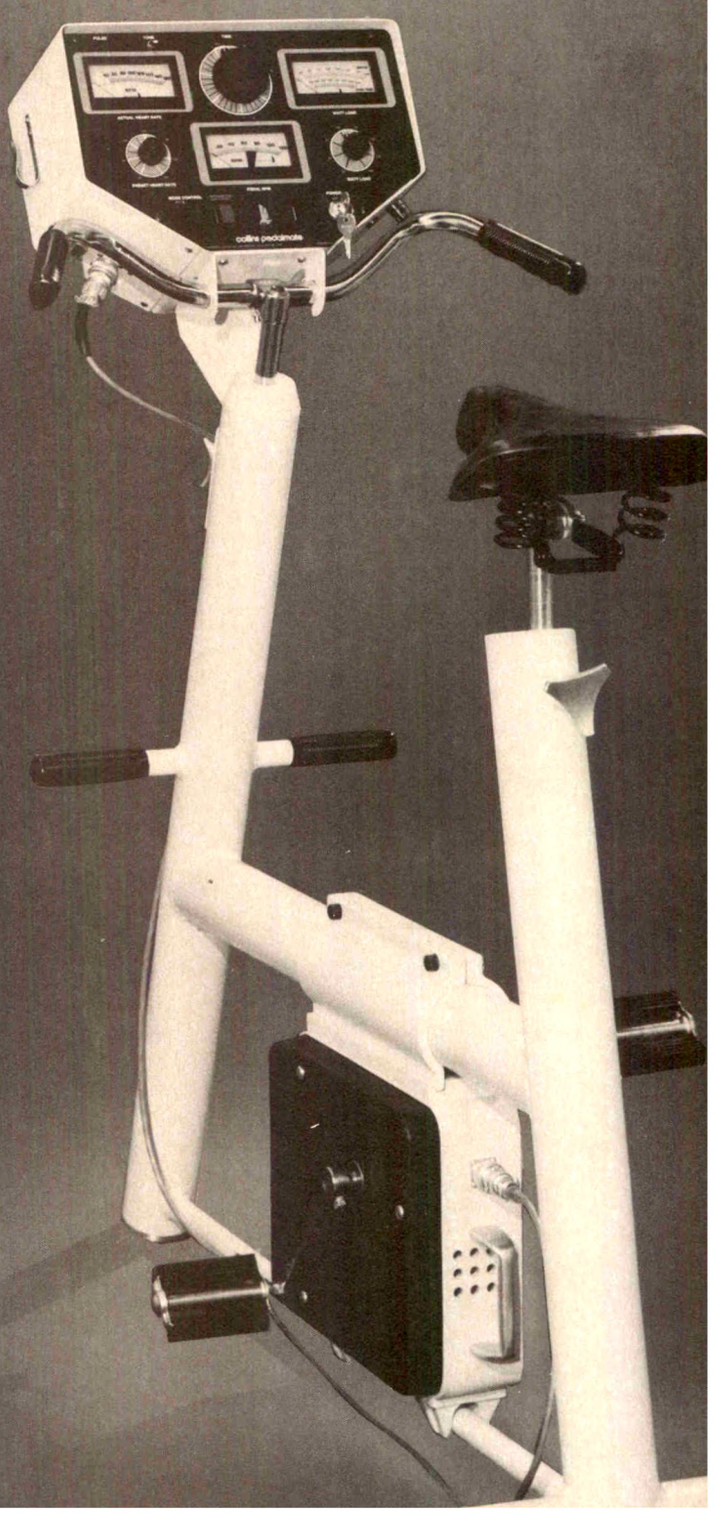
PERFORMING *STRESS* TESTS?

CONTROL THEM WITH *COLLINS*



Stress testing requires accurate control and monitoring of cardiac output. That means utilizing an exercise device which will maintain the subject's heart rate at a constant BPM by varying the work load. That means Pedalmate!

The Pedalmate is an ergometer which offers two modes of operation. In the 'Heart Rate Control Mode,' the work load is automatically varied by means of a feedback control signal which is proportional to the difference between the subject's actual heart rate and a preset, selectable heart rate. The subject's actual heart rate is detected by a blood pressure wave transducer which attaches comfortably to the earlobe. The fine adjustment in work load makes it possible to exercise the subject at a preset heart rate level for a preselected time.

When in the 'Manual Mode,' the Pedalmate presents the subject a constant load (manually variable) which remains constant independent of pedal rate.

SPECIFICATIONS

Heart Rate Control Accuracy:	±5 BPM
Heart Rate Accuracy:	±2% of reading
Watt Load Accuracy:	±5% of reading
Pedal Rate Accuracy:	±2% of reading (0-120 rpm)
Heart Rate Range:	40 to 180 BPM
Watt Load Range:	25 to 200 watts (150 to 1200 KPM/min.)
Pedal rpm Range:	0-120 rpm (30-120 rpm constant work)
Timer Range:	0 to 30 minutes
Lamp Indicators:	AC Power Lamp, Heart Beat LED, Heart Control Program Run Lamp
Meters:	Heart Rate (BPM), Pedal Rate (rpm), Work Load (watts)
Other Controls:	Mode Select Switch, Preset Heart Rate Dial, Manual Watt Load Control, Key Power Switch
Output Signals:	Heart Rate CAL Factor = 1 BPM/50 mv. Watt Load CAL Factor = 1 watt/50 mv.

Dobutrex®
Dobutamine HCl

For I.V. Injection
250 mg* in 20-ml-size vials
* Equivalent to dobutamine

Brief Summary
Consult the package literature for prescribing information.

Indications and Usage: Dobutrex® (dobutamine hydrochloride, Lilly) is indicated when parenteral therapy is necessary for inotropic support in the short-term treatment of adults with cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures.

In patients who have atrial fibrillation with rapid ventricular response, a digitalis preparation should be used prior to instituting therapy with Dobutrex.

Contraindication: Dobutrex is contraindicated in patients with idiopathic hypertrophic subaortic stenosis.

Warnings: 1. *Increase in Heart Rate or Blood Pressure*—Dobutrex may cause a marked increase in heart rate or blood pressure, especially systolic pressure. Approximately 10 percent of patients in clinical studies have had rate increases of 30 beats/minute or more, and about 7.5 percent have had a 50-mm Hg or greater increase in systolic pressure. Reduction of dosage usually reverses these effects promptly. Because dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of developing rapid ventricular response. Patients with preexisting hypertension appear to face an increased risk of developing an exaggerated pressor response.

2. *Ectopic Activity*—Dobutrex may precipitate or exacerbate ventricular ectopic activity, but it rarely has caused ventricular tachycardia.

Precautions: 1. **During the administration of Dobutrex, as with any adrenergic agent, ECG and blood pressure should be continuously monitored. In addition, pulmonary wedge pressure and cardiac output should be monitored whenever possible to aid in the safe and effective infusion of Dobutrex.**

2. Hypovolemia should be corrected with suitable volume expanders before treatment with Dobutrex is instituted.

3. Animal studies indicate that Dobutrex may be ineffective if the patient has recently received a beta-blocking drug. In such a case, the peripheral vascular resistance may increase.

4. No improvement may be observed in the presence of marked mechanical obstruction, such as severe valvular aortic stenosis.

Usage Following Acute Myocardial Infarction—Clinical experience with Dobutrex following myocardial infarction has been insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

Usage in Pregnancy—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

Pediatric Use—The safety and effectiveness of Dobutrex® (dobutamine hydrochloride, Lilly) for use in children have not been studied.

Drug Interactions—There was no evidence of drug interactions in clinical studies in which Dobutrex was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

Adverse Reactions: *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10 to 20-mm increase in systolic blood pressure and an increase in heart rate of five to 15 beats per minute have been noted in most patients. (See Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5 percent of patients have had increased premature ventricular beats during infusions. These effects are dose related.

Miscellaneous Uncommon Effects—The following adverse effects have been reported in 1 to 3 percent of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex have been observed.

Longer-Term Safety—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

Overdosage: In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex until the patient's condition stabilizes. Because the duration of action of Dobutrex is short, usually no additional remedial measures are necessary.

Administration and Dosage: *Reconstitution and Stability*—Dobutrex® (dobutamine hydrochloride, Lilly) is incompatible with alkaline solutions and should not be mixed with products such as 5% Sodium Bicarbonate Injection.

Dobutrex may be reconstituted with Sterile Water for Injection or 5% Dextrose Injection. To reconstitute, add 10 ml of diluent to Vial No. 7051, Dobutrex, 250 mg. If the material is not completely dissolved, add an additional 10 ml of diluent. The reconstituted solution may be stored under refrigeration for 48 hours or at room temperature for six hours.

Reconstituted Dobutrex must be further diluted to at least 50 ml prior to administration in 5% Dextrose Injection, 0.9% Sodium Chloride Injection, or Sodium Lactate Injection. Intravenous solutions should be used within 24 hours.

Solutions containing Dobutrex may exhibit a color that, if present, will increase with time. This color change is due to slight oxidation of the drug, but there is no significant loss of potency during the reconstituted time periods stated above.

Recommended Dosage—The rate of infusion needed to increase cardiac output usually ranges from 2.5 to 10 mcg/kg/min (see table). On rare occasions, infusion rates up to 40 mcg/kg/min have been required to obtain the desired effect.

Rates of Infusion for Concentrations of 250, 500, and 1000 mcg/ml

†500 mg per liter or 250 mg per 500 ml of diluent
‡1000 mg per liter or 250 mg per 250 ml of diluent

The rate of administration and the duration of therapy should be adjusted according to the patient's response, as determined by heart rate, presence of ectopic activity, blood pressure, urine flow, and, whenever possible, measurement of central venous or pulmonary wedge pressure and cardiac output.

Concentrations up to 5000 mcg/ml have been administered to humans (250 mg/50 ml). The final volume administered should be determined by the fluid requirements of the patient.

INTRODUCING STATUS 1000

WITH AN IMAGINATION TO MATCH YOUR OWN

Status 1000, The ECG Monitor That Gives You Programmable Control Over Every Aspect Of The Stress Test.

Quinton's Status 1000 is the first ECG stress test system that lets you use your imagination to modify or reprogram at will the various elements of a stress test.

Not just treadmill protocol, but lead selection, ST sample point, recorder speed, patient name, final report content and length, blood pressure prompting, etc. Everything is in your control like it should be.

Use your professional imagination to create and program customized test procedures for pediatric, research, post-M.I., rehab., or out-patient situations.

Each physician in your institution can have their own preferred test procedure stored in memory.

With the Status 1000 you and your colleagues can customize test procedures based on the requirements of the patient, not the restrictions of the ECG system.

How The Sophisticated Status 1000 Makes Test Flexibility So Complete And Easy

With The Status 1000, Quinton introduces a new term, the "Stress Test Environment". It consists of 16 test elements. Each element, such as exercise lead set, or final report content, has parameters which you can establish or modify to suit your needs.

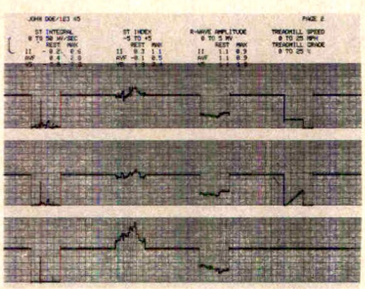
Yet, programming the Status 1000 is as easy as operating a pocket calculator so special training is not required.

Comprehensive Data, Professionally Presented

In a single glance you see three channels of diagnostic quality ECG, averaged beats (both resting and current), heartrate, computed parameters, trend displays, stage number, stage time and elapsed time.

Plus, any abnormal beat will be instantly highlighted on the screen, then recorded and labeled automatically.

Your control extends to test reports, too. Printouts during the test may include averaged beats, rhythm strips, or full 12-leads. Final reports may include a wide variety of information. And each report is automatically labeled with pertinent data. Good bye work sheet.



Stay Ahead With The Status 1000

Because of the Status 1000's unparalleled flexibility and microprocessor technology its susceptibility to obsolescence is far less than other systems. And that makes it a good investment for you and your institution. Call Quinton toll free at 1-800-426-0538.

Quinton

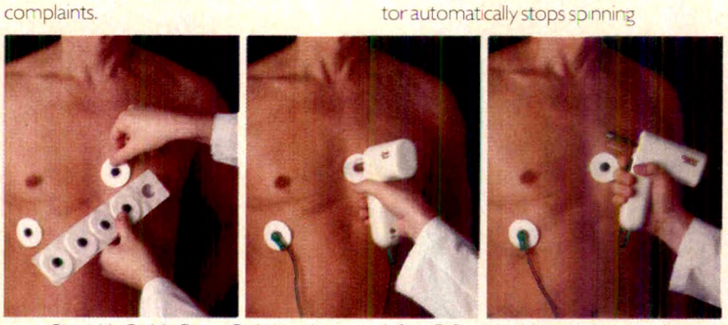
FINALLY, A STABLE ECG BASE-LINE WITHOUT PATIENT PAIN

With The Quick-Prep™ Method, A Three-Second Prep Per Electrode Provides Both High Quality Tracings And Happy Patients

Inconsistent skin preparation is the leading cause of wandering ECG baselines and patient complaints.

Under-abrade and you fail to reach the necessary impedance level for a high quality tracing (no matter how sophisticated your ECG monitor).

Over-abrade and you tend to cause skin trauma and patient complaints.



But with Quick-Prep, Quinton gives you a fool-proof method of skin preparation that makes everyone happy.

Quick-Prep Consistently Delivers High Quality ECG Tracings

The Quik-Prep method includes a silver/silver chloride electrode with a patented rotating center section spun precisely by the rechargeable applicator to gently abrade the skin. No gritty creams, sandpaper or burs.

As the photo series (below) illustrates, the Quik-Prep method is fast, convenient and consistent.

After the first electrode (Right Leg) has been positioned and prepped with the applicator a reference wire is used to connect the electrode to the applicator while prepping other sites. The applicator automatically stops spinning (after .5-3 seconds) each electrode's center section when the correct impedance level has been achieved.

The incidence of over- and under-abrasion is greatly reduced. And that means consistently high quality tracings without patient suffering. Test after test.

Quik-Prep Reduces Prep Time For Greater Schedulin Flexibility.

How many minutes of each stre test appointment do you devote to p 15, 20, 25?

Quik-Prep can cut that time dra matically. For instance, after cleaning a shaving, ten sites can be prepped in ur two minutes.

Think what this time savings can mean to you. More time for patient c sultation. More tests per day. Greater scheduling flexibility.

Seeing is Believing. Call Toll Free For A Quik-Prep Demonstration.

Call The Stress Test People at C ton, 1-800-426-0538 for more infor or to schedule a demonstration of Quik-Prep.

Antiarrhythmia Bulletin No. 1

Recent Literature Implicates Quinidine in Raising Serum Digoxin Levels

Evidence that serum digoxin concentrations are increased by concomitant treatment with quinidine has been reported by several investigators. Excerpts are presented here.

"After digoxin radioimmunoassay became available...we noticed that serum digoxin concentrations rose, often markedly, when quinidine was administered to stable patients receiving digoxin. Our retrospective study...investigates this important interaction between quinidine and digoxin and demonstrates that quinidine administration causes an increase in plasma digoxin concentration. In addition, our findings suggest that some of the toxicity previously attributed to quinidine may actually represent quinidine-induced digitalis toxicity."

—From Reiffel, J. A., and others: A Previously Unrecognized Drug Interaction Between Quinidine and Digoxin, Clin. Cardiol. *2*:40–42, 1979.

"The present study has shown a consistent change in the disposition of digoxin in the presence of quinidine, suggesting that this interaction may be extremely common....Digoxin toxicity appears to be enhanced in the presence of quinidine, and therefore a decrease in digoxin dosage is suggested when the drugs are given concurrently. Frequent assessment of the plasma concentration of digoxin and careful attention to the clinical symptoms of toxicity are suggested when the two drugs are given in combination."

—From Hager, W. D., and others: Digoxin-Quinidine Interaction: Pharmacokinetic Evaluation, N. Engl. J. Med. *300*:1238–1241, 1979.

"All 12 patients showed a rise in plasma digoxin concentrations when quinidine was given (mean value 1.1 nmol/l (0.85 ng/ml) before quinidine, and 2.0 nmol/l (1.6 ng/ml) after quinidine). Five determinations of plasma digoxin were made in each patient after the start of quinidine treatment. One of the six patients whose plasma concentrations rose above the therapeutic range on one or more occasions developed symptoms of digitalis intoxication."

—From Ejvinsson, G.: Effect of Quinidine on Plasma Concentrations of Digoxin, Br. Med. J. *1*:279–280, 1978.

"It is of interest that the most dangerous cardiac side effect of quinidine, syncope, has occurred primarily in patients treated with both quinidine and digoxin. In retrospect it appears likely that their serum digoxin levels were elevated....

"The extent of the serum digoxin elevation depends on the dosage of quinidine. In our studies ...the usual therapeutic dose (1000 mg per day) led to a 2.5-fold increase in the digoxin concentration within four to six days."

—From Doering, W.: Quinidine-Digoxin Interaction: Pharmacokinetics, Underlying Mechanism and Clinical Implications, N. Engl. J. Med. *301*:400–404, 1979.

"...Leahey et al....showed intensification of typical digitalis effects in the ECG when quinidine was given. In one patient the serum digoxin concentration increased from 2.2 to 4.1 ng per milliliter during quinidine treatment, the ventricular rate in atrial fibrillation decreased markedly, and ventricular premature contractions appeared. In a second patient the doses of quinidine and digoxin were altered such that the serum digoxin concentration fluctuated over a wide range; the PR interval rose and fell in parallel with the changes in serum digoxin concentration. In a third patient, non-paroxysmal atrioventricular junctional tachycardia developed as the serum digoxin concentration increased during quinidine therapy....Thus, there is some evidence that adverse gastrointestinal and cardiac effects of digoxin occur when the serum digoxin concentration increases as a result of simultaneous quinidine treatment....

"Do other antiarrhythmic drugs cause a similar increase in serum digoxin concentration? Doering examined the serum digoxin concentration before and after administration of several antiarrhythmic drugs, including two drugs that are currently used in the United States, lidocaine (three cases) and disopyramide (four cases). None of the drugs caused an increase in serum digoxin concentration."

—From Bigger, J. T., Jr.: The Quinidine-Digoxin Interaction: What Do We Know About It?, N. Engl. J. Med. *301*:779–781, 1979.

From what has appeared in the literature concerning the elevation of digoxin levels with concomitant quinidine use and reported lack of elevation of digoxin levels with concomitant Norpace use,[1,2] it would appear that Norpace should be a logical alternative to quinidine.

Please see the next page for a brief summary of prescribing information.

Norpace®
(disopyramide phosphate)
a logical therapeutic choice

Before prescribing Norpace (disopyramide phosphate), please consult current complete prescribing information, a summary of which follows:

Indications: *Norpace is indicated for suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion).*

Norpace is equally effective in treating the above arrhythmias in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Oral Norpace has not been adequately studied in patients with acute myocardial infarction or in patients with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established.

Contraindications: *Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug.*

Warnings: Severe hypotension has been observed primarily in patients with primary cardiomyopathy or inadequately compensated congestive heart failure. If hypotension develops Norpace should be discontinued promptly unless hypotension is due to the arrhythmia.

Norpace should not be used in the presence of poorly compensated or uncompensated congestive heart failure unless it is exacerbated by or caused by an arrhythmia and proper treatment including optimal digitalization has been accomplished. *In patients with marginally compensated heart failure or with a history of heart failure, Norpace may worsen cardiac decompensation. In these patients, progressing congestive heart failure should generally be treated with cardiac glycosides and diuretics and the course of treatment closely followed. Norpace dosage should be reduced or discontinued if adequate control of congestive failure is not attained. Patients receiving concomitant therapy with more than one antiarrhythmic drug must be carefully monitored for serious negative inotropic effects or excessively prolonged conduction, evidenced by widening of the QRS complex and/or prolongation of the Q-T interval.*

If first-degree heart block develops, the dosage of Norpace should be reduced. If the block persists, continuation of Norpace must depend upon an assessment of the benefit versus the risk. Development of second- or third-degree AV block or uni-, bi- or trifascicular block requires discontinuation of Norpace, unless the ventricular rate is adequately controlled by a pacemaker.

Because of its anticholinergic properties, Norpace should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken.

Precautions: *If significant widening (greater than 25%) of the QRS complex occurs, Norpace should be discontinued. If Q-T prolongation greater than 25% occurs and if ectopy continues, monitor closely and consider discontinuing Norpace.*

Patients with atrial flutter or fibrillation should be digitalized prior to Norpace administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits.

The effect of Norpace is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block.

Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of Norpace.

Norpace should be administered cautiously to patients who are receiving or who have recently received other antiarrhythmic drugs. Excessive widening of the QRS complex and/or prolongation of the Q-T interval may occur in such instances.

Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage.

Antiarrhythmic drugs may be ineffective in patients with hypokalemia. Therefore, any potassium deficit should be corrected before instituting Norpace therapy.

Use in Pregnancy and Lactation: *Safe use in pregnancy has not been established. Norpace has been reported to stimulate contractions of the pregnant uterus. The use of Norpace in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus.*

It is not known whether disopyramide is excreted in human milk. However, studies in rats have shown that the concentration of disopyramide and its metabolites is up to three times greater in milk than in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted.

Labor and Delivery: *The effects of Norpace on the fetus during delivery or on the course of labor and delivery are unknown.*

Pediatrics: *The safety and effectiveness of Norpace in children have not been established.*

Adverse Reactions: Anticholinergic: *dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention.* Genitourinary: *urinary frequency and urgency.* Gastrointestinal: *nausea, pain/bloating/gas, anorexia, diarrhea, vomiting.* General: *nervousness, dizziness, general fatigue/muscle weakness, headache, malaise.* Cardiovascular: *hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain.* Dermatologic: *generalized rash/dermatoses. The following have occurred, but a causal relationship is uncertain: impotence, depression, insomnia, dysuria, and hypoglycemia (usually in patients with impaired liver function). Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported.*

Dosage and Administration: *Dosage must be individualized for each patient on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg per day given in divided doses four times daily. The recommended dosage schedule for most adults is 150 mg every six hours. For patients weighing less than 110 pounds (50 kg) the recommended dosage is 100 mg every six hours.*

If rapid control of arrhythmia is essential, an initial loading dose of 300 mg of Norpace (200 mg for patients weighing less than 110 pounds) is recommended. For patients with cardiomyopathy or possible cardiac decompensation, a loading dose should not be given and the initial dose limited to 100 mg every six hours, with subsequent dosage adjustments made gradually under close monitoring.

See current complete prescribing information for dosage recommendations.

How Supplied: *Capsules containing 100 mg or 150 mg of disopyramide base. Available in bottles of 100, 500, and 1,000 capsules, and cartons of 100 unit-dose individually blister-sealed capsules.*

John Hunter, Angina Pectoris and Medical Education

PAUL KLIGFIELD, MD

New York, New York

The cardiac death of John Hunter, the 18th century surgeon and anatomist, occurred during a period of emerging understanding of the relation between angina pectoris and coronary artery disease. Although this association was first recognized by Edward Jenner, Hunter's pupil, consideration for his friend and teacher kept Jenner's insight unpublished during Hunter's lifetime. A fascinating controversy on medical education surrounded Hunter during his final year and probably contributed to his death.

Certain episodes in medical history bear retelling because of the significance of their scientific contribution. Others are important for their insight into personalities and events. The death of John Hunter, the eminent 18th century surgeon and anatomist, during a tense board meeting at St. George's Hospital, London, is a fascinating episode in which both historic aspects are intertwined. It provides important insight into the development of our understanding of angina pectoris and into medical education and affairs of the late 18th century.

The Anatomist

John Hunter (Fig. 1) was born at Long Calderwood in Lanarkshire, Scotland in 1728. His early education suffered after the death of his father. Manually skilled, at the age of 17 he became a carpenter's apprentice but soon traveled to London to assist his older brother William, who was just establishing what was to become a prominent theater for anatomic demonstration. Displaying great skill in dissection, the younger Hunter qualified in surgery at St. George's Hospital and in 1759 entered the army as a staff surgeon.[1–3]

Practice, particularly for a Scot in England during this period, was slow after Hunter's return to London in 1762. Largely because of his skill in anatomic demonstration, he was elected Fellow of the Royal Society in 1767. One year later he was appointed surgeon to St. George's, where his growing practice competed with a parallel interest in natural history and the development of a museum of rare anatomic specimens.

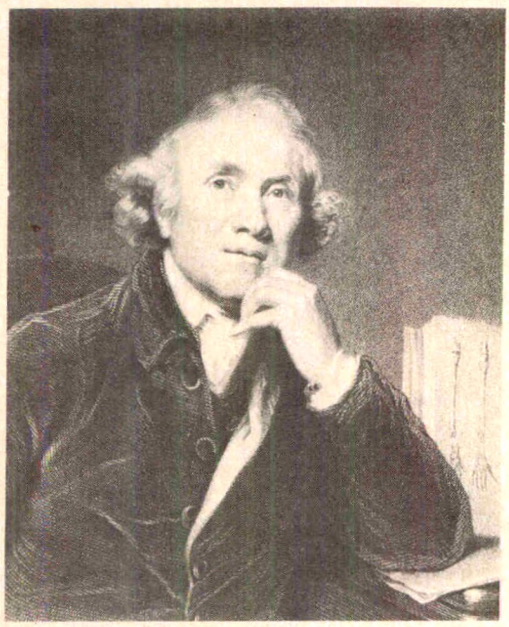
Among his earliest students was Edward Jenner, who became best known as the discoverer of vaccination but was also the originator of the coronary artery theory of angina pectoris. During 1770 and 1771, Jenner was a boarder in Hunter's Jermyn Street home. The two maintained a lifelong correspondence regarding various aspects of natural history but, as we shall see, angina pectoris was never mentioned.

The Disease

The year of Hunter's appointment to St. George's, William Heberden read "some account of a disorder of the breast" before the College of Physicians in London. This report of 20 cases of angina, published in 1772 in the second volume of the Medical Transactions,[4] was purely descriptive and offered no speculation regarding etiology.

From the Division of Cardiology, Department of Medicine, The New York Hospital-Cornell Medical Center, New York, New York. Manuscript received August 20, 1979, accepted October 3, 1979.

Address for reprints: Paul Kligfield, MD, Division of Cardiology, Department of Medicine, the New York Hospital-Cornell Medical Center, 525 East 68 Street, New York, New York 10021.



John Hunter, after a portrait by Sir Joshua Reynolds.

Shortly after its publication, Heberden received a letter from a physician suffering from the disease, offering his body for examination following death. This examination of "Dr. Anonymous" was performed by John Hunter, assisted by Jenner, and both the letter to Heberden and the autopsy findings were published in the third volume of the Medical Transactions.[5] It appears that the coronary arteries in this early attempt at clinical-pathologic correlation were not examined.

Within several years, Hunter himself began to experience paroxysms of chest pain and palpitation consistent with angina pectoris. These attacks were not only exertional, but emotional in precipitation. As Kobler[3] observed:

> Wrath, to which John was so prone, exposed him to the direst attacks. A tardy coachman, an inattentive secretary, would throw him into volcanic rages. He realized his danger, yet was powerless to control his temper. "My life," he said, "is at the mercy of any rogue who chooses to provoke me."

During this period Edward Jenner, now a successful practitioner in Gloucestershire, was accumulating further autopsy experience with angina. About 1785 he wrote to Caleb Hillier Parry of Bath,[6] describing the extraordinary examination of a patient who had died of this disease:

> My knife struck something so hard and gritty as to notch it. I well remember looking up at the ceiling, which was old and crumbling, conceiving that some plaster had fallen down. But on further scrutiny the real cause appeared; the coronaries were become bony canals.

Further clarification is seen in Jenner's 1786 letter to Heberden, in which he stated his belief that coronary artery disease is the basis for angina pectoris.

Why then did Jenner not publish his findings, and why is no mention of the subject found among his voluminous correspondence with Hunter? The disease was clearly of great interest to both men. As Jenner noted to Heberden[7]:

> When you are acquainted with my motives, I presume you will pardon the liberty I take in addressing you. I am prompted to it from a knowledge of the mutual regard that subsists between you and my worthy friend Mr. Hunter. When I had the pleasure of seeing him at Bath last Autumn, I thought he was affected with many symptoms of the Angina Pectoris.

Concern for his former teacher appears to have prompted his silence:

> As I frequently write to Mr H I have been some time in hesitation respecting the propriety of communicating the matter to him. . . . I am fearful (if Mr H should admit this to be the cause of the disease) that it may deprive him of the hopes of a recovery.

As Jenner reported to Parry[6]: ". . . this circumstance prevented any publication of my ideas on the subject, as it must have brought on an unpleasant conference between Mr. Hunter and me."

The Controversy

In 1793, suffering from effort-related and anxiety-induced angina, Hunter became embroiled in a bitter controversy with some of the other surgeons at St. George's. Although a considerable part of the disagreement involved financial arrangements, the insight it provides into medical affairs and education of the period is fascinating. In an open letter explaining his viewpoint,[1] Hunter complained of the general neglect paid to students:

> I paid more attention to the pupils than had been usual, or was then the practice of the other surgeons. The pupils of course looked up to me, and to me they resorted on all occasions, they all wished to be dressers under me and at last complained to me and even threatened to recommend their young acquaintances to other hospitals if more general attention was not paid to them. . . .

Apparently, the students had been unsuccessful in achieving recognition of their grievances:

> The pupils have even made complaints in writing to the Weekly Board against the Surgeons for their neglect, but their complaints being only signed 'Pupils' were thought unworthy of any notice. . . .

Hunter tried to encourage the other surgeons to expand their formal courses of instruction, but with little success:

> When I mentioned what the medical gentlemen of other hospitals did, and what I thought we should do, one gentleman said: "He did not choose to lose any reputation he might have in surgery by giving lectures," which at least was modest. . . .

Academic argument was likewise fruitless:

> Talking of the improvement of the art one of the surgeons confessed "he did not see where the art could be improved;" the natural conclusion from this declaration was that such a man would never improve it. . . .

Financial consideration was not foreign to the controversy. As Hunter explained:

The senior surgeons found an advantage in allowing the junior to share equally with them; and this union has been the means of keeping some from doing their duty; because by any labours they could only get one fourth of the whole profit; and by doing nothing they still got a fourth. . . .

Hunter's attempted solution to the academic quarrel was likewise not devoid of financial consideration:

Finding all my efforts ineffectual to bring the gentlemen to their real duty, I conceived that as the increase of the pupils became very considerable and the greater number entered with me the only method left was to keep the money I received by the pupils as my own property.

The Conclusion

We arrive at the synthesis of these events. The St. George's controversy was clearly capable of raising Hunter's ire and, as he had predicted, this was a source of personal danger. Several months later, he again went before the Board with a related quarrel. As tempers soared, Hunter left the room, and collapsed and died shortly afterward, presumably of acute myocardial infarction. It was 25 years after Heberden's descriptive presentation of angina, and 20 years after Hunter's autopsy of "Dr. Anonymous." Edward Jenner, Hunter's most illustrious student and friend, had been aware of the prognosis for about 10 years.

John Hunter's concern for his students, in contrast to the attitude of other surgeons of the time, thus promoted a conflict that may well have resulted in his death. The complaints of the 18th century pupils that partially precipitated this conflict serve as a reminder of the supervision and attention required by students. Although the giving of lectures has achieved current respectability, Hunter's criticism of earlier faculty performance is still worthy of review.

It is of similar note that Edward Jenner's concern for his former teacher was so great that he left unpublished his emerging understanding of the pathophysiology underlying angina pectoris. One wonders whether current academic progress would allow similar restraint.

Shortly after Hunter's death, Everard Home reported the autopsy findings to Jenner[8]:

It is singular that the circumstance you mentioned to me, and was always afraid to touch upon with Mr. Hunter, should have been a particular part of his own complaints, as the coronary arteries of the heart were considerably ossified.

Two Dimensional Echocardiographic Visualization of Ventricular Septal Rupture After Acute Anterior Myocardial Infarction

JEAN C. FARCOT, MD
LOUIS BOISANTE, MD
MICHEL RIGAUD, MD
JEAN BARDET, MD, FACC
JEAN P. BOURDARIAS, MD, FACC

Boulogne, France

In three consecutive cases of ventricular septal rupture after acute anterior myocardial infarction, wide angle two dimensional echocardiography readily visualized the septal defect, permitting the defect to be localized and its size estimated. In addition, negative contrast echoventriculography identified a left to right shunt at the ventricular level. The echocardiographic findings were corroborated by cardiac catheterization data in all patients, by perioperative examination in two and by postmortem findings in one patient. Postoperative echocardiographic studies afforded demonstration of the patch closing the defect.

In patients with acute myocardial infarction associated with the sudden appearance of a systolic murmur, two dimensional echocardiography should be performed promptly in order to guide the diagnosis and management of these critically ill patients. In some patients with severe cardiogenic shock, in whom a favorable prognosis depends on rapid treatment, two dimensional echocardiography may allow the patient to be taken to surgery immediately without further study.

Although rupture of the interventricular septum occurs relatively infrequently, it is a very severe complication of acute myocardial infarction: Twenty-four percent of patients die within 24 hours and 65 percent within 2 weeks after septal perforation.[1] Clinically, the differential diagnosis from mitral valve regurgitation secondary to muscle rupture or dysfunction is frequently difficult or even impossible without the aid of cardiac catheterization.[2] Current reports emphasize the desirability of early operation in these patients whose condition is hemodynamically unstable.[3,4] However, symptoms and signs of left-sided heart failure may be absent during the period immediately after rupture.[5,6] Indeed, once the circulatory deterioration has begun, its course is usually unremitting and can be only, and at best transiently, reversed with intraaortic balloon pumping.[7,8] It is therefore of utmost importance to identify the septal perforation as rapidly as possible.

Echocardiography is a noninvasive bedside technique that can be carried out promptly in the coronary care unit. The apical left ventricular approach of two dimensional echocardiography has overcome the limitations of M mode echocardiography in assessing the total interventricular septum. Furthermore, the peripheral injection of a small bolus dose of fluid is useful in outlining the right cardiac cavities.[9–13] Recently, Weyman et al.[14] suggested that negative contrast echocardiography could detect left to right shunting.

We report herein the two dimensional echocardiographic findings in three consecutive cases of ventricular defects occurring after acute myocardial infarction. The septal rupture was subsequently confirmed at operation in two patients and on postmortem examination in the third patient.

From the Ambroise-Paré Hospital, Department of Cardiology, Boulogne, France. Manuscript received August 13, 1979; revised manuscript received September 25, 1979; accepted September 26, 1979.

Address for reprints: Jean P. Bourdarias, MD, Department of Cardiology, Ambroise-Paré Hospital, 9 Avenue Charles de Gaulle, 92100 Boulogne, France.

Methods

Echocardiography: Two dimensional echocardiographic examination was performed at the bedside using a Varian (V 3000) phased array 82° ultrasonic sector scanner. The examination was performed using a modified apical approach[15,16] with the patient in the left lateral position. The ultrasonic window was in the vicinity of the cardiac impulse but slightly inferior and lateral to it. This approach made it possible to find the longest longitudinal left ventricular axis (joining the apex to the mid aortic cusps) and to isolate the anterior and inferior walls. With continuous recording, while the patient was asked to hold his breath, rotation of the transducer 90° around the same axis afforded demonstration of the septal and lateral walls. Correct setting of the reject control and adjustment of coarse gain were necessary to visualize the endocardium optimally. The azimuthal resolution has been tested in our laboratory using animal and human specimens of the aorta, mitral valve and left ventricular myocardium immersed in optically different media (water, mineral oil) at different depths. The azimuthal resolution ranged from 2 to 5 mm and was closely dependent on receiver gain settings for any transmitted power level.

Contrast echoventriculography: This procedure was performed according to the following method: A continuous isotonic glucose infusion line was connected to a three-way stopcock. After closure of the infusion line, a 10 ml sample of the patient's blood was withdrawn and promptly reinjected into the patient's infusion line. Special care was taken to connect the syringe perpendicularly to the patient's line and to open the stopcock partially. In our experience the microcavitation contrast method proved to be more satisfactory than use of any other agent (saline solution, Cardiogreen®, dextran). With this technique optimal visualization of the right heart chambers was obtained in fewer than four trials.

The tapes were analyzed and Polaroid® still frames were selected sequentially from end-systole (maximal inward motion) to end-diastole (R wave of the electrocardiogram) during the same cardiac cycle. The films were obtained by photographing a stop-action frame on the video tape screen. Because only one field of a two field video frame is displayed in each photograph, the quality of the stop frame image is considerably lower than that of the dynamic display. Negative contrast echocardiography was considered present when there was an obvious washout of the contrast material in front of the defect with the onset of end-diastole (complete opacification of the right ventricular cavity), and this washout increased in size in subsequent frames up to end-systole and disappeared during the succeeding diastole.

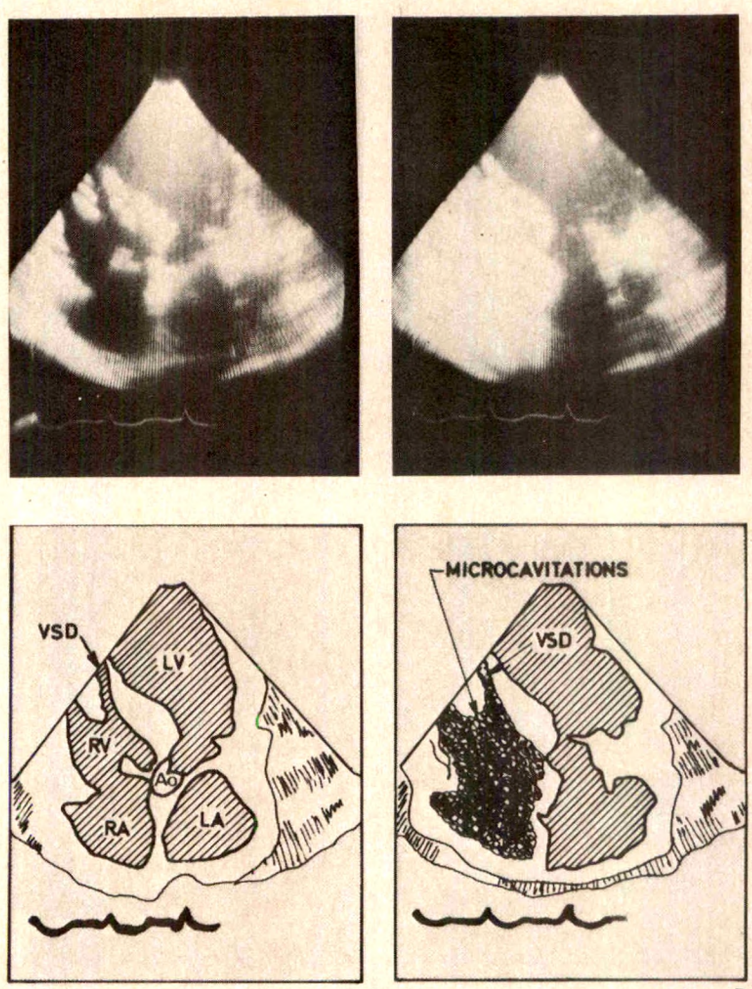

FIGURE 1. Case 1. Two dimensional echocardiograms obtained with Polaroid films (**upper panel**) and corresponding schematic diagrams (**lower panel**) of a four chamber view. **Left,** an obvious defect is seen across the ventricular septum (VSD); note the abnormal curvature of the upper septum, which is convex toward the left ventricular outflow tract, just beneath the aortic root (Ao). **Right,** microcavitations opacify both right heart chambers. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

Case Reports

Case 1

This 78 year old woman was admitted to a community hospital with an acute anterior myocardial infarction. Five days later, a grade 3/6 pansystolic murmur was noted at the lower left sternal border, radiating to the left axilla and the right sternal border. Within a few hours cardiogenic shock developed and the patient was referred to our coronary care unit for further investigation and eventual intraaortic balloon support. Catheterization of the right side of the heart with use of a Swan-Ganz catheter and two dimensional echocardiography were carried out. A left to right shunt at the ventricular level and a pulmonary to systemic flow ratio of 3.4:1 were demonstrated. During the ensuing 12 hours cardiogenic shock could not be reversed despite intensive pharmacologic support (dopamine and nitroprusside), and the patient died.

Echocardiographic findings: Paradoxic systolic expansion involving the lower septum, the apex as well as the lower portion of the lateral wall was evident; the upper portion of the septum protruded into the left ventricular outflow tract. The posterolateral wall had a normal contractile pattern. The right ventricle appeared to have satisfactory contractile function.

A tunnel-like echo-free image was visualized in the septum. The defect appeared to start from the left apical side, going obliquely up to the right ventricular endocardium, facing the septal papillary muscle of the tricuspid valve. The size of the tunnel was three times larger in systole (Fig. 1A) than in diastole (Fig. 1B). In contrast, during diastole, the channel narrowed progressively so that at end-diastole almost complete anatomic reconstruction of the higher septum was achieved by coaptation of the walls of the tunnel. At this time of the cycle, high density echoes were noted close to the defect.

Negative contrast ventriculography demonstrated a left to right shunt through the previously identified tear. Figure 1B shows total opacification of the right ventricle during

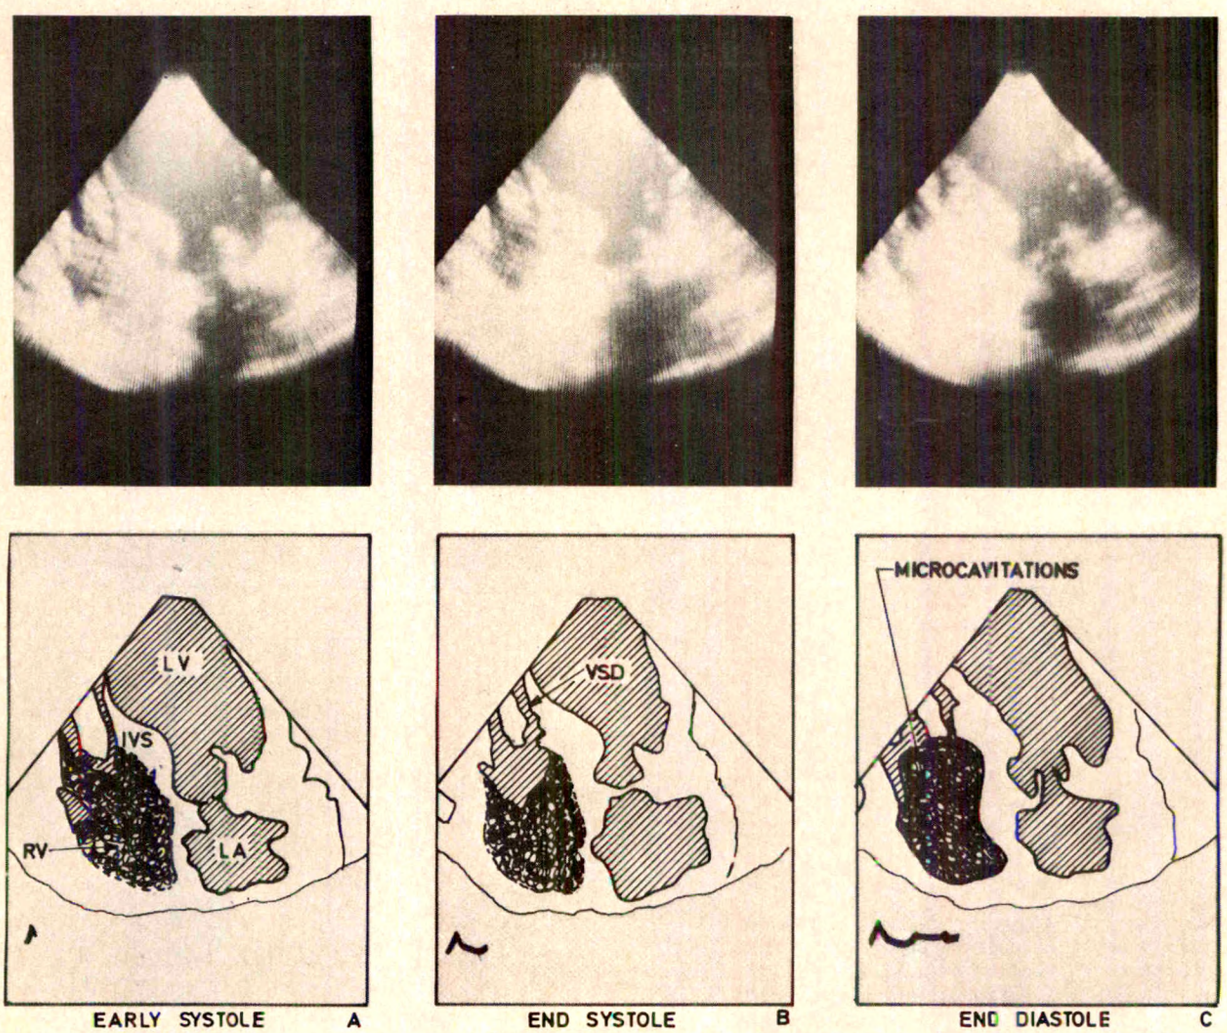

FIGURE 2. Case 1. Sequential echoventriculograms with still frames (**top**) and schematic representation (**bottom**). During early systole (**A**) most of the right ventricular cavity (RV) is opacified by microcavitations but the septal defect is still visible. Later during the same cardiac cycle, at end-systole (**B**), the channel-like defect is larger in diameter and the negative contrast due to left to right shunting is maximal. During the subsequent diastole, as indicated by the patient's electrocardiogram, microcavitations again fill the entire cavity. Abbreviations as in Figure 1.

diastole. From early to late systole, progressive washout of the contrast medium was observed (Fig. 2A to 2B).

Postmortem examination revealed a large recent anterior myocardial infarction associated with complete proximal occlusion of the left anterior descending coronary artery. In addition, a septal defect caused by an oblique dilaceration of the septum extended from the apex to the base of the medial papillary muscle of the tricuspid valve.

Case 2

Four months before admission this 56 year old woman had an anteroseptal myocardial infarction. She refused hospitalization but remained under the care of her personal cardiologist. During the first 3 weeks, the course was uneventful. In February 1979, she complained of increasing dyspnea, and physical examination revealed a loud 4/6 apical holosystolic murmur associated with a thrill. Congestive heart failure and mild hypotension developed, and she was transferred to our hospital. She refused to undergo invasive study but finally agreed to a noninvasive examination. After two dimensional echocardiography identified a mid apical septal rupture, she was persuaded to undergo cardiac catheterization. A left to right shunt was demonstrated at the ventricular level, with a pulmonary to systemic flow ratio of 3:1. Coronary angiography revealed complete and proximal occlusion of the left anterior descending artery and an anterior wall aneurysm. No significant mitral regurgitation was noted. The patient was operated on and 1 week after successful closure of the defect, she was doing well. No systolic murmur was heard postoperatively and echocardiography was again performed.

Echocardiographic findings: As in the preceding case, an echocardiographic window located near the maximal cardiac impulse was used. In the four chamber view (Fig. 3A), a defect in the form of a tunnel-like echo-free image was easily visualized in the lower portion of the septum. The defect increased in diameter during systole and narrowed during diastole. It appeared to extend from the left ventricular apex up to the point of coaptation of the free edges of the tricuspid valve leaflets (Fig. 3A). The superior portion of the septal contour was abnormally convex toward the left ventricular outflow tract and was thicker than normal below the aortic valve. The higher lateral wall still had a normally contracting pattern. No lesion of the mitral valve apparatus was noticeable. Rotation of the transducer 90° around the same longitudinal apex-aortic root axis provided an anteroinferior view, but this view was of no help in visualizing the defect. The left ventricle was enlarged and the anteroapical wall was akinetic.

After contrast microcavitation, frame by frame analysis revealed that after complete right ventricular opacification

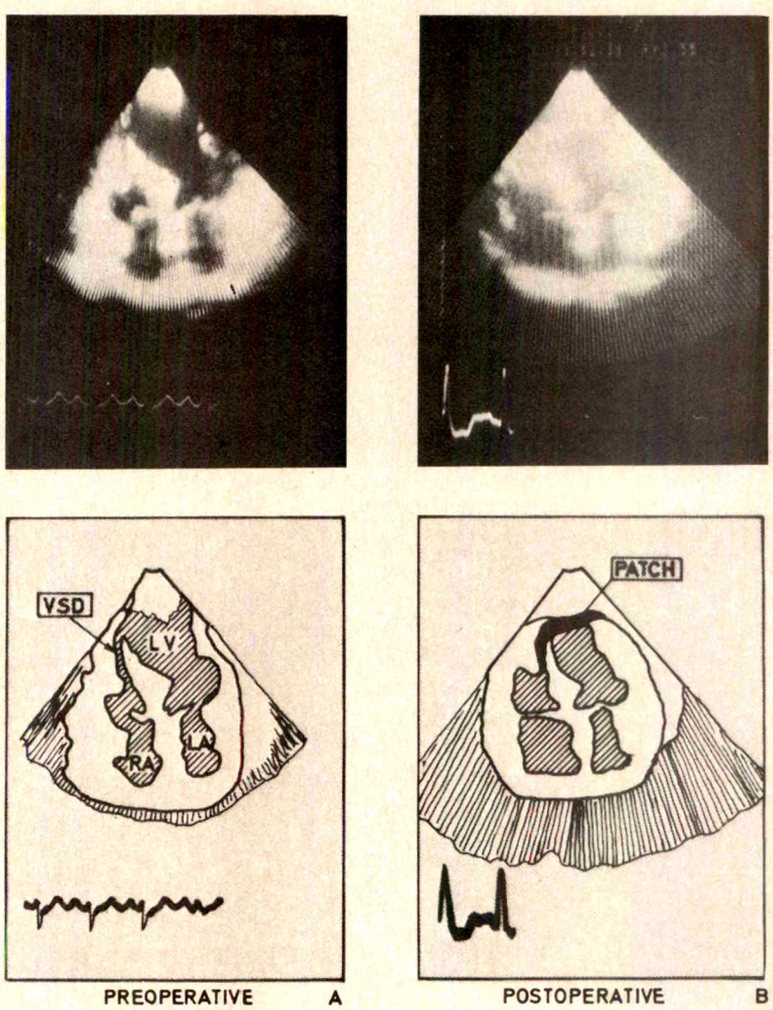

FIGURE 3. Case 2. Pre- and postoperative echocardiograms (four chamber view). Note the bright echoes arising from the velvet patch (**right**) closing the ventricular septal defect (**left**). As in Case 1, the upper interventricular septum protrudes into the left ventricular outflow tract. Abbreviations as in Figure 1.

in diastole (Fig. 4), progressive washout from early to late systole occurred in front of the defect. During the succeeding diastole, microcavitations again outlined the right endocardial contour, close to the defect and without crossing to the left side. The postoperative echocardiogram revealed the patch (Fig. 3B).

Case 3

A 58 year old man had an acute myocardial infarction and was admitted to another hospital. On the 4th day, a grade 4/6 holosystolic murmur associated with a thrill was heard mid way between the left sternal border and the cardiac apex. After 2 days of refractory pulmonary edema, oliguria and hypotension, the patient was transferred to our hospital. On admission he had severe cardiogenic shock. Two dimensional echocardiography performed at the bedside visualized a large septal perforation. Swan-Ganz cardiac catheterization confirmed the septal rupture. A left to right shunt at the ventricular level and a pulmonary to systemic flow ratio of 3:1 were demonstrated. Because the patient's condition had further deteriorated, he was immediately taken to surgery without additional investigation. Surgical closure of the defect was successful and the postoperative course was remarkably event-free. No residual systolic murmur was heard. Two weeks after operation, the patient was restudied with two dimensional echocardiography.

Echocardiographic findings: Good visualization of the cardiac structures was obtained. The four chamber view (that is, septolateral) revealed in the lower interventricular septum a large defect, 3 cm in length (Fig. 5A). When the transducer was rotated 90°, the defect was still visualized.

Right-sided contrast echoventriculography was performed. Total opacification by contrast microcavitation could be obtained and the same phenomenon of negative contrast resulting from a left to right shunt was noted. Unusual bright echoes surrounding the defect and abnormal thickening of the upper septum were also noted.

Perioperative examination revealed a large (3 by 2 cm) septal defect located in the lower third of the anterior portion of the septum. Postoperative echocardiograms 2 weeks later clearly revealed the velvet patch used to close the defect (Fig. 5B).

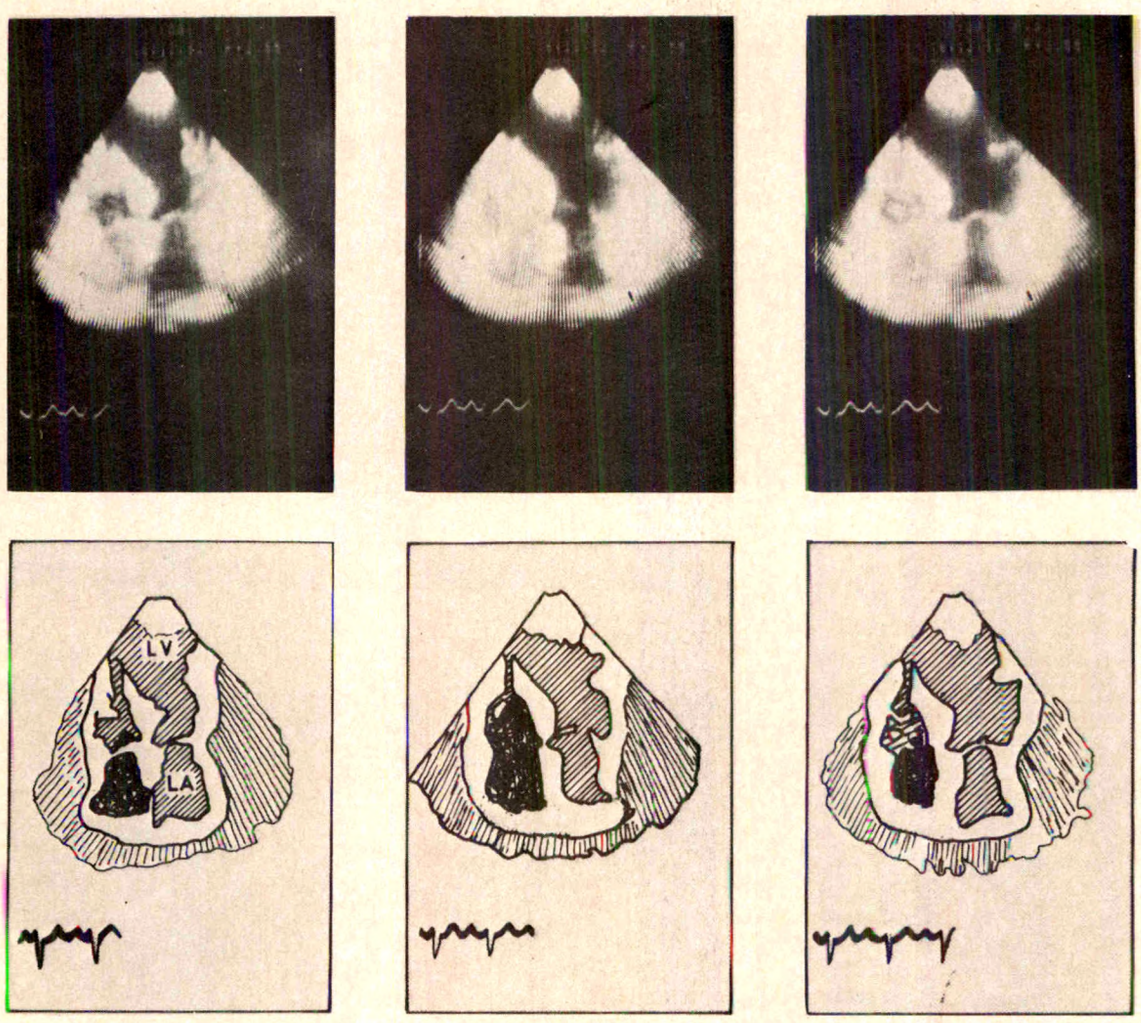

FIGURE 4. Case 2. Echoventriculograms with still frames (**upper panel**) and schematic diagrams (**lower panel**). During the same cardiac cycle the echoventriculogram is displayed from end-systole (**A**) through end-diastole (**B**) to the next early systole (**C**). Negative contrast seen in **A** disappears in **B** and reappears in **C**. Abbreviations as in Figure 1.

Discussion

In the setting of acute myocardial infarction the sudden appearance of a systolic murmur represents a difficult diagnostic challenge to the physician. The differential diagnosis includes differentiation from septal rupture and papillary muscle dysfunction or rupture with resultant mitral regurgitation; the clinical course, prognosis and treatment may differ greatly with each of these entities. Frequently, the clinical findings do not allow the distinction to be made with confidence.[2,4,17] Cardiac catheterization is required for a definite diagnosis and identification of all the factors that compromise cardiac function. However, this procedure carries a substantially increased risk in the critically ill patient[4] unless intraaortic balloon assistance is instituted.[7,8]

M mode echocardiographic findings in septal rupture: Previous echocardiographic studies[18–21] relating to the noninvasive diagnosis of septal rupture used the M mode technique. These studies suggested that the following findings may be of value in the diagnosis of septal rupture: (1) dilatation of the right ventricle[18,19]; (2) unusual mitral valve movement, that is, complete closure of the valve after initial opening early in diastole, suggestive of increased blood flow through the mitral valve[18]; and (3) occurrence of an abrupt posterior motion of the interventricular septum with the onset of ventricular diastole.[18] None of these findings are specific although their combination may provide clues to the diagnosis of septal perforation.[20]

Two dimensional echocardiographic findings in septal rupture: Real time wide angle echocardiography provides images of the heart in multiple cross-sectional planes including long axis sections of the left ventricle that display the entire length of the interventricular septum.[15,22] Previous studies have shown that two dimensional echocardiography is a highly reliable technique that can visualize, size and locate congenital ventricular septal defects with a diameter of 5 mm or greater.[23,24] Identification and sizing of a ventricular septal defect depends on (1) demonstration of a discontinuity in the pattern of echoes arising from the septum; (2) identification of the edges of the defect; and (3) visualization of a left to right shunt at the ventricular

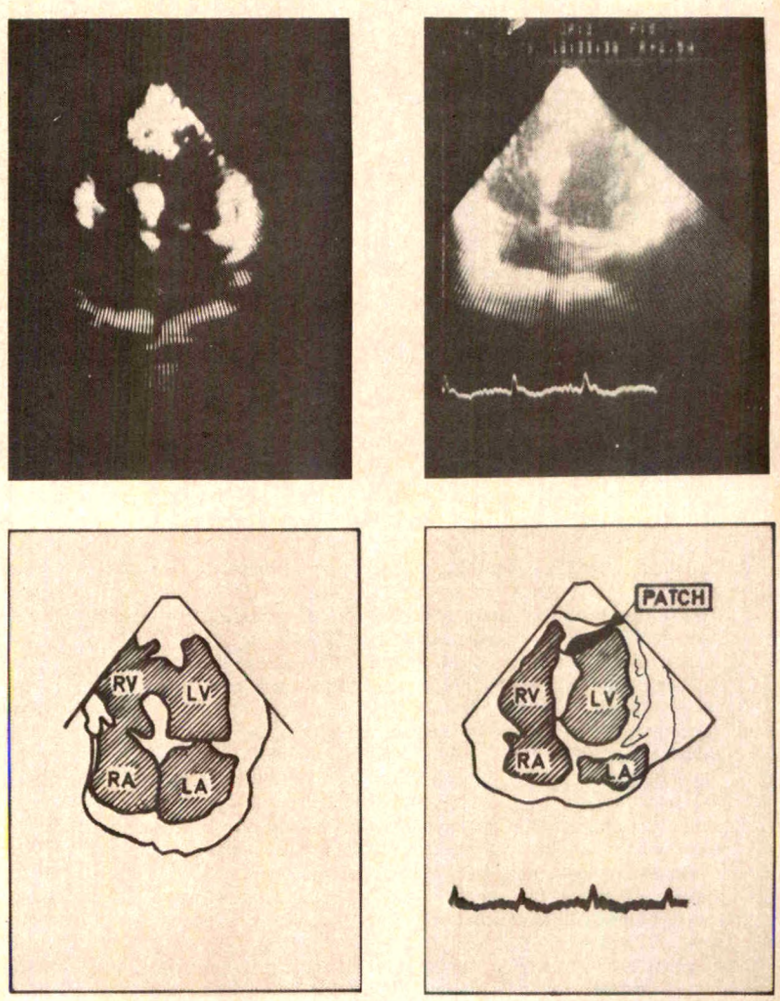

FIGURE 5. Pre- and postoperative Polaroid frames of two dimensional echocardiograms. **Left,** a large defect is evident in the lower interventricular septum. **Right,** postoperative study showing successful repair as indicated by the bright echoes from the patch closing the defect. Abbreviations as in Figure 1.

level. In patients with a small congenital defect, false negative results may occur, resulting from insufficient examination of the septal surface, location of the defect in an inaccessible area and incorrect adjustment of the gain characteristics.[23] Conversely, in detecting defects in cardiac structures, differentiation between technical dropout and real structural discontinuity is of primary importance.[25,26]

After an acute myocardial infarction, a ventricular septal defect is usually large and located in the muscular portion of the septum, which is most easily visualized with real time ultrasonography. This structure is thick enough to remain, despite inadequate setting of ultrasonic signals, an acceptable interface. Furthermore, massive left to right shunting can clearly be recognized by detecting the jet of contrast-free left ventricular blood entering the contrast-filled right ventricle. Two dimensional echocardiography may also provide an approximation of the size of the defect as well as its location. The importance of distinguishing between anterior and inferior septal defects because of the differences in surgical approach has already been pointed out.[8,27,28] Postoperatively the ventricular septal patches used to close the defect can also be identified because of their brighter echoes.

On postmortem cardiac radiographs Hutchins et al.[6] noted an unusual distortion of the septal configuration. In anterior septal defects the apex to base septal contour was convex toward the left ventricular cavity, a reversed pattern of the normal concavity. The leftward convexity of the upper septum caused it to protrude into the left ventricular outflow tract. This distinctive septal contour was noted in two of our cases.

Role in confirming diagnosis before surgery: In patients with acute myocardial infarction who suddenly manifest a loud systolic murmur, some investigators[4] claim that if a left to right shunt at the ventricular level can definitely be identified, the patient may be taken to surgery immediately. Our three patients could have been operated on without confirmation of the diagnosis with cardiac catheterization. Although associated coronary and mitral valve deficiencies should be identified before operation,[3,8,29] one of our two surgically treated patients did not undergo coronary angiography or left ventriculography. This patient was taken to the operating room moribund, and it was believed that the coronary angiography might have produced an additional risk to the patient in this condition. Although there is no definite agreement on the need for coronary angiography,[4,8] left ventricular studies may be obtained noninvasively from two dimensional echocardiography. Indeed, real time echocardiography has been shown to be reliable in assessing residual left ventricular contractile function after infarction[30–33] as well as associated mitral valve lesions.[20]

Clinical implications: In our three patients with acute myocardial infarction and septal rupture, two dimensional echocardiography proved highly reliable for the diagnosis and localization of anterior septal rupture and therefore should be clinically useful in this setting. Left ventricular failure has frequently been reported to be absent in the immediate period after rupture.[5,6] In addition, clinical deterioration, once initiated, usually progresses rapidly in these patients.[4,5,8] Thus, prompt diagnosis of septal perforation before severe deterioration of the patient's condition occurs is of primary importance. At times, when the urgency of the situation is great, the diagnosis should be executed with simple noninvasive methods and immediate surgery considered without further investigation.

Early Diastolic Sound of Constrictive Pericarditis

W. JAY NICHOLSON, MD, FACC*
B. WOODFIN COBBS, Jr., MD
ROBERT H. FRANCH, MD, FACC
I. SYLVIA CRAWLEY, MD

Atlanta and Decatur, Georgia

In two patients with constrictive pericarditis an absent or faint early diastolic sound became prominent with squatting, phenylephrine infusion or injection of contrast medium and was obliterated by nitroglycerin. The lability of the sound allowed correlations to be made with acute changes in the right ventricular pressure curve. By eliciting an otherwise inaudible early diastolic sound, squatting may be a useful bedside maneuver in the diagnosis of constrictive pericarditis.

The important auscultatory clue to the diagnosis of constrictive pericarditis is an early diastolic sound[1] or "pericardial knock," [2] present in 30 to 70 percent of cases.[1,3–5] The sound occurs 0.09 to 0.16 second after the second heart sound and is often almost as sharp as an opening snap.[1,6] The right ventricular pressure tracing of constrictive pericarditis characteristically shows an early diastolic dip followed by rapid upstroke to a plateau diastolic pressure.[7] The early diastolic sound occurs at or very close to the nadir point of the diastolic dip. Mounsey[1] carefully studied the right ventricular pulse tracings of patients with constrictive pericarditis in an attempt to explain why the early diastolic sound was present in some and absent in others. He concluded that the sound occurred when early diastolic inflow was especially rapid and more suddenly interrupted, as indicated by a quick upstroke of the diastolic dip with a coarse after-vibration.

We have observed two patients with calcific constrictive pericarditis in whom the early diastolic sound was absent or faint until the patient was examined in the squatting position. Auscultation soon after squatting is a valuable diagnostic maneuver in aortic regurgitation, obstructive cardiomyopathy, mitral valve prolapse and pulmonic stenosis,[8,9] but has not previously been used in constrictive pericarditis. The physiologic effects of squatting include increases in peripheral resistance and in venous return.[10–12] The ability to turn the sound on and off at will allowed us to examine its hemodynamic correlates more closely.

Case Presentations

Case 1: In a 21 year old man peripheral edema and easy fatigability had developed at age 19. The heart was normal in size but pericardial calcification was detected on fluoroscopy. Two liters of straw-colored ascitic fluid had been removed by paracentesis from the abdomen with a subsequent diuresis of 11.7 kg. The patient's condition was stable for 11 months while he was on digoxin and diuretic therapy; but he regained 5.4 kg of ascites and edema during a 2 week trial of withdrawal from medication.

On our first examination he was free of edema and had sinus rhythm (rate 85/min; the blood pressure was 130/80 mm Hg without pulsus paradoxus. The jugular venous pulse was elevated 2 cm above the clavicle at 45° with prominent *x* and *y* descents, forming an M-shaped venous pattern. There was a quick diastolic cardiac impulse but no early diastolic sound when he was in the recumbent or upright position. Yet, immediately on squatting a prominent early diastolic sound, as loud as either of the other heart sounds, was audible at 0.14 second after the second heart sound and was confirmed on phonocardiography. It persisted

From the Department of Medicine, Division of Cardiology, Emory University School of Medicine, Atlanta, Georgia and the Cardiology Section, (Atlanta) Veterans Administration Hospital, Decatur, Georgia. Manuscript received April 4, 1979; revised manuscript received June 25, accepted July 1, 1979.

for 3 to 4 minutes and then faded despite continued squatting. Small doses of phenylephrine (0.6 μg/kg per min), which barely raised the blood pressure, also elicited the sound. The Valsalva maneuver, handgrip exercise, elevation of the legs and tourniquets around the limbs had no effect. Left and right heart catheterization was performed. The patient initially refused surgery and was treated with drugs and followed up closely for 6 months. On repeated occasions the early diastolic sound was inaudible but readily evoked by squatting. During a period when diuretic therapy was temporarily withdrawn, the sound appeared and was constant. The volume load resulting from the administration of contrast medium at cardiac catheterization also evoked the sound, which then persisted for several hours.

At operation, there was severe biventricular pericardial constriction without effusion. After operation the patient has done well without medication. Venous pressure is normal. No early diastolic sound is present even during squatting or phenylephrine infusion, although the cardiac impulse remains diastolic.

Case 2: A 28 year old black man and former professional baseball player had a viral-like illness associated with pericarditic chest pain 8 years before his presentation with a chief complaint of fatigability. He was a muscular, healthy-appearing young man with a blood pressure of 120/80 mm Hg and no pulsus paradoxus. The rhythm was atrial flutter with 4:1 and 2:1 atrioventricular conduction. The jugular venous pulse was elevated 4 cm above the clavicle at 90° with a prominent early diastolic collapse. The first heart sound was normal; the second sound was split physiologically. A faint early diastolic sound was heard when he was recumbent. With squatting the early diastolic sound at once became prominent and equal in intensity to the second heart sound. The chest roentgenogram revealed pericardial calcification that was confirmed at fluoroscopy. The patient underwent cardiac catheterization.

At operation the pericardium was thickened and adherent to both ventricles with dense calcification anteriorly. After operation, the patient's exercise tolerance improved and no early diastolic sound is present even in the squatting position.

Methods

During cardiac catheterization, pressures were measured by means of a fluid-filled catheter with a Statham P23Db transducer, with the zero level set at the mid chest. A right ventricular pressure tracing and a conventional external phonocardiogram were recorded simultaneously with the patient in the supine, supine passive squatting (legs flexed on abdomen) and (Case 1) vertical squatting positions. Systemic blood pressure, heart rate and right ventricular diastolic pressure were then allowed to return to baseline levels. Recordings were repeated with the patient supine (1) during slow infusion of phenylephrine at a rate just sufficient to duplicate the auscultatory changes associated with squatting, which were achieved with identical small elevations (5 to 8 mm Hg) of left ventricular systolic pressure; and (2) after sublingual administration of nitroglycerin, 0.4 mg. Recordings were made on an Electronics for Medicine DR-8 multichannel recorder during relaxed expiration. All maneuvers were performed before the administration of contrast material.

Changes in the right ventricular pressure contour during the development of the early diastolic sound were closely scrutinized: Both the magnitude of the right ventricular diastolic dip (measured from the nadir of the dip to the end-diastolic pressure) and the slope of both limbs of the dip were examined. Right ventricular systolic and end-diastolic pressures and systemic arterial pressure were also measured. The left side of the heart was also routinely catheterized. The results reported are the average of five consecutive cycles recorded during relaxed expiration.

TABLE I

Intracardiac Pressures (mm Hg) and Blood Pressure Changes During Phenylephrine and Nitroglycerin Administration

	Case 1	Case 2
Right atrium		
a wave	15	. . .
x descent	7	5
v wave	13	18
y descent	13	6
Mean	11	14
Right ventricle	45/12	33/15
Pulmonary artery	45/13	33/16
Pulmonary capillary wedge		
a wave	19	. . .
v wave	18	22
Mean	14	17
Left ventricle	112/13	. . .
Systemic blood pressure		
Control	115/60	120/70
Phenylephrine	122/70	130/96
Nitroglycerin	105/80	100/80

Results

Hemodynamic data (Table I) revealed near approximation of right atrial mean, right ventricular end-diastolic, pulmonary arterial diastolic and pulmonary capillary wedge pressures, findings typical of constrictive pericarditis.[13,14] Right atrial pressure contours showed a typical *y* trough of constrictive pericarditis.[7] The right ventricular pressure curve showed the typical early diastolic dip followed by a diastolic plateau. Simultaneous external phonocardiograms and right ventricular pressure curves are shown in Figures 1 and 2. Significant

TABLE II

Right Ventricular Events During Squatting, Phenylephrine (P) and Nitroglycerin (NTG) Administration and Correlation of Diastolic Dip Magnitude With Right Ventricular End-Diastolic Pressure

	Case 1				Case 2			
	Supine	Squat	P	NTG	Supine	Squat	P	NTG
Right ventricular pressure (mm Hg)								
Systolic	45	46	48	45	33	40	36	36
End-diastolic	15	20	18	11	12	22	16	13
Diastolic dip magnitude	12	20	18	10	10	14	13	10

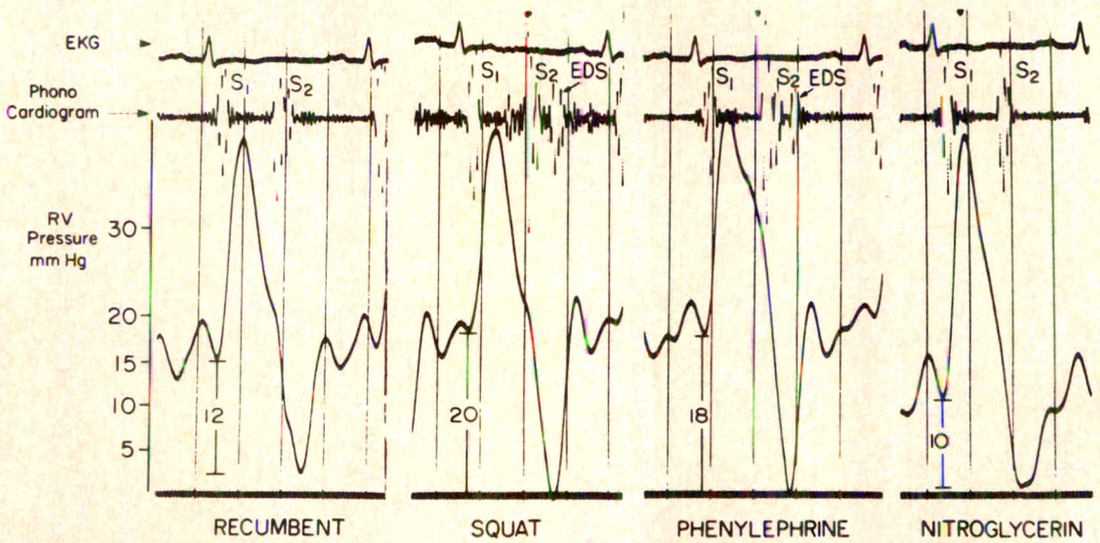

FIGURE 1. Case 1. Simultaneous right ventricular pressure curve and external phonocardiogram demonstrating the behavior of the early diastolic dip and the early diastolic sound (EDS) during active squatting and phenylephrine and nitroglycerin administration. **Brackets** indicate the depth of the right ventricular (RV) early diastolic dip (in mm Hg), measured from the nadir point of the dip to the onset of right ventricular end-diastolic pressure. Paper speed = 50 mm/s; EKG = electrocardigram; S_1 and S_2 = first and second heart sound, respectively.

changes in the right ventricular pressure curves are summarized in Table II.

In Case 1 (*Fig. 1*) no early diastolic sound was present when the patient was recumbent, although the diastolic dip was 12 mm in magnitude. During active squatting, as the sound appeared, the diastolic dip increased to 20 mm. Phenylephrine increased the dip to 18 mm and provoked a huge early diastolic sound. After the administration of nitroglycerin the magnitude of the diastolic dip was reduced to 10 mm, with prompt disappearance of the early diastolic sound. End-diastolic pressure also increased 3 to 5 mm as the sound appeared.

In Case 2 (*Fig. 2*) the early diastolic sound was faintly present when the patient was recumbent, and the diastolic dip measured 10 mm. With passive squatting (simulated supine) the early diastolic sound sharply increased and the dip increased to 14 mm. Phenylephrine increased the diastolic dip to 13 mm and induced the appearance of a prominent early diastolic sound. These maneuvers also increased the end-diastolic pressure 4 to 8 mm. After the administration of nitroglycerin the early diastolic sound disappeared as the magnitude of the early diastolic dip and the end-diastolic pressure fell to control levels.

In both cases as the sound appeared, right ventricular systolic and end-diastolic pressures tended to increase slightly. However, the most significant change was a 30 to 75 percent deepening of the diastolic dip, a larger movement occurring within the same time scale. This observation suggests that the slope of one or both limbs of the dip had steepened but, in fact, changes in slope were small and hard to measure. We were unable to confirm Mounsey's findings of steepening of the upstroke of the dip as the sound developed.

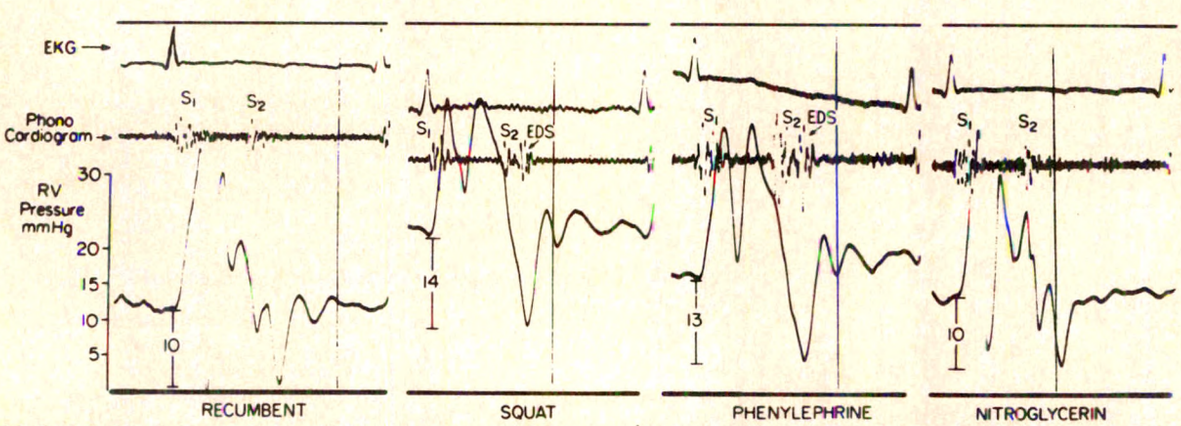

FIGURE 2. Case 2. Simultaneous right ventricular pressure curve and external phonocardiogram, demonstrating the behavior of the early diastolic dip and the early diastolic sound during passive squatting and phenylephrine and nitroglycerin administration. Measurements and abbreviations as in Figure 1.

Discussion

Genesis of early diastolic sound: Early diastolic filling of the constricted ventricle begins freely and continues very rapidly under a large head of pressure until the limit set by the unyielding pericardial envelope is suddenly reached. At this point the pressure abruptly increases, flow just as abruptly diminishes, and the early diastolic sound may occur. Our data suggest that sound production is a threshold phenomenon, resulting from only moderate and sometimes temporary accentuation of hemodynamic abnormalities, given the basic substrate of constrictive pericarditis. We agree with the concepts of Piemme et al.[15] and Mounsey[1] that abrupt deceleration of rapid inflow is the chief factor in the production of filling sounds. The labile factors in sound production are probably the impetus of inflow (its pressure and velocity) and the end-systolic volume. The larger excursion of the diastolic dip in the presence of the sound seems to be evidence for more sudden deceleration of inflow.

Effect of squatting and phenylephrine: Squatting has dual effects on the circulation, increasing both venous return and peripheral resistance. In cases of hemodynamically obvious pericardial constriction, diuresis and a decrease in intravascular volume have led to decreased filling pressures and loss of diastolic pressure equilibration.[16] Conversely, hemodynamically occult pericardial constriction has been unmasked by volume loading.[17] It is easy to see how volume expansion (Case 1) or augmented venous return could excite a filling sound and how this sound could be reduced by nitroglycerin, which produces venous pooling.[18] But it is harder to explain why phenylephrine, which does not augment filling, has no direct effect on the right ventricle and acts as a systemic vasoconstrictor,[19] could also affect both the right ventricular pressure curve and the sound. The mechanism of phenylephrine's action is probably sudden dilatation and increase in the diastolic pressure of the acutely afterloaded left ventricle.[20] Perhaps during the mutual confinement of constrictive pericarditis hemodynamic manipulation of the left heart chambers has a more immediate effect on the right chambers. Yet the possibility remains that the early diastolic sound is biventricular. Similar augmentation of the sound by equipressor doses of phenylephrine and squatting is most simply explained by direct effects on the left ventricle, which were not carefully studied in our cases.

The early diastolic dip: Our failure to duplicate Mounsey's correlation of sound with a sharpened upstroke of the diastolic dip may be due to the lesser damping of our pressure tracings, particularly in Case 2. Possible differences in the magnitude and slope of the dip pressure (nadir level) could also be related to critical damping and response characteristics of fluid-filled catheters versus manometer-tipped catheters. Yet, Mounsey's records also appear to show that the sound correlated with a deeper dip, which may be the most constant hemodynamic equivalent and less dependent on the pressure recording system.

Implications: Squatting may be a valuable maneuver to elicit or intensify the early diastolic sound of constrictive pericarditis. Phenylephrine seems to have a similar effect that is reversed by nitroglycerin. Maneuvers that elicited the early diastolic sound in our two cases were consistently accompanied by a deepening of the diastolic dip but the amount of change often seemed modest in proportion to the intensification of sound, suggesting that production of the early diastolic sound is a threshold event. It has long been known that gallop sounds are often labile and can be made to vary with vasoactive maneuvers. Not surprisingly, the early diastolic sound seems to fall into the same category.

Mitral Valve Prolapse: Jet Stream Causing Mural Endocarditis

MORRIS RINGER, MD
DENNIS J. FEEN, MD
MARK S. DRAPKIN, MD

Newton Lower Falls, Massachusetts

A 53 year old man died of cerebral hemorrhage while being treated for Streptococcus mutans endocarditis. At autopsy the only endocarditic lesion was on the left atrial mural endocardium. The noninfected mitral valve demonstrated prolapse and mucinous degeneration. The latter had led to rupture of several chordae tendineae, with the resultant jet stream predisposing to endocarditis at its point of atrial impact. The case provides confirmation of current concepts of the pathogenesis of endocarditis and has important therapeutic implications.

Infective endocarditis is one of the major complications of the mitral valve prolapse syndrome.[1] We recently observed a patient with fatal endocarditis who was found at autopsy to have clinically unsuspected mucinous degeneration of the mitral valve with associated rupture of noninfected chordae tendineae. The location of the only infected cardiac lesion, on the left atrial mural endocardium, affords unique confirmation of current concepts of the pathogenesis of infective endocarditis and has important therapeutic implications.

Case Report

Clinical findings: A 53 year old man was admitted because of 6 weeks of daily fever to 40° C, weakness, malaise and anorexia with a 5.5 kg weight loss. He had not seen a physician in many years and was unaware of a previous heart murmur.

On examination, he was pale and weak. The body temperature was 38.7° C, pulse rate 92/min, respirations 20/min and blood pressure 130/80 mm Hg. There were no peripheral manifestations of endocarditis. The teeth were carious and periodontal disease was present. The point of maximal cardiac impulse was 2 cm to the left of the mid clavicular line. The first heart sound was normal, the second sound was physiologically split and a fourth sound was present. A grade 4/6 holosystolic murmur was heard along the lower left sternal border, radiating to the axilla and increasing with the Valsalva maneuver. There was no diastolic murmur.

Laboratory findings: The chest roentgenogram and electrocardiogram were normal. Urinalysis revealed a protein level of 27 mg/100 ml and 5 white blood cells and 3 red blood cells per high power field. The hematocrit reading was 41 percent and the leukocyte count 18,700 mm^3 with 22 percent band cells, 63 percent neutrophils, 7 percent lymphocytes and 7 percent monocytes. Sedimentation rate (Westergren) was 66 mm/h. Results of a latex fixation test were positive at 1:20 and an antinuclear antibody test was positive at 1:40 with a peripheral pattern. Cerebrospinal fluid examination was normal. No valve vegetations were seen in the echocardiogram, which did not visualize the posterior mitral leaflet adequately to assess valve prolapse.

Clinical course: Late on the 1st hospital day, the patient manifested an expressive aphasia. On examination at that time he had moderate weakness of the right arm and leg and central facial weakness. Cerebrospinal fluid protein was 49 mg/dl and glucose 64 mg/dl (blood glucose 126), and there were 271 red blood

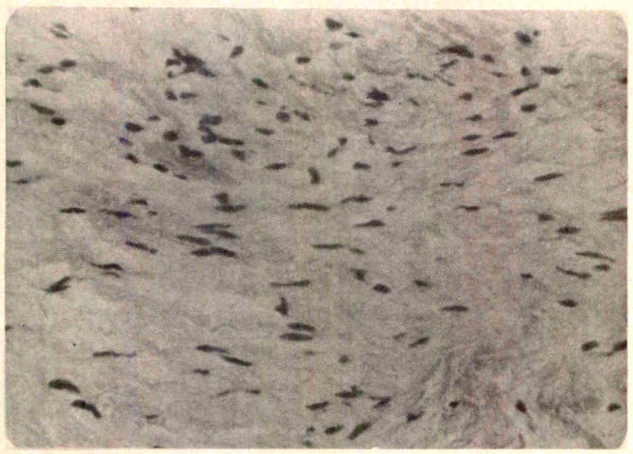

FIGURE 1. Photomicrograph of ruptured chordae tendineae of mitral valve, showing fibromyxomatous degeneration. (X400, reduced by 23 percent.)

cells and 5 white blood cells (60 percent lymphocytes)/mm^3. He was given penicillin G, 24 million units/day, and gentamicin, 1.5 mg/kg every 8 hours intravenously. Twelve blood cultures yielded growth of an alpha hemolytic streptococcus identified as *S. mutans* by the Massachusetts State Laboratory. Because penicillin at a concentration of 0.125 μg/ml or less was bactericidal against the organism, administration of gentamicin was discontinued.

The fever, aphasia and malaise decreased over the next 2 days. He then suddenly became apneic and was resuscitated. A left carotid angiogram revealed two distal aneurysms in the left middle cerebral arterial distribution and a large avascular intracerebral mass displacing the midline vessels to the right and the middle cerebral group downward. A left frontotemporal craniotomy was performed with evacuation of subdural, intracerebral and intraventricular hematoma, but the patient did not regain consciousness and died 4 days later.

Pathologic findings: At autopsy the heart demonstrated moderate cardiomegaly (weight 530 g) with left atrial and biventricular dilatation. Moderate atherosclerosis involving all major arteries was present. There was no evidence of an acute myocardial infarct or papillary muscle ischemia. The mitral valve ring was slightly dilated (circumference of 12 cm). The mitral valve leaflets were moderately thickened, glistening and semitransparent, with a bluish-grey "myxomatous" appearance. The chordae tendineae were similar in appearance, markedly attenuated and reduced to threadlike strands. Several had ruptured between their leaflet and papillary muscle attachments. There were no vegetations on either the mitral leaflets or chordae tendineae.

A localized 2 by 2 cm circular lesion was present on the left atrial mural endocardium immediately superior to the posterior mitral valve leaflet but beyond reach of the leaflet itself. This endocarditic lesion contained fibrin, nuclear debris, platelets and gram-positive cocci. The remaining left atrial endocardium was intact.

Microscopic sections of the mitral valve leaflets and chordae tendineae (Fig. 1) demonstrated increased ground substance and disruption of the normal fibroelastic matrix. Excessive acid mucopolysaccharide accumulation was confirmed by Alcian blue stain. These pathologic changes have previously been described.[2,3] Aschoff bodies were not seen.

Discussion

Mitral valve prolapse is a common entity[4] that assumes importance mainly because of the possible occurrence of life-threatening arrhythmias, sudden death, severe mitral regurgitation or endocarditis. The incidence of endocarditis is unclear, but in one prospective study[5] endocarditis developed in 5 of 58 patients, and elsewhere[6] reports of about 115 cases are collected, one series alone[7] contributing 35 cases.

The anatomic location and pathologic features of endocarditis have not been emphasized. In a series of 137 necropsies on patients with active endocarditis, Arnett and Roberts[8] reported two cases of underlying "floppy valve"; in both cases, the infection was on the valve itself. In the same series, there were eight cases of infective endocarditis limited to mural endocardium but, unlike our case, all eight cases were fungous. More recently,[1] 10 infected floppy mitral valves were examined pathologically. Ruptured chordae were found in six and valve vegetations in four, but no mural endocarditis was described.

Our patient illustrates several points. First, as previously noted,[1,7] endocarditis can be the initial presentation of mitral valve prolapse, and the presence of that predisposing condition can be unsuspected even after the diagnosis of endocarditis has been established. Second, endocarditis in such patients may have a fatal outcome, thus emphasizing the risk associated with the syndrome of mitral valve prolapse.

Third, the cardiac infection need not be confined to the mitral valve and may not even involve that valve. The pathophysiologic sequence of events in our case are unique and merit emphasis. The primary underlying defect appears to have been excessive accumulation of acid mucopolysaccharide ground substance in mitral valve leaflets and chordae tendineae, causing "myxomatous" degeneration of both structures. Hemodynamic stresses probably resulted in spontaneous rupture of several chordae tendineae. This allowed mitral regurgitation (jet stream effect) to occur and induce a localized area of erosion in the left atrial endocardium. The location of the left atrial mural endocarditis demonstrates that the regurgitant jet stream was directed posteriorly as a result of spontaneous rupture of the anterior mitral valve chordae tendineae. The lesion became infected consequent to transient bacteremia, probably from a dental source. Subsequent septic cerebral embolization resulted in death.

We interpreted the patient's holosystolic murmur as indicating infection either of the mitral valve itself or of its chordae tendineae, whereas in fact the murmur was caused by degeneration and spontaneous rupture of uninfected chordae tendineae. This misinterpretation might have had serious consequences. For example, if the patient had survived but had continued to experience cerebral embolization, we might have considered mitral valve replacement advisable. Clearly, such surgery, unless it included removal of the left atrial seeding focus, would not have had the desired effect. Likewise,

had we experienced difficulty in sterilizing the bloodstream and contemplated mitral valve replacement for that reason, the operation would also not have accomplished its goal.

It is impossible to know how many cases of infective endocarditis associated with mitral valve prolapse share the pathogenetic mechanism seen in our case. Twelve previous cases[1,8] did not. However, one should consider the possibility of such a mechanism in patients with infective endocarditis associated with mitral valve prolapse, especially if valve replacement is being considered.

Clotted Hemopericardium With the Hemodynamic Characteristics of Constrictive Pericarditis

WILLIAM C. LITTLE, MD
R. KIRBY PRIMM, MD
ROBERT B. KARP, MD, FACC
WILLIAM P. HOOD, Jr., MD, FACC

Birmingham, Alabama

Cardiac catheterization in a patient 4 weeks after coronary arterial bypass surgery demonstrated the typical hemodynamic findings of constrictive pericarditis, which completely resolved after removal of 500 ml of clotted pericardial blood. The pericardium was not responsible for the findings because it was left in place. This case demonstrates that clotted hemopericardium may mimic constrictive pericarditis.

Although constrictive pericarditis and cardiac tamponade both impair cardiac filling, they also have distinct hemodynamic differences.[1–4] We report a case of postoperative hemopericardium with the hemodynamic characteristics of constrictive pericarditis rather than cardiac tamponade and propose a possible explanation.

Case Report

A 65 year old man with three vessel coronary artery disease and normal left ventricular function underwent insertion of saphenous vein bypass grafts to each of the three major coronary arteries. At operation the pericardium was normal and was left open. Two weeks after operation the patient had a syncopal episode. Because of the clinical suspicion of a pulmonary embolus he was treated with an intravenous infusion of heparin. Twenty-four hours later his condition deteriorated. The blood pressure decreased to 90/70 mm Hg with less than 5 mm Hg of respiratory variation, central venous pressure increased to 22 cm H_2O, and the pulse rate increased to 120/min. The chest was clear on auscultation and the heart sounds were slightly diminished. An early diastolic sound was intermittently present. The electrocardiogram revealed sinus tachycardia and left ventricular hypertrophy. An echocardiogram demonstrated a posterior echo-free space. Administration of heparin was discontinued.

Cardiac catheterization was performed because of the possibility of cardiac tamponade or pulmonary embolism. Simultaneous pulmonary capillary wedge pressure measurement and right heart pullback revealed equalization of the pulmonary capillary wedge and right heart diastolic pressures at 20 mm Hg (Fig. 1). There was a prominent early diastolic dip and plateau pattern in the right ventricular pressure and the right atrial pressure tracing had a prominent y descent and a loss of respiratory variation. Left ventricular pressure was not measured. The aortic pulse pressure was narrow (Fig. 2) and there was less than 10 mm Hg of respiratory variation. Pulmonary arterial and aortic root angiograms were normal.

The patient was immediately taken to the operating room where the median sternotomy wound was reopened. Removal of approximately 500 cc of clotted pericardial blood produced marked immediate hemodynamic improvement. The blood pressure promptly increased to 160/80, pulmonary arterial pressure decreased to 25/14 and right atrial pressure decreased to 5 mm Hg. No bleeding site was identified and the pericardium was not resected. The postoperative course was uncomplicated and the patient was discharged 1 week later.

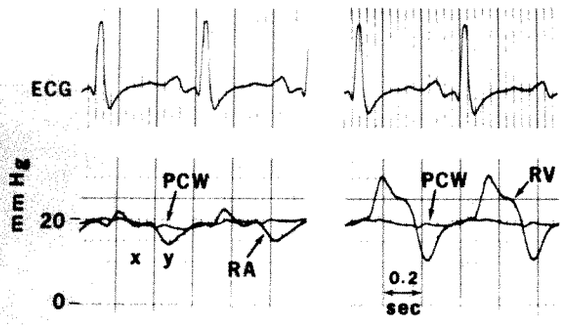

FIGURE 1. Simultaneous recording of the pulmonary capillary wedge (PCW) with right atrial (RA) and right ventricular (RV) pressures. There is equalization of end-diastolic pressures at 20 mm Hg, the *y* descent is more prominent than *x* descent in the right atrial pressure, and the right ventricular pressure has a prominent diastolic dip and plateau pattern suggestive of pericardial constriction. ECG = electrocardiogram.

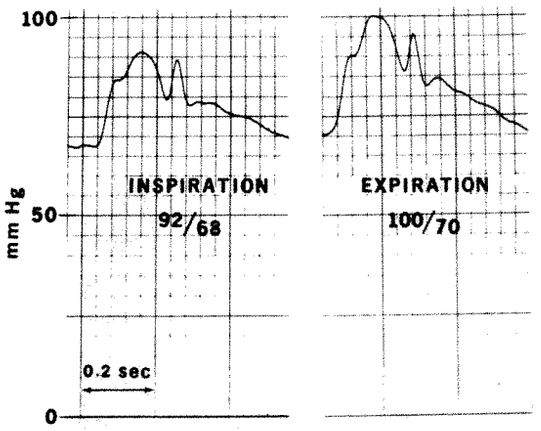

FIGURE 2. Central aortic pressure with a respiratory variation in systolic pressure (pulsus paradoxus) of 8 mm Hg.

Comment

Hemodynamics of cardiac tamponade versus constrictive pericarditis: Cardiac tamponade and constrictive pericarditis both impair ventricular filling, but in different ways.[3] In constrictive pericarditis the heart is surrounded by an unyielding shell of noncompliant pericardium. The resistance to initial diastolic filling is relatively normal and the heart fills rapidly until a critical cardiac volume is reached early in diastole. Then the compliance of the combined myocardial-pericardial system abruptly decreases, causing cessation of ventricular filling and an abrupt increase in the ventricular and atrial pressures.[3,4] This produces the early diastolic dip and plateau of the ventricular pressure tracing and the sharp *y* descent of the atrial pressure tracing. Venous return remains biphasic in constrictive pericarditis, occurring both in early diastole and during ventricular systole; thus the right atrial *x* descent is preserved.[1] The respiratory variation in venous return may be lost and right atrial pressure may even increase during inspiration.[1]

In contrast, cardiac tamponade is due to accumulation of pericardial fluid that causes an elevation in intrapericardial pressure, producing cardiac compression and interference with venous return throughout the cardiac cycle.[3,4] In tamponade, venous return becomes monophasic and occurs primarily during ventricular systole; thus, the right atrial *x* descent is prominent, and the *y* descent is lost.[1–4] The ventricular pressure does not display an early diastolic dip and plateau pattern.[1,2,8] The respiratory variations of the intrathoracic pressure are transmitted to the intrapericardial space[5] and inspiratory augmentation of systemic venous return is preserved,[1] leading to the development of pulsus paradoxus, a hallmark of cardiac tamponade.[6] In contrast, pulsus paradoxus is a less frequent finding in constrictive pericarditis.[7]

Explanation of features of constrictive pericarditis with clotted pericardial blood: The accumulation of enough blood in the pericardial space to produce hemodynamic impairment normally results in cardiac tamponade.[8] Our patient with clotted pericardial blood did not have the expected hemodynamic characteristics of tamponade but instead the typical features of constrictive pericarditis: equalization of left- and right-sided filling pressures, prominent right atrial *y* descent, right ventricular diastolic dip and plateau pattern, loss of respiratory variation of right atrial pressure and lack of marked pulsus paradoxus. The hemodynamic impairment was due to the presence of the clotted blood in the pericardium because its removal produced a prompt normalization of the hemodynamics. The pericardium was not responsible for the hemodynamic changes because it was left in place at reoperation.

A possible explanation is that, because the pericardial space was filled primarily by clotted blood, the heart was surrounded by a noncompliant shell of clotted blood rather than by a pericardial space filled with fluid under pressure. Early diastolic filling was not impaired until the cardiac volume reached that of the surrounding shell of clotted blood. This shell also isolated the heart from respiratory changes in intrathoracic pressure. Thus, hemopericardium with clotted blood may mimic the pathophysiologic features of constrictive pericarditis and not produce the typical hemodynamic changes of cardiac tamponade. In a recently reported case[9] of "constrictive pericarditis" occurring 2 weeks after cardiac surgery, resolution of the hemodynamic picture of constriction occurred after removal of 50 g of clotted pericardial blood and the resection of large sections of thickened and adherent pericardium. It is possible that the hemodynamic changes were at least partly due to the clotted hemopericardium.

Implications: The recognition that clotted hemopericardium may not produce the classic hemodynamic and clinical features of cardiac tamponade but instead mimic constrictive pericarditis may be clinically important. When clotted hemopericardium is a possibility, as in the period after cardiac surgery or chest trauma, the lack of marked pulsus paradoxus and the preservation of a right atrial *y* descent may not rule out hemopericardium as the cause of hemodynamic impairment.

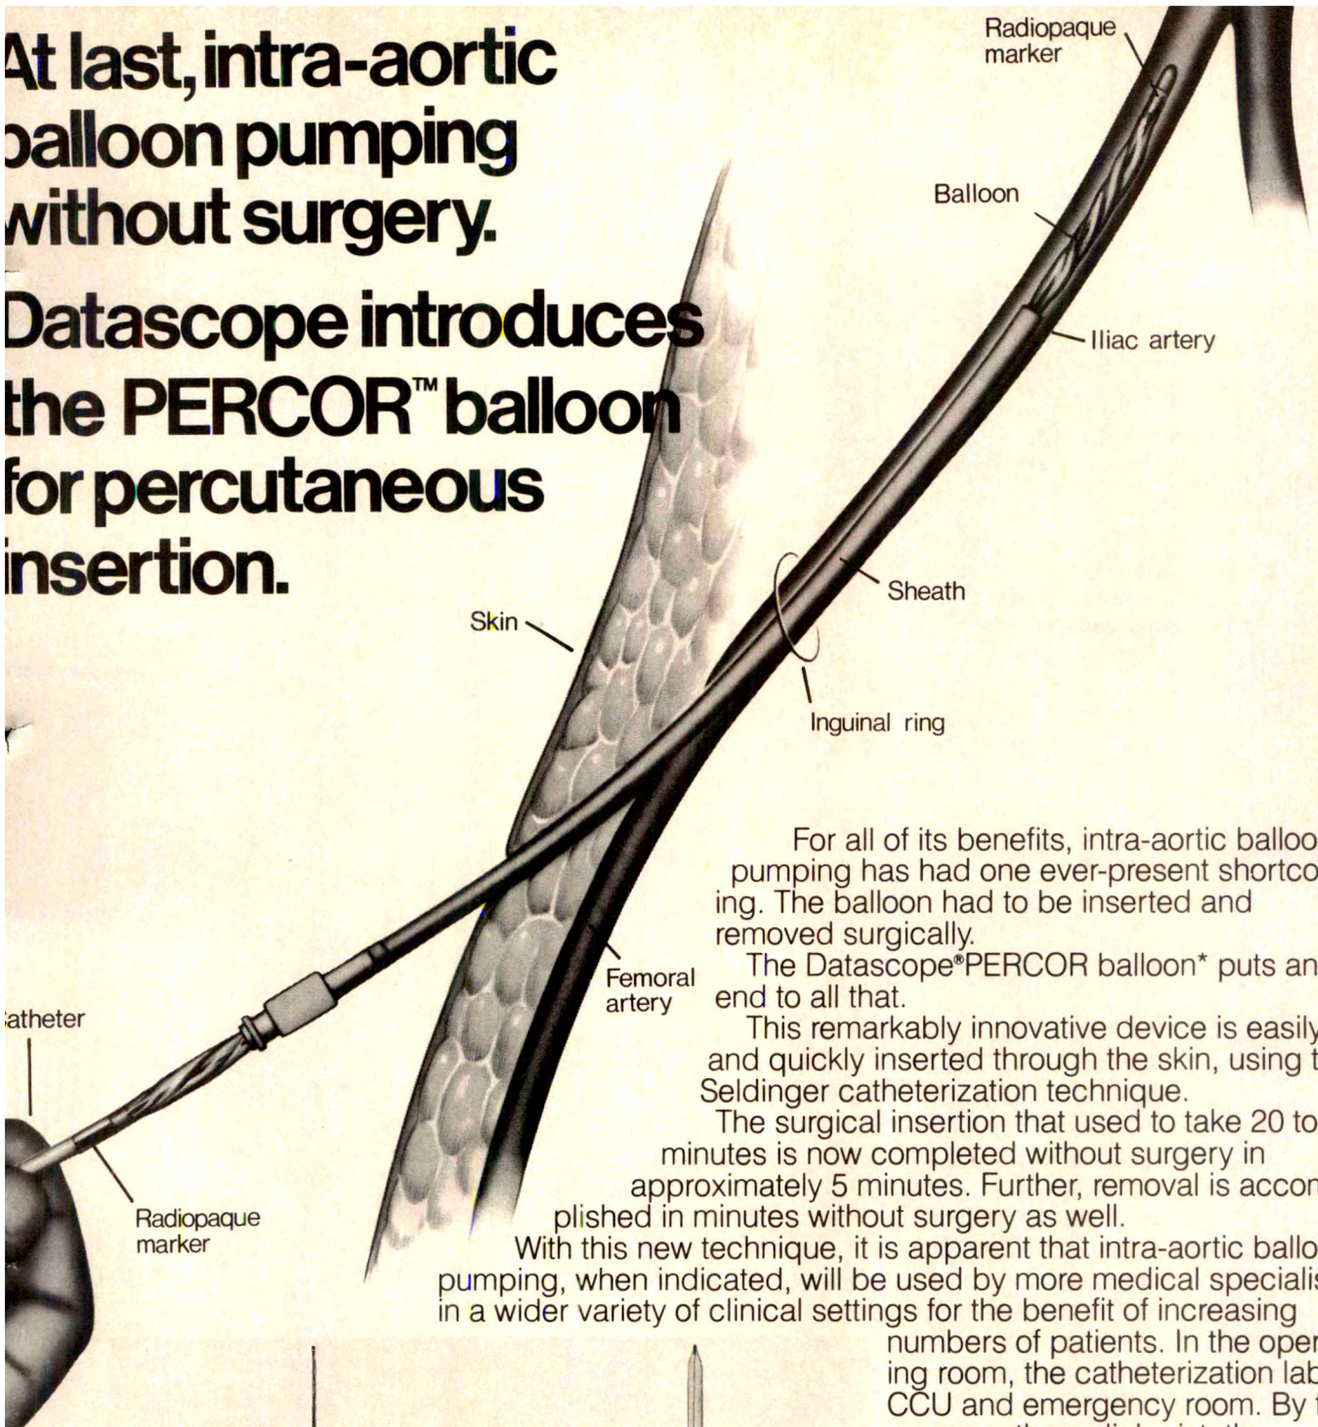
At last, intra-aortic balloon pumping without surgery.

Datascope introduces the PERCOR™ balloon for percutaneous insertion.



For all of its benefits, intra-aortic balloon pumping has had one ever-present shortcoming. The balloon had to be inserted and removed surgically.

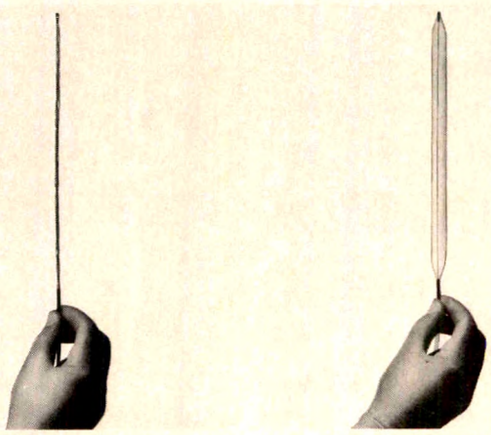
The Datascope®PERCOR balloon* puts an end to all that.

This remarkably innovative device is easily and quickly inserted through the skin, using the Seldinger catheterization technique.

The surgical insertion that used to take 20 to 45 minutes is now completed without surgery in approximately 5 minutes. Further, removal is accomplished in minutes without surgery as well.

With this new technique, it is apparent that intra-aortic balloon pumping, when indicated, will be used by more medical specialists in a wider variety of clinical settings for the benefit of increasing numbers of patients. In the operating room, the catheterization lab, CCU and emergency room. By the surgeon, the radiologist, the cardiologist.

We would be pleased to send you more information about our revolutionary device and to schedule a filmed demonstration of its use. Call Robert Rewolinski, Manager, Cardiac Assist Products, at 201-265-8800 or write him at Datascope Corp., Dept. #5-S, 580 Winters Avenue, Paramus, NJ 07652.



PERCOR™ balloon ready for insertion.

PERCOR™ inflated.

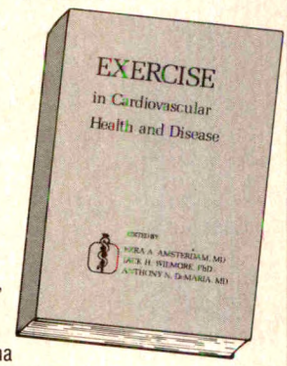
EXERCISE in Cardiovascular Health and Disease



Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS. $33.00

This comprehensive work covers every aspect of exercise and its role in **Diagnosis, Treatment,** and **Prevention** of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

"The list of contributors bespeaks its authority: outstanding physicians in cardiovascular medicine and distinguished physical educators . . . No serious student or practitioner in the field would wish to be without this remarkably thorough account . . ."

David H. Spodick, MD, St. Vincent Hospital, Worcester, Mass. in ***The Journal of the American Medical Assoc.****, June 16, 1978, Vol 239, No. 24*

"Many areas in this field which have not as yet been addressed under one cover and a few rather unique ones are mentioned . . . an important synthesis of our current knowledge in the field."

Harold T. Mankin, MD, Division of Cardiovascular Diseases and Internal Medicine, ***Mayo Clinic Proceedings****, May 1978*

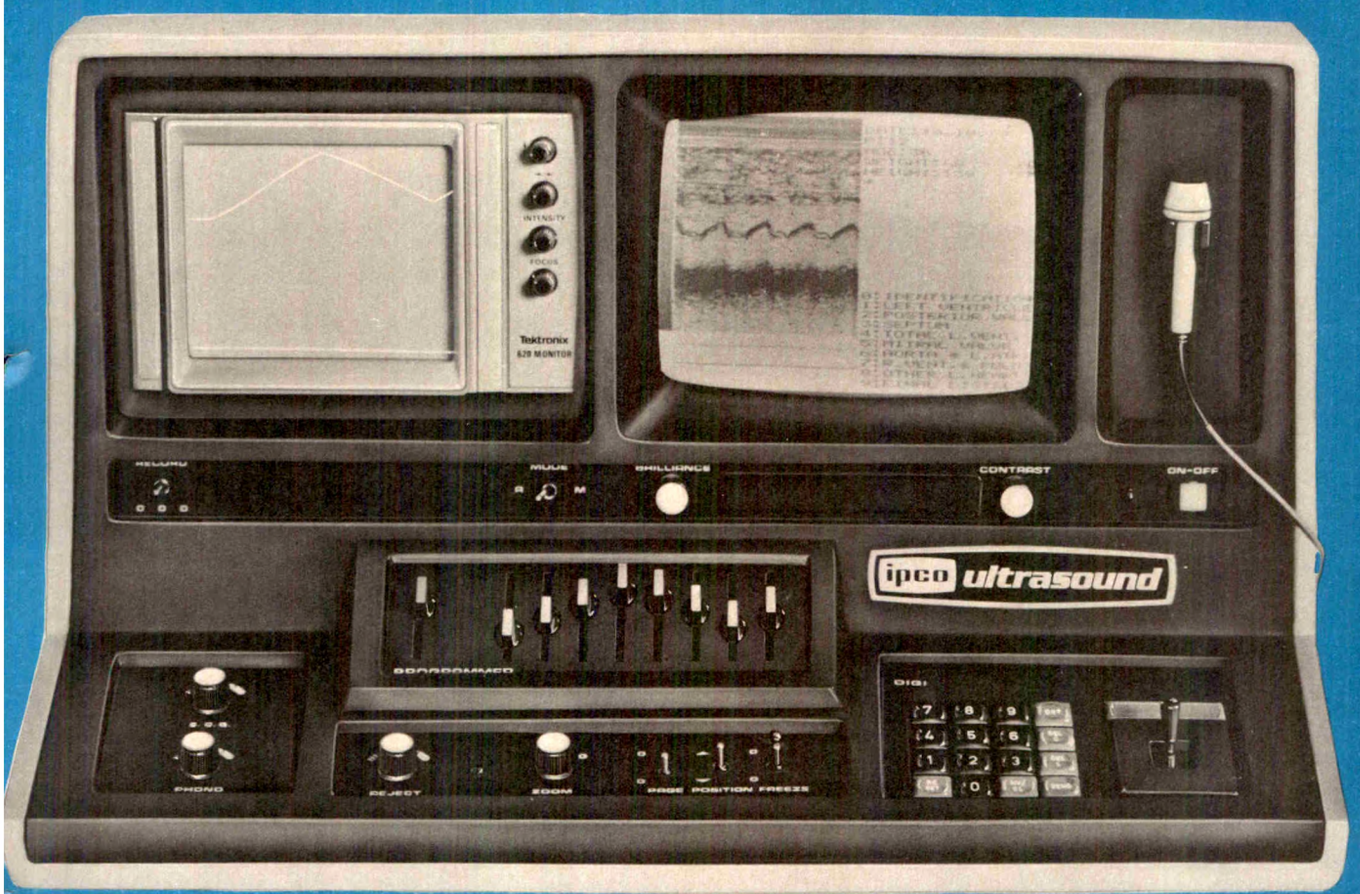
Introducing The M-101 Echocardiograph... The system that listens to the heart...with a brain™



The M-101 Echocardiograph System integrates the most important features currently utilized in the new and rapidly developing science of non-invasive ultrasound examination.

The M-101 Echocardiograph is designed for maximum effectiveness as a system. Central features facilitate examination: independent T.G.C. programmer (pinpoints echoes for finer diagnostic information), 16 shades of gray, "frozen" display pictures, and 2 memory pages for storage of 2 or 4 seconds of image display while storing calculated data, to name a few. Modular design provides a number of optional features and ensures system upgrade. In addition, M-101 listens to the heart with a unique and exciting "brain": the Intelligent Digi-Analyzer or "Digitizer."

The Digitizer is an on-line micro-processor that may be connected to the M-101 system for calculations of various parameters from displayed echo pictures. Essential patient data is shown next to "frozen" echo pictures. 59 cardiac functions and parameters may be measured with computer electronics accuracy, by joy-stick controlled cursors. Calculations are fast, "real-time" (during the examination) and may be stored for future reference. The Digitizer ensures computer certain precision and simplifies the examination process.

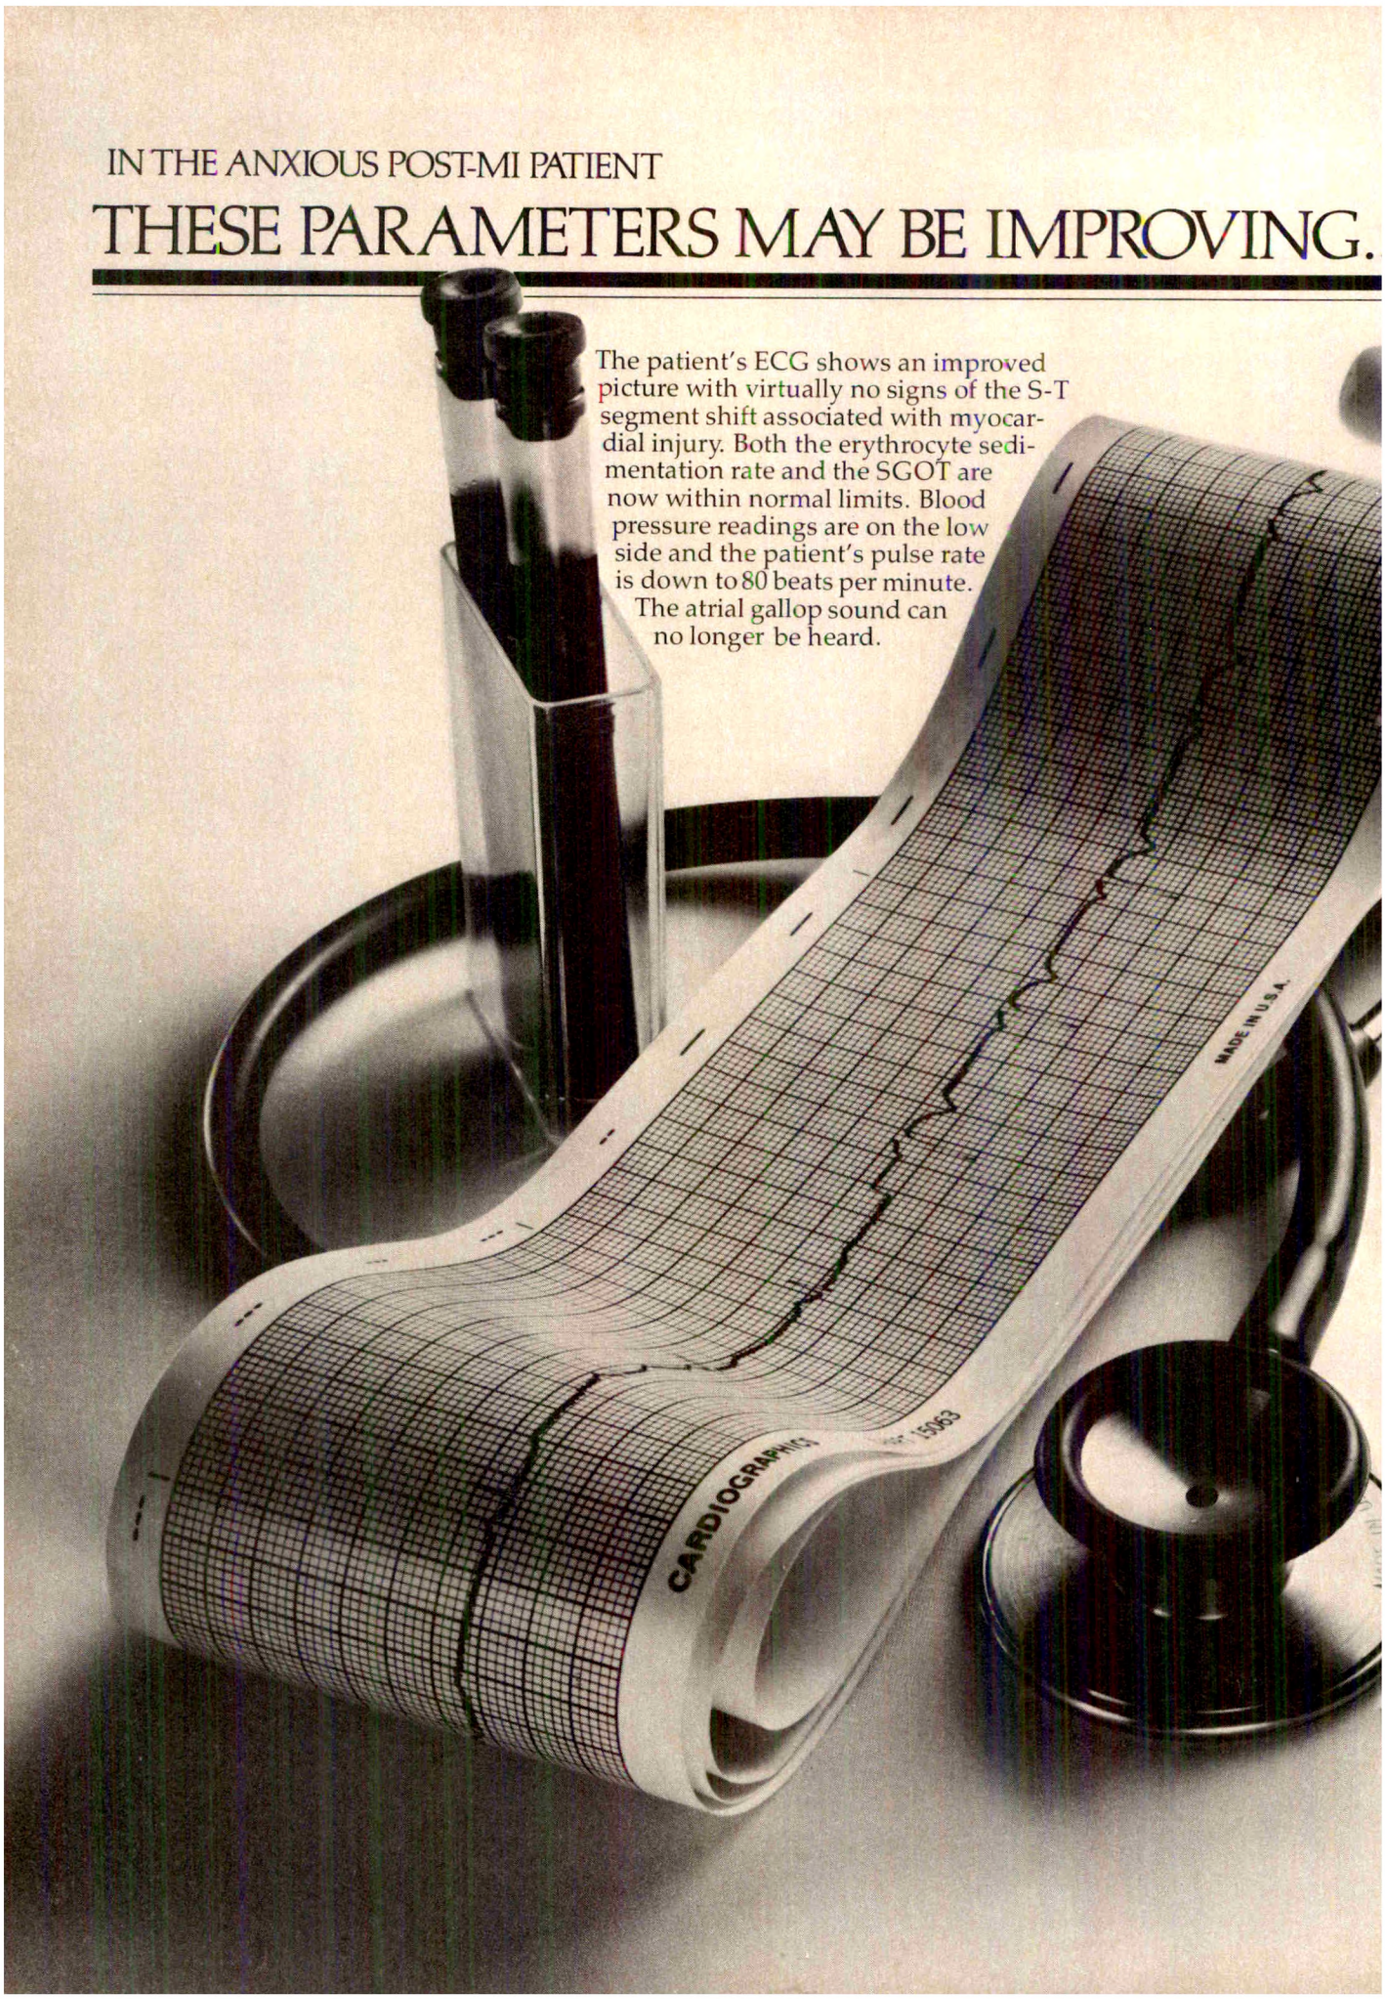
IN THE ANXIOUS POST-MI PATIENT

THESE PARAMETERS MAY BE IMPROVING.



The patient's ECG shows an improved picture with virtually no signs of the S-T segment shift associated with myocardial injury. Both the erythrocyte sedimentation rate and the SGOT are now within normal limits. Blood pressure readings are on the low side and the patient's pulse rate is down to 80 beats per minute. The atrial gallop sound can no longer be heard.

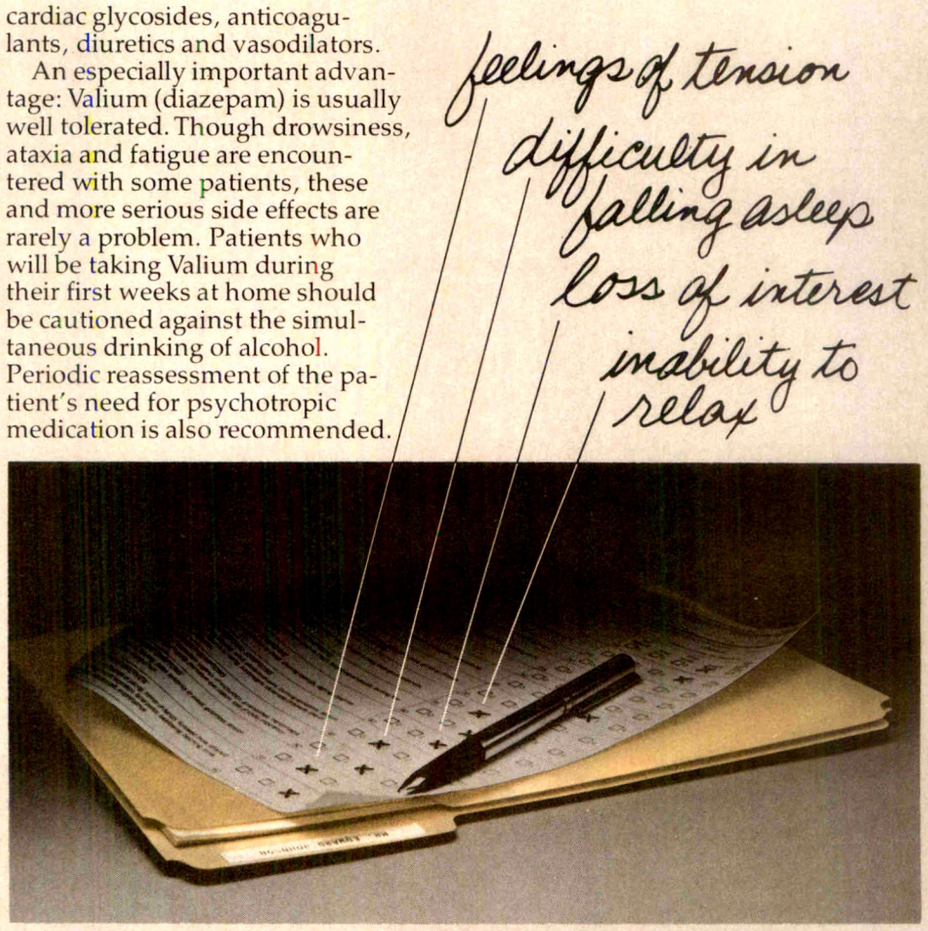
BUT THESE MAY NOT.

You've assured the patient, time and again, that he's making excellent progress, that all signs point to a marked improvement in his condition. He *seems* to understand... and yet, his excessive anxiety and psychic tension continue to pose problems.

For patients like this, adjunctive Valium (diazepam) can be particularly useful. Valium works promptly: patients often feel distinctly calmer in hours, usually report significant symptomatic relief within days. And once calmer and in better control of their emotions, they tend to be more optimistic as well and to enter more willingly into rehabilitative programs.

Valium can also alleviate the anxiety-linked insomnia so often seen in post-MI patients. In most cases, adding an *h.s.* dose of Valium to the usual *t.i.d.* schedule helps relieve "nighttime apprehensions" and encourages sleep. And Valium is used with most classes of primary medications, including cardiac glycosides, anticoagulants, diuretics and vasodilators.

An especially important advantage: Valium (diazepam) is usually well tolerated. Though drowsiness, ataxia and fatigue are encountered with some patients, these and more serious side effects are rarely a problem. Patients who will be taking Valium during their first weeks at home should be cautioned against the simultaneous drinking of alcohol. Periodic reassessment of the patient's need for psychotropic medication is also recommended.



VALIUM® (IV)
diazepam/Roche
2-mg, 5-mg, 10-mg scored tablets

TO REDUCE EXCESSIVE ANXIETY TO MORE MANAGEABLE LEVELS

Before prescribing, please see following page for a summary of product information.

ROCHE

Valium® (diazepam/Roche)

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).

The effectiveness of Valium (diazepam) in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

***Usage in Pregnancy:* Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10.

CARDIO-PROBE

CONDUCTION CARDIOGRAPH/BUNDLE OF HIS DETECTOR/ automated-audible localization of cardiac conduction tissue/ myocardial ischemia/infarction and facilitated recording of HIS Bundle Electrograms

For the cardiovascular surgeon concerned with . . .
- congenital cardiac repair
- infarctectomy/ aneurysmectomy
- revascularization
- valve replacement
- electrosurgery

For the cardiologist concerned with . . .
- HIS Bundle electrograms
- arrhythmia studies
- pacemaker selection

For the investigator concerned with . . .
- conduction-system electrophysiology
- cardiac pharmacology
- cardiac toxicology

The CARDIO-PROBE includes . . .
- *an audible pacemaker* to help establish pacing
- *a conduction cardiograph,* fully patient-isolated, tripolar probe included. Adjustable gain 40-500 Hz bandwidth
- *Bundle-of-HIS detector,* with fixed alarm threshold

Inputs include . . .
both tripolar probe and tripolar catheter for flexibility in use

Applications include . . .
- localization of Bundle-of-HIS
- delineation of aneurysms
- delineation of ischemia/infarcts
- mapping conduction pathways
- recording HIS Bundle electrograms

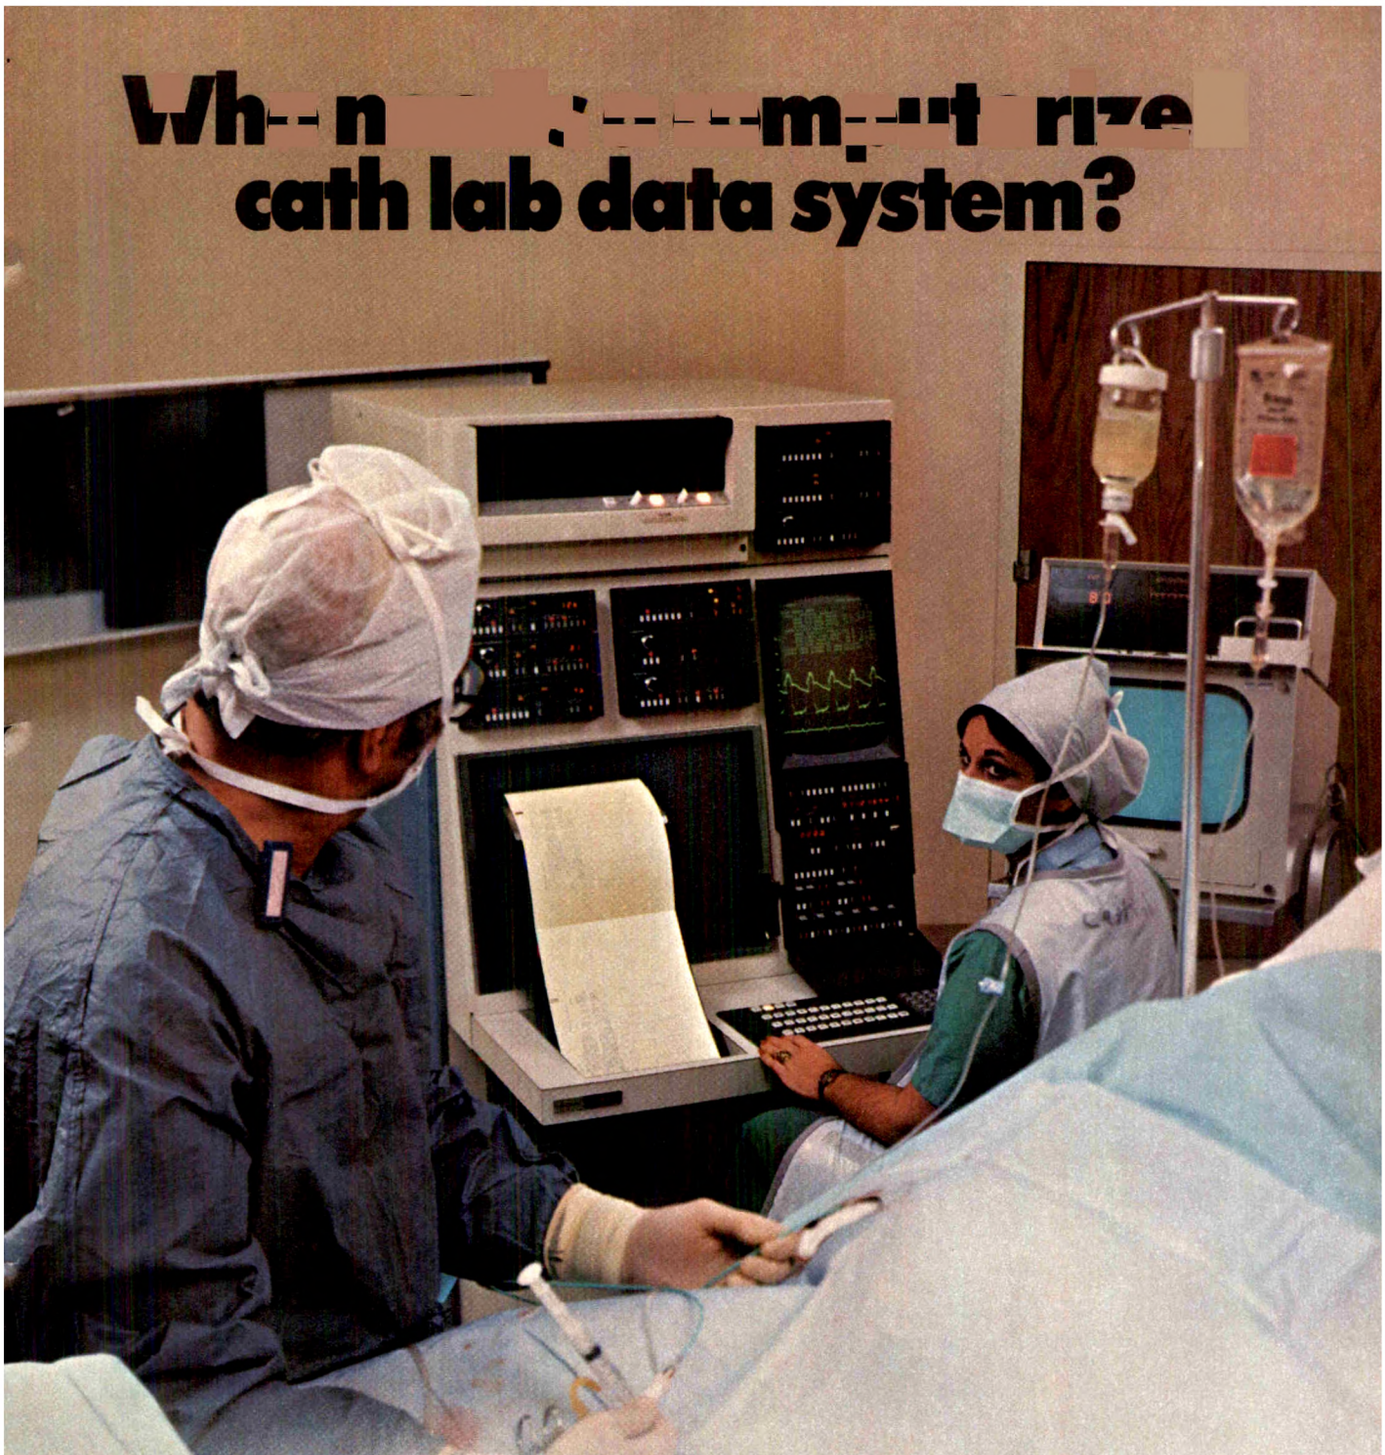
Wh--n .'---m-ut rize cath lab data system?



You do. Catheterization procedures yield an immense amount of information about a patient's cardiac function. But assembling all of this data into a coherent diagnostic picture can be a time-consuming process. That's why our MEDDARS computerized cath lab data system is proving its usefulness every day.

MEDDARS displays all data on a bright, nonfade display. It records everything you want to save on black-on-white records, and it performs hemodynamic calculations in seconds. When the case is complete, MEDDARS generates the final report before you leave the lab.

Your MEDDARS can start as a basic display and recording system. You can later upgrade it – right in your lab – into a fully automated system. You can also add options for left ventricular volume analysis, and even data base management.

For complete details about MEDDARS or our complementary SIMULTRACE Recorders, call us today or see these systems in Booths 452 and 556-563 at the ACC Meeting in Houston, March 10-13.

TOGETHER, WE'LL SHOW YOU A BETTER WAY.

E FOR M / Honeywell

Electronics for Medicine, Honeywell Inc.,
One Campus Drive, Pleasantville, New York 10570

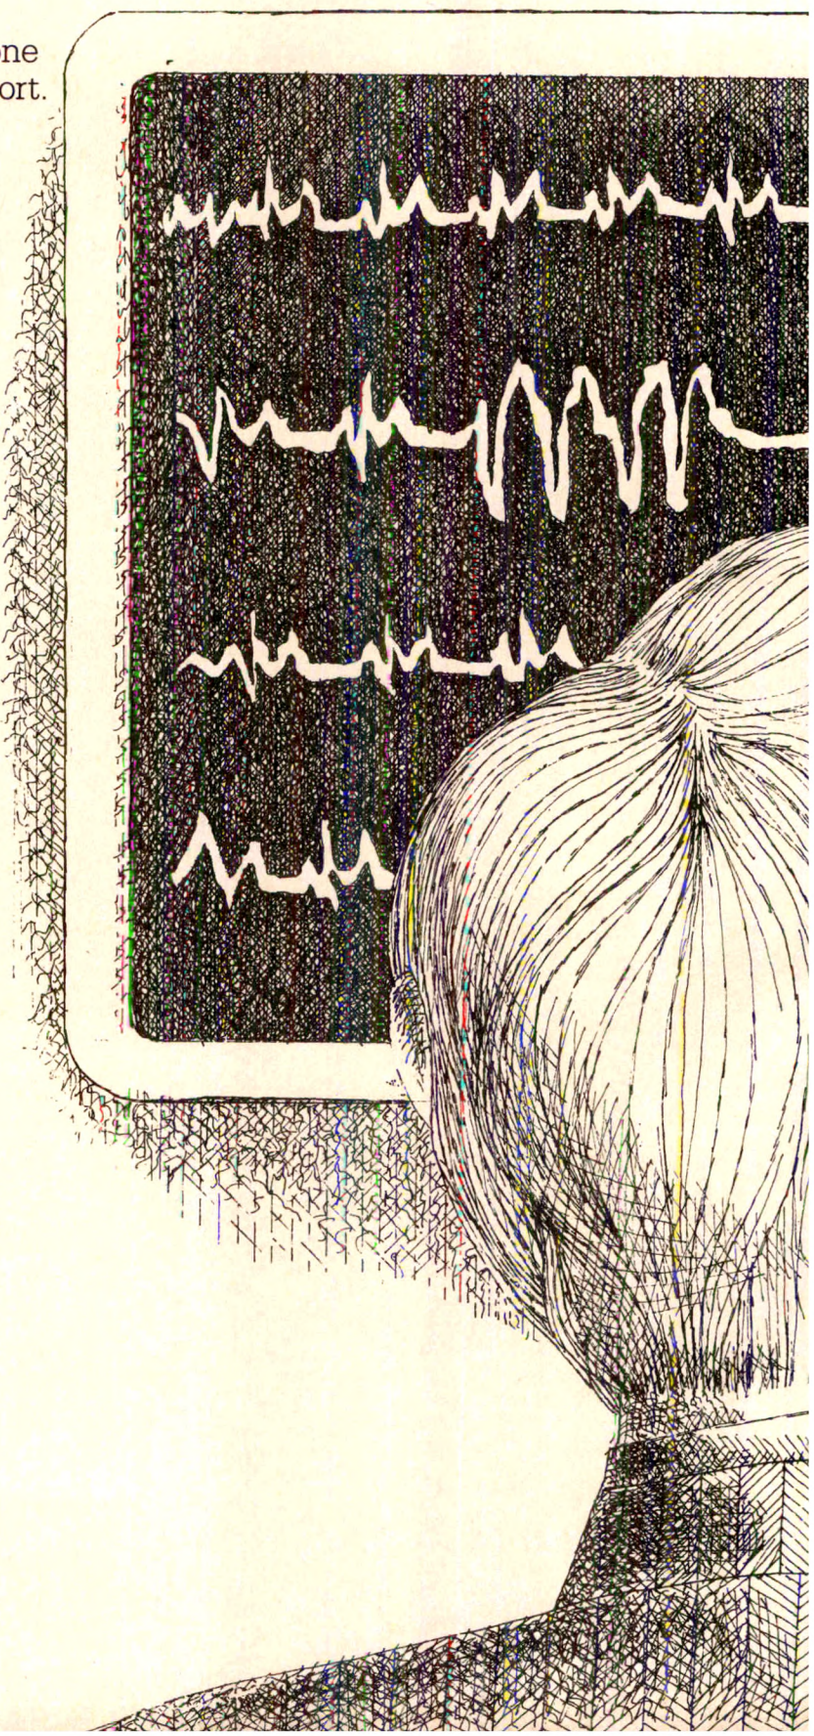
While half of us watch the recordings.

At Clinical Data, accuracy is just one important part of every LCG™ Report. It's a basic part of the quality that has allowed us to become the largest long term ECG recording and reporting service in the country. It's why we design and build our own lightweight recorders; it's why we looked hard at the old superimposition method of scanning and came up with a better way—our exclusive Stein/Peterson™ Examination Technique.

And it's why we also looked at reporting techniques. Our LCG Report is the result of constant awareness not only of the information you desire, but the format you prefer. Real time printouts of significant ECG tracings; quality control standards that include observer validated quantitation of ectopic activity by morphology; graphic printout of each quantitated QRS morphology so *you* can validate the data—all are presented clearly on convenient Z-fold paper.

And none of it means a thing without one other basic:

Prompt delivery.



.the other half watches the clock.

At Clinical Data, we review tapes 24 hours a day, seven days a week on over a dozen systems. Saturday nights are reserved for system maintenance. We have installed remote printers in seven U.S. cities (with more scheduled) that allow us to transmit reports cross country in a matter of minutes. We process thousands of tapes a month.

To keep all of that happening, we've organized.

Our expediting department is on a first name basis with key personnel at major courier and postal offices nationwide. Working with each new customer, they define pick-up and delivery priorities, establish schedules, and evaluate performance.

We enter every incoming tape into our computerized tracking system. We can tell in an instant where it's from, when it arrived, who delivered it, when it's been examined, by whom, and how and when it should be delivered.

We've prepared a sample LCG Report and a brochure that describes in step-by-step detail how we can convert a 24-hour ECG recording into a 24-hour LCG Report and deliver it on time anywhere in the U.S.—often within 24-hours.

So call us toll-free at 800-225-9180: We'll prove to you that our commitment is to long-term recording *and* short-term delivery.

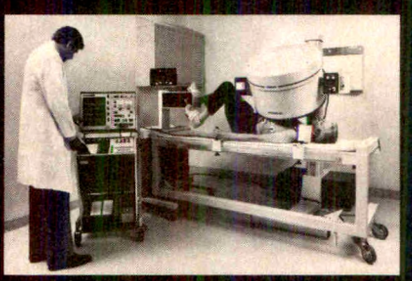
ScintiStress™
Stops the Wheelchair Express!

You all agree — shuttling critically ill patients, or even ECG carts, back and forth between the Cardiology and Nuclear Medicine labs is not the way to go. ScintiStress lets you do it all in one lab.

Cambridge Instrument Company developed the first ECG equipment. Now, Cambridge is the first to organize stress testing logically, for combined nuclear and electrocardiographic stress protocols.

So, if you are looking for a stress system that you can also use for nuclear studies, Cambridge has one for you. Our electrodes and patient cables are radio-translucent, especially important with low energy Thallium-



201 studies . . . and we can supply a complete system for use with your gamma camera, including an ECG output for a gated trigger and a horizontal exercise table with pedal ergometer for gated blood pool studies. Treadmill systems with plug-in program cartridges, too. A special filter eliminates camera noise; and the full feature 3-channel ECG recorder with 4-channel stress test monitor, and heart rate meter, are packaged in a compact, mobile console.

Call or write for the ScintiStress brochure and a list of nuclear stress test references: Cambridge Instrument Company, Inc., 73 Spring Street, Ossining, New York 10562, Tel: (914) 941-8100.

PROGRAMALITH®
IS
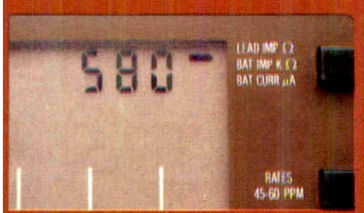
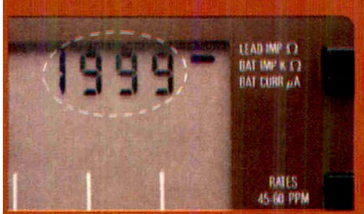
DIAGNOSTIC

LEAD IMPEDANCE



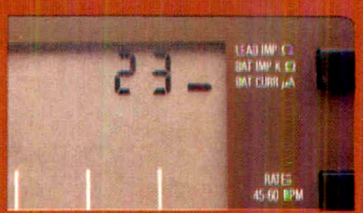
Non-invasive measurement of lead impedance can be used to monitor changes with time.



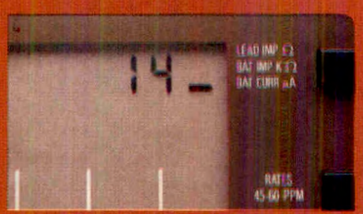
Shows fractured or improperly connected leads.

Shows shorted leads, insulation faults or low impedance lead systems.

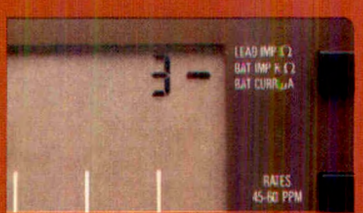
BATTERY CURRENT



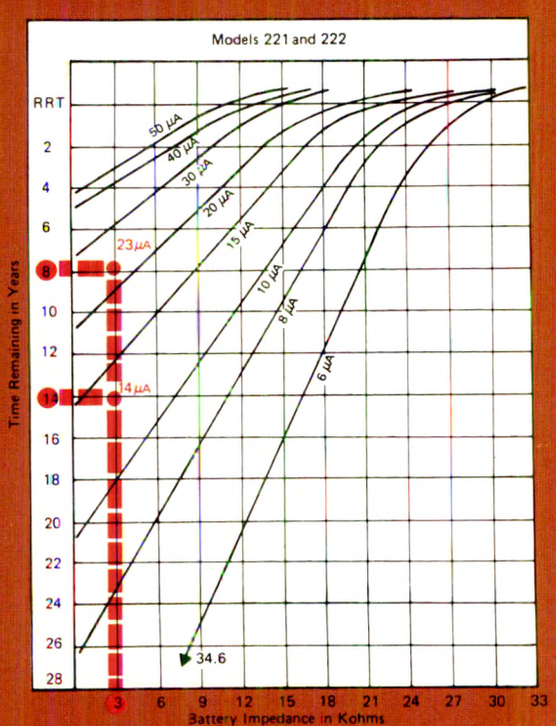
Battery current (80 PPM, 0.8 ms pulse width and 5.0 volt output pulse).



Battery current (same parameters but programmed to 2.5 volt output pulse) adjusted to optimal efficiency



In addition to rate decrease and pulse width increase, a third RRT indicator is provided. RRT is approximately 21 kilohms at standard settings. Remaining service life is simply determined.



OPTIMIZING THE SYSTEM

With Programalith you can determine all parameters affecting pacemaker performance and optimize the system to best satisfy the patient's needs while extending service life.

ABSTRACTS

Abstracts of Papers to be Presented at the 29th Annual Scientific Session of the American College of Cardiology Houston, Texas, March 9 to 13, 1980

This year a record number of abstracts, 1755, were submitted for evaluation. Each was graded by 10 recognized authorities in the special field of interest. Acceptance of abstracts for presentation was based on grade ranking in proportion to total number of abstracts assigned by the authors in each category.

Our membership has varied backgrounds and interests so that the Scientific Sessions were planned to maintain a balance between structured and abstract sessions. The total of 424 abstracts selected for presentation this year is a record for the College. The percent of submitted abstracts selected remains essentially unchanged from last year, i.e., 25 percent. The Program Committee is aware of the important role of the abstract sessions and regrets that many excellent studies could not be accepted. The Committee has sought and will continue to look for ways to expand the abstract sessions for future meetings.

CORONARY ARTERY DISEASE: ROLE OF VASOSPASM
10:30-12:00

THE EFFECTS OF VERAPAMIL ON CORONARY HEMODYNAMICS AND VASOMOBILITY IN PATIENTS WITH CORONARY ARTERY DISEASE

Christopher Y.C. Chew, MD; B. Greg Brown, MD; Maylene Wong, MD; Pravin M. Shah, MD; Bramah N. Singh, MD, Ph.D., VA Wadsworth Hospital, Los Angeles, California, and Edward L. Bolson, MD; Harold T. Dodge, MD, University of Washington, Seattle, Washington

Verapamil (V), a potent Ca^{2+}-antagonist, is effective in exertional and rest angina with its mode of action remaining unclear. Its I.V. effects (0.145 mg/kg in 2 min with 0.005 mg/kg/min infusion) on mean aortic pressure (MAP), mean pulmonary wedge pressure (PCW), cardiac index (CI), coronary sinus flow (CSF), systemic resistance (SR), pulmonary resistance (PR), coronary resistance (CR) and myocardial oxygen consumption (MVO_2) were determined in 7 pts during coronary angiography. Lumen cross sectional area at "normal" (A_n) and most narrowed (A_{min}) points and the stenosis flow resistance (R_S) were determined by a computer-based angiographic analysis of 18 diseased coronary segments. Results (means±SD; ↑increased; ↓decreased; *p< .01): MAP↓ (100±9 to 85±11 mmHg*); SR↓ (1280±320 to 1032±272 dyne·sec·cm^{-5}*); PCW↑ (12±1 to 16±2 mmHg*) with insignificant changes in HR, PR and CI. MVO_2 decreased 18%±2% (N=3). Pressure-rate product (PRP) ↓ 23±7%.

	CSF (ml/min)	A_n (mm^2)	A_{min} (mm^2)	R_S	CR (dyne·sec·cm^{-5}x10^3)
Control	102±37	6.8±5	2.9±1.9	7±21	77±22
V	119±39	15%↑*	12%↑*	18%↓*	52±17*

Thus, verapamil decreased MAP, PRP, and MVO_2 while CSF tended to rise due to dilatation of both resistance and conductance coronary vessels. The results are consistent with the drug's observed salutary effects on myocardial ischemia in man.

ANTI-ANGINAL ACTION OF VERAPAMIL - A CONTROLLED STUDY

V. Balasubramanian, MD, FACC; A. Lahiri, MBBS; P. Sivam, MD; E.B. Raftery, MD, BSC, FACC, FRCP Northwick Park Hospital & Clinical Research Centre, Harrow, England.

The anti-anginal efficacy of verapamil hydrochloride, a calcium channel blocker, in a dose of 120 mgs t.i.d. was investigated utilising a combination of conventional trinitrin consumption estimations and serial quantitated treadmill exercise tests. The trial design was double-blind cross-over and treadmill tests were performed at 2 weekly intervals. The exercise electrocardiogram was analysed by an on-line digital computer and a number of objective parameters were obtained. Out of 28 patients who developed angina during treadmill exercise while on placebo, 16 became angina free at 2 weeks and 19 on 4 weeks of treatment. There was a statistically significant reduction of anginal attacks and trinitrin consumption. The objective parameters such as exercise time, ST segment changes, ST segment indices corrected to exercise, time taken to develop 1 mm and 2 mm ST depression showed significant improvement. The side effects noted included constipation in 7 and reversible PR interval prolongation in 2. No congestive cardiac failure was noted. It appears that verapamil is a powerful anti-anginal agent free from significant side effects and is a suitable alternative to beta blockers in chronic stable angina.

EFFICACY OF NIFEDIPINE IN THE INTERMEDIATE SYNDROME REFRACTORY TO PROPRANOLOL AND NITRATE THERAPY

Jeffrey Moses, MD; Michael S. Feldman, MD, FACC; Richard H. Helfant, MD, FACC, Presbyterian-University of Pennsylvania Medical Center, Philadelphia, Pennsylvania.

The intermediate syndrome (recurrent angina at rest with ST segment and/or T wave changes without serum enzyme elevations) is often refractory to conventional medical therapy. The utility of nifedipine was evaluated in 13 patients with obstructive coronary disease (3 with 3 vessel disease (VD), 5 with 2 VD, 4 with 1 VD and 1 with acute inferior myocardial infarction) and the intermediate syndrome. Seven had continued rest pain 3 days to 6 weeks after an acute myocardial infarction. One had variant angina. All were refractory to propranolol (80-320 mg/day) oral nitrates (isosorbide 240-320 mg/day) and nitroglycerin ointment (4-12 inches/day) to tolerance. The addition of nifedipine in oral doses of 30-120 mg daily abolished rest pain in 11 patients. Two patients considered non-responsive (1 - 2VD, 1 - 3VD) underwent bypass surgery. After initial titration with nifedipine, 5 patients were NYHA class I, 7 class II and 1 class IV. After 3 weeks to 6 months followup, 8 patients remained on nifedipine. One patient with 3 VD had recurrent rest pain at 5 weeks and had bypass surgery. One patient stopped nifedipine due to diarrhea and 1 was lost to followup. Of those who continued nifedipine 5 remained NYHA class I and 3 class II. Three of 4 patients who had reduced the dose of nifedipine had recurrent rest pain. Side effects were: 1 patient with congestive failure, 1 with diarrhea and 1 with ankle edema. Thus, nifedipine is a potentially useful drug in patients with the intermediate syndrome and may help defer or avoid the need for coronary bypass surgery.

FIXED VS. NON-FIXED CORONARY STENOSIS: THE RESPONSE TO A FALL IN CORONARY PRESSURE.

Jeffrey S Schwartz, MD, Peter Carlyle, BS, Jay N Cohn MD, FACC; University of Minnesota, Minneapolis, Minnesota.

The resistance of a coronary stenosis capable of passive vasomotion may change in response to alterations in transmural pressure. We studied the effects of a fall in perfusion pressure on the hemodynamics of 3 types of coronary stenosis in 17 open chest dogs: 1) a noncircumferential stenosis (NCS) produced by placing sutures into either side of the artery and invaginating part of the arterial wall by tying the sutures, 2) a stenosis produced by placing a soft wire snare (WS) around the artery, and 3) a fixed circumferential stenosis (CS) produced by introducing and tying a short section of hollow plastic tubing into the coronary artery. Aortic pressure, coronary pressure proximal and distal to the stenosis and coronary flow were measured. Pressure in the stenotic artery was lowered by tightening a snare placed very proximally on the artery. In arteries with a NCS, lowering proximal coronary artery pressure (PCP) by 52±5 mmHg caused a rise in stenosis resistance from 0.43±0.05 to 1.10±0.25 units ($p<0.02$). In arteries with a WS, lowering PCP by 32±1 mmHg also caused a rise in stenosis resistance from 0.86±0.06 to 1.40±0.15 units ($p<0.001$). However, in arteries with a CS lowering PCP by 31±2 mmHg caused a fall in stenosis resistance from 0.36±0.04 to 0.21±0.03 units ($p<0.001$). The increase in resistance of the NCS as pressure was lowered may be attributed to passive narrowing of the stenotic segment. The WS showed the same response thus suggesting that it also is not a fixed stenosis. However, the CS did not show an increase in resistance as pressure fell because the tubing was not capable of passive narrowing. Therefore, the hemodynamics of a coronary stenosis depend importantly on the type of stenosis that is present and whether it is capable of vasomotion.

REFRACTORY ERGONOVINE INDUCED CORONARY VASOSPASM: IMPORTANCE OF INTRACORONARY NITROGLYCERIN

Alfred Buxton, MD; Sheldon Goldberg, MD; John W. Hirshfeld, MD; John Wilson, MD; Tift Mann, MD; David O. Williams, MD; Philip Oliva, MD, FACC; John A. Kastor, MD, FACC, Hospital of the University of Pennsylvania, Philadelphia, PA

Recent experience has suggested that the ergonovine maleate test is a safe procedure for the diagnosis of variant angina pectoris, since ergonovine-induced coronary vasospasm has generally been reversible by sublingual nitroglycerin. We report 4 cases of ergonovine-induced coronary vasospasm which were refractory to sublingual nitroglycerin and resulted in cardiac arrest. In one patient the vasospasm was responsive only to intracoronary nitroglycerin administration. Three patients died as a result of intractable coronary vasospasm. The one survivor differed from the nonsurvivors in the total dose of ergonovine (0.1mg versus 0.15, 0.3, and 0.3mg respectively), and in the method of administration of ergonovine. The survivor was given serial doses of 0.05 each whereas the three nonsurvivors received either larger initial doses (0.1mg followed by 0.07mg) or progressive incremental doses (0.05mg, 0.1mg, and 0.15mg serially). Sublingual nitroglycerin, given to all 4 patients and intravenous nitroglycerin, given to 3 of the 4 were ineffective in reversing vasospasm. Multiple doses of intracoronary nitroglycerin reversed coronary vasospasm in the survivor. Thus, the ergonovine maleate test is not benign and may cause severe coronary vasospasm that is unresponsive to sublingual and intravenous nitroglycerin, but may be reversed by intracoronary nitroglycerin.

FREQUENCY OF PROVOCATED CORONARY ARTERY SPASM IN 273 PATIENTS WITH CHEST PAIN

Michel E. Bertrand,MD,FACC;Jean M.Lablanche,MD; Pierre Y.Tilmant,MD:University Hospital,Division of Cardiology,Hopital Cardiologique,Lille,France

Provocative test with methergine was systematically performed in a group of 273 patients(pts) referred by coronary arteriography for evaluation ofchest pain.The provocative test was performed after the routine procedure using a protocol with a single IV bolus injection of 0.4 mg of metherg ine.Aortic pressure,ECG and corcnary arteriogram were repeated 1,3 and 5 minutes later.The pts were divided into 4 groups:Group 1(n=94):Atypical chest pain.Group 2(n=39):Typical angina pain during exercise 5(15 pts had previous myocardial infarction)Group 3(n=98):Typical angina pain at rest.Group 3(n=42):Both angina at rest and during exercise.32 pts in group 3 and 5 in group 4 had ST segment elevation during the attacks.

	n	Spasm	No spasm
Group 1	94	0	94
Group 2	39	1	38
Group 3	98	45	53
Group 4	42	7	35
Total	273	53	220

Coronary spasm(CS) was observed in 19.4% of pts. Spasm was seldom observed in pts with atypical chest pain or angina on exertion.In contrast spasm is frequently induced in pts with angina at rest (group 2+3):52/140=37%.35 of 37 pts with ST segment elevation had coronary spasm.In conclusion:It appears that chest pain is related to spasm in approximatively 20% of pts and most often in pts with spontaneous angina at rest:In this way ,these pts represent the best indication for the provocative test.

AGE RELATED CHANGES IN THE LEFT VENTRICULAR EJECTION FRACTION RESPONSE TO EXERCISE

Steven Port MD, Kevin Bowyer BS, Frederick R. Cobb MD and Robert H. Jones MD, FACC. Duke University Medical Center, Durham NC

This study examined the effects of increasing age on the left ventricular ejection fraction (EF) at rest and during upright bicycle exercise in 63 healthy volunteers ranging in age from 21-95. All subjects were screened for the absence of historical or physical evidence of any cardiac disorder, hypertension, diabetes, pulmonary or active systemic illness. Twelve-lead ECGs were normal at rest in all subjects. First-pass radionuclide angiocardiography was used to measure EF at rest (REF) and during exercise (ExEF) and to detect exercise-induced wall motion abnormalities (ExWMA). All subjects exercised to at least 85% predicted maximum heart rate. Exercise ECGs were normal in 62/63 subjects.

Age	REF(%)	ExEF(%)	ΔEF<5%	ExWMA
21-30 (n=14)	64.0 ± 6.8	78.6 ± 6.7	0	0
31-40 (n=11)	62.9 ± 6.9	80.6 ± 6.2	0	0
41-50 (n= 8)	62.8 ± 6.8	76.0 ± 7.0	0	0
51-60 (n= 8)	65.7 ± 8.8	76.4 ± 13.4	2/8	1/8
61-70 (n= 9)	65.4 ± 10.4	66.6 ± 11.3	5/9	3/9
71-95 (n=13)	64.5 ± 8.6	56.7 ± 8.0	12/13	7/13

REF did not change with age. ExEF was significantly lower in the 7th decade ($p<0.01$) and in the 8th-10th decades ($p\leq0.0007$) compared to the younger subjects. After age 50 there was a progressive increase in the frequency of a subnormal EF response so that by the 8th-10th decades 92% of the subjects had a ΔEF<5% ($p<0.001$). The frequency of this subnormal response exceeds the reported prevalence of obstructive coronary artery disease and suggests an independent effect of aging on left ventricular function.

SPONTANEOUS IMPROVEMENT IN AEROBIC CAPACITY BETWEEN 3 AND 11 WEEKS AFTER MYOCARDIAL INFARCTION

William M. Savin, MA; Robert F. DeBusk, MD, FACC; Nancy Houston, RN; William L. Haskell, PhD, FACC, Stanford University, Stanford, CA.

To assess the response to exercise soon after uncomplicated myocardial infarction (MI), 48 men (mean age 54) completed symptom limited, graded treadmill exercise tests at 3 and 11 wks post-MI. O_2 consumption (VO_2), ventilation (V_E), respiratory exchange ratio (RER), heart rate, systolic blood pressure (SBP), and oxygen pulse (VO_2/heart rate) were measured during submaximal exercise (3 miles/h and 2.5% grade) and at peak exercise. Patients received no formal exercise conditioning 3-11 wks post-MI. RESULTS:

	Submaximal Exercise		Peak Exercise	
	3 wks	11 wks	3 wks	11 wks
Heart Rate	114	106 *	137	150 *
SBP	160	157	172	185 *
VO_2	15.5	14.6 †	21.0	26.4 *
V_E	36.1	31.1 *	55.2	72.8 *
RER	0.91	0.84 *	1.02	1.05

*$p<0.001$, †$p<0.02$. VO_2 in ml/kg/min, V_E in L/min. Peak VO_2, V_E, RER, SBP, heart rate, and O_2 pulse were unrelated to site of MI. O_2 pulse was unchanged at submaximal exercise and increased (.15 to .17, $p<0.001$) at peak exercise from 3 to 11 wks. CONCLUSIONS: 1) Aerobic capacity improves spontaneously between 3 and 11 wks post uncomplicated MI. This results from a) an increased cardiorespiratory efficiency (decreased heart rate, V_E, and RER during submaximal work and increased peak O_2 pulse) and b) the ability to exercise to a higher heart rate. 2. This spontaneous improvement must be taken into account when assessing the efficacy of any treatment regimens instituted during early convalescence from MI.

CHARACTERISTICS OF EXERCISE PERFORMANCE IN MEN WITH PREVIOUS MYOCARDIAL INFARCTION: (NON) INFLUENCE OF INFARCT LOCATION.

Alan G. Wasserman, M.D., Patrick A. Gorman, M.D. Roy Leiboff, M.D., Allan M. Ross, M.D., FACC, Jorge C. Rios, M.D., for the National Exercise and Heart Disease Project staff, George Washington University Medical Center, Washington, D.C.

Exercise treadmill testing (ETT) is frequently performed in post myocardial infarction (MI) patients but there are few recognized norms for this group. We established baseline performance profiles in a large post MI population as part of the National Exercise and Heart Disease Project. ETT prior to randomization was performed in 651 men, ages 30-64 yrs (m=52), 3-36 mos (m=9.6) post MI. Since MI location is thought to affect function and prognosis, patients were also stratified by qualifying ECG Q wave location: Anterior 113 (17%), Extensive Anterior 41 (6%), Infero-Posterior 291 (45%), Infero-Lateral 84 (13%), Lateral 38 (6%), Subendocardial 58 (9%), and Multiple sites 26 (4%).

Exercise tolerance for the entire group represents an approximate 20% reduction compared to non-MI populations. Endpoints were: METs 7.6±0.1 (mean + SE), heart rate 143±1.0/min, peak diastolic BP 87.9±0.4mm Hg, peak systolic BP 166.8±1.1mm Hg, and double product 24.12±0.24 X 10^3mm Hg/sec. The values were similar for each location subgroup. The Extensive Anterior and Infero-Lateral patients had less percent rise in systolic BP (29.9±3.1% and 31.2±2.0%) vs 35.6±0.8% for all other locations ($p<0.05$).

CONCLUSION: The location and extent of a previous MI as evaluated by the resting ECG does not significantly influence subsequent exercise tolerance.

THE TRAINING EFFECT: DO ATHLETES HAVE IMPROVED LEFT VENTRICULAR PERFORMANCE DURING EXERCISE?

Ben-Zion Bar-Shlomo, M.D., John E. Morch, M.D., David Feiglin, M.D., Peter R. McLaughlin, M.D.,F.A.C.C. Toronto General Hospital, Toronto, Ontario

In order to assess the central effect of training on ventricular performance, we compared left ventricular function during exercise in 9 endurance trained athletes (A, mean age 19) and 11 sedentary controls (C, mean age 28). Gated radionuclide angiograms were obtained at rest and serially during graded supine bicycle exercise performed for 3 minute intervals with increments of 300 KPM to exhaustion. Heart rate (HR), systolic pressure (SP), ejection fraction (EF), and relative change in end-diastolic (EDV) and end-systolic volumes (ESV) from rest to each level of exercise were assessed. Peak workload was much greater in A (mean 22.1 KPM/Kg.) than C (13.7 KPM/Kg. $p<.001$). Mean results at peak exercise are presented.

	HR		SP(mm.Hg.)		EF		% of Rest at Ex	
	Rest	Ex	Rest	Ex	Rest	Ex	EDV	ESV
C	68	159	123	205	67	78	139	98
	$p<.001$		$p<.001$		$p<.001$		$p<.05$	p=ns
A	68	175	113	195	65	80	103	62
	$p<.001$		$p<.001$		$p<.001$		p= ns	$p<.01$
CvsA	p = ns		p = ns		p = ns		$p<.05$	p =ns

We conclude 1)trained and untrained healthy subjects have similar increases in EF during exercise although the peak workload is much greater in A. 2)athletes maintain the same EDV but decrease ESV during exercise whereas untrained subjects increase EDV to achieve the same increase in EF. The ability of athletes to exercise without increasing pre-load may be an effect of training on the heart, and has important implications in reducing myocardial oxygen demand during exercise.

EFFECT OF CORONARY COLLATERALS ON EXERCISE PERFORMANCE. Julian L. Berman, MD; David A. Levin, MD; Peter F. Cohn, MD, FACC, Peter Bent Brigham Hospital, Boston, MA

To evaluate the effect of well-developed collateral circulation (WDCC) on response to maximal exercise, 142 patients (pts) with angiographically proven coronary artery disease (CAD) who underwent maximal treadmill exercise were studied. WDCC was considered present when the distal segment of an obstructed vessel was well opacified via collateral channels and had an average distal lumen diameter > 1.0 mm. We compared exercise duration (ED), peak systolic blood pressure-heart rate product (HRXBP), ST depth and duration, increase in R wave sum, and occurrence of chest pain in 2 groups of pts. Group I consisted of 48 pts with 1 vessel CAD with (17) and without (31) collaterals; Group 2 consisted of 103 pts with 2 or 3 vessel CAD with complete (9) and partial (71) collateralization, as well as 23 pts without collaterals. No significant differences were obtained in any of the variables tested except for significantly lower HRXBP (19.4±0.7 vs. 23.3±1.4, mean±SEM) ($p<.05$) and ED (5.9±0.3 vs. 7.6±0.7, $p<.05$) in Group 2 pts with partial collateral formation. The small number of Group 2 pts totally collateralized did not differ significantly in these variables from either Group 1 pts or Group 2 pts without collaterals. We conclude 1) collaterals do not appear to decrease manifestations of exercise induced ischemia, nor do they improve maximal exercise tolerance or myocardial oxygen uptake; 2) pts with multivessel CAD and partial collateralization appear to have more limitation in exercise tolerance and myocardial oxygen uptake than pts with multivessel CAD who have not formed collaterals, possibly because the latter pts have less severe degrees of ischemia.

PHYSICAL CONDITIONING IN PATIENTS WITH SEVERELY DEPRESSED LEFT VENTRICULAR FUNCTION. Eric H. Conn, MD, R. Sanders Williams, MD; Andrew G. Wallace, MD; Duke University Medical Center, Durham, North Carolina.

The purpose of this study was to determine if patients with severely depressed left ventricular function could demonstrate physical conditioning (PC). Ten patients were identified with documented prior myocardial infarction and a resting left ventricular ejection fraction of < 27% (range 13-26% mean 20%) assessed by radionuclide angiography. Subjects exercised (walk/jog/ergometry) to maintain exercise heart rates at 70-80% of their symptom limited maximum rate 3 to 5 times weekly for periods ranging from 4-21 months, mean 11 months. Performance was evaluated by treadmill testing using a modified Balke protocol. Heart rate at 50% of the initial maximal workload was used to assess (PC), and decreased from a mean of 135 ± 13 to 114 ± 7 beats/min with training ($p < .001$). Maximal treadmill time was used to assess functional capacity and increased from 7.75 min to 10.55 min, $p = .05$. There were no cardiovascular complications during the exercise sessions. Mortality in this group was 2/10 (both non-exercise related) which compared with a one year mortality of 35% in a group of 95 patients with coronary artery disease matched for age and ventricular function.

We conclude that (1) a low ejection fraction per se does not identify a group which is physically incapacitated, (2) these patients can undergo supervised exercise without clinical deterioration, (3) despite extensive cardiac impairment a definite training effect can be demonstrated and functional capacity improved. Though preliminary, these data indicate that selected patients with a low ejection fraction can participate safely and benefit from a supervised conditioning program.

VENTRICULAR DIASTOLIC FUNCTION
10:30-12:00

INFLUENCE OF ASYNCHRONOUS EARLY DIASTOLIC LEFT VENTRICULAR RELAXATION ON DIASTOLIC FUNCTION Philip A. Ludbrook, M.D., F.A.C.C., Joseph D. Byrne, CPT, Washington University, St. Louis, Mo.

Asynchronous early diastolic segmental left ventricular (LV) relaxation (ASR) is observed commonly in patients (pts) with, and without coronary disease. To define the relationship between ASR and altered diastolic LV function, we examined early diastolic wall motion in 21 pts during catheterization, also measuring LV pressure (P) by micromanometer, and simultaneous volume (V) by angiography. Diastolic relaxation was assessed by T, reflecting the rate of isovolumic LV relaxation independent of loading conditions. Normal synchronous diastolic wall motion was present in 11 pts (group I) all of whom also had normally synergic systolic contraction; ASR was seen in 10 pts (group II), 6 of whom had systolic asynergy. Ejection fraction (EF) was subnormal (50%) in the 6 group II pts with systolic asynergy, but was normal in the other 4 group II pts with normal contraction. EF was normal in all group I pts. Aortic; LV systolic; minimal and end diastolic pressures; peak + dP/dt; peak LV systolic pressure to end-systolic volume ratio; mean Vcf; and mean systolic ejection rate were similar in both groups. LV chamber stiffness rate constant of exponential LV P-V relation, volume normalized chamber stiffness, operational chamber stiffness at end diastole, and the slope of the LV log P-log V relation at end diastole, were also similar in each group. Conversely, T was prolonged in group II (55 ± 2.3 msec) compared to values in group I (46 ± 3.6), and peak - dP/dt was lower in group I (1310 ± 57 mm Hg/sec) than group II (1544 ± 93) ($p < .05$ for both). Thus, ASR is unrelated to systolic asynergy or contractility, LV pre- and/or afterload, or diastolic chamber stiffness, but is associated with prolongation of T, and reduction of peak - dP/dt, suggesting global impairment of LV relaxation.

INFLUENCE OF ABRUPT PRESSURE INCREMENTS ON LEFT VENTRICULAR RELAXATION. Marc A. Goethals, MD, Ivo E. Kersschot, MD, Victor A. Claes, Carlo F. Hermans, Antony H. Jageneau and Dirk L. Brutsaert, MD. Department of Physiology, University of Antwerp, Antwerp, Belgium.

In view of the marked load-sensitivity of relaxation in mammalian heart muscle, load-sensitivity of left ventricular relaxation was investigated in the anesthetized open chested dog (n=5). Resistance to ejection was suddenly augmented at various instants during the ejection phase by inflating a balloon occluder, placed around the ascending aorta and controlled by an electromagnetic valve system, allowing for step increases in pressure within 10 ms. Relaxation of the left ventricle was characterized by the onset of isovolumic relaxation and by the time constant of isovolumic pressure decline (τ). The onset of isovolumic relaxation was derived from the interval between the onset of the QRS complex and the aortic incisura (QRS-INC). When the time of the occlusion was progressively delayed after the onset of ejection, QRS-INC shortened from a control value of 278 ± 15 ms (without occlusion) to a minimum value of 256 ± 15 ms ($p < 0.001$) with occlusions imposed at 60.5 ± 2.8 % of the ejection time, whereas τ progressively increased from a control value of 33.5 ± 2.9 ms (without occlusion) to a peak value of 43.6 ± 3.3 ms ($p < 0.001$) with occlusions imposed at 54.7 ± 4.3 % of the ejection time. Pressure increments in the second half of the ejection phase thus elicited an early onset of isovolumic relaxation and concomitantly a slower pressure decline. These data imply that left ventricular relaxation, as evaluated from QRS-INC and τ is significantly influenced by acute alterations in the impedance loading conditions.

DISTRIBUTION OF PRESSURE ACROSS THE LEFT VENTRICULAR WALL IN THE BEATING AND ARRESTED HEART: EVIDENCE OF EPICARDIAL MUSCLE TONE DURING DIASTOLE

Paul D. Stein, MD, FACC; Hani N. Sabbah, BS, Mario Marzilli, MD, Henry Ford Hospital, Detroit, Michigan

Computations of compliance of the left ventricle (LV) assume passive tissue characteristics. To evaluate this assumption, LV intramyocardial pressure was measured simultaneously in the subepicardium and subendocardium during diastole in 9 open chest dogs using 1 mm diameter micromanometers. Subepicardial pressure, 28 ± 2 mm Hg, exceeded subendocardial pressure, 15 ± 2 mm Hg, ($P < .001$) and it exceeded LV end-diastolic pressure (10 ± .4 mm Hg) ($P < .001$). Following an infusion of dextran-40, subepicardial pressure increased to 42 ± 4 mm Hg which was higher than both subendocardial pressure, 27 ± 3 mm Hg ($P<.001$) and LV end-diastolic pressure (25 ± 2 mm Hg) ($P < .001$). Following death of the animal, with the intramyocardial probes unchanged in position, LV pressure 10 ± 1 mm Hg, and subendocardial pressure, 13 ± 3 mm Hg, did not differ significantly from pressure in life. However, subepicardial pressure, 10 ± 1 mm Hg, was lower than in life ($P < .001$). Following distension of the arrested heart with dextran-40 introduced through a LV cannula, subepicardial pressure, 22 ± 3 mm Hg, was lower than subendocardial pressure, 41 < 4 mm Hg, ($P <.001$) and LV pressure, 41 ± 5 mm Hg ($P < .001$). These observations indicate that tone is maintained in the subepicardium during diastole, and the LV wall does not behave as a passive homogenous shell during ventricular filling. Therefore, methods of evaluation of the diastolic properties of the LV that assume passive elastic mechanical properties of the walls fail to account for diastolic subepicardial muscle tension.

EFFECT OF NITROPRUSSIDE ON END-DIASTOLIC PRESSURE-DIAMETER RELATIONS OF THE HUMAN LEFT VENTRICLE AFTER PERICARDIOTOMY

C.Y.H. Wong, M.D. and H.M. Spotnitz, M.D., F.A.C.C. Columbia University, New York, N.Y.

Several investigators have suggested that sodium nitroprusside (NP) may increase diastolic compliance of the left ventricle (LV), but animal models have provided contradictory evidence following pericardiotomy (PERI). Effects of NP on the human LV after PERI have not been reported.

Accordingly, we studied effects of NP in 7 patients during open heart surgery after PERI. Curves relating LV end-diastolic pressure (EDP) (micromanometer) to echocardiographically determined end-diastolic diameter (EDD) were measured during transfusion of volume from the reservoir of the heart-lung machine before and after NP administration (1-5 mcg kg min). EDP varied from 5 to 35 mm Hg. An average relation

$EDP=(.45\pm.18(SE))e^{(1.10\pm.24)EDD}$ was obtained for the 7 patients by exponential curve fitting ($r=.82\pm.02$, unweighted regressions). NP decreased systolic left ventricular pressure (117±6 to 99±5mm Hg, $p<.002$) but did not alter the control curve relating EDP to EDD (variation in EDD less than ±10% at any given EDP).

In conclusion, EDD-EDP relations of the human LV are not altered by NP administration in the absence of the restraining influence of the pericardium. This suggests no direct effect of NP on diastolic properties of the human myocardium.

PRESERVATION OF MYOCARDIAL COMPLIANCE DURING ISCHEMIC ARREST BY APPLIED INTERMITTENT VENTRICULAR STRETCH.

Lance Briggs, BA, J. David Ogilby, MD, and Carl S. Apstein, MD, FACC. Cardiac Muscle Research Laboratory, Boston University School of Medicine, Boston, Mass.

During ischemic arrest (IA) "rigor" bonds may form which decrease diastolic compliance (DC) and, if marked, cause contracture and the "stone heart". We hypothesized that rigor bonds could be lysed by a stretch (S) applied to the myocardium. Isolated, balloon-in-LV rabbit hearts underwent 90 min of IA at either 35° or 25°C and 60 min of recovery (R) at 35°C. Contracture pressure (CP) = increase in LV diastolic pressure at constant balloon vol. and reflected decreased LV DC. In the no-S groups, the LV balloon remained empty during IA. In the S groups, the LV balloon was intermittently filled and emptied (either q 5 or q 30 min) by syringe with a vol. (S vol.) which increased the arrested intra-LV pressure to the pre-arrest systolic pressure. After 90 min of IA, at 35°C, the no-S group (n=10) had 110 ± 4 mm Hg CP; the q 5 min S group (n=10) had CP = 0 ± 1 mm Hg($P<0.001$). During the 5 min inter-S intervals a CP of 20 mm Hg occurred and was completely lysed by a single S. After 60 min of R, CP remained lower in the S group (20 ± 4 vs 42 ± 7 mm Hg, $P<0.001$); recovery of developed (systolic-diastolic) pressure (DP) was 38 ± 3 vs 27 ± 7% of pre-I DP for the S vs no-S groups ($P=0.05 - 0.1$). After 90 min of hypothermic IA at 25°C, the q 30 min S group (n=10) had CP = 15 ± 3 mm Hg vs 91 ± 18 mm Hg for the no-S group (n=10), $P<0.001$. After 60 min R, however, DC was not significantly preserved: CP=33 ± 7 vs 43 ± 9 mm Hg for S vs no-S (P= N.S.) and DP was the same in both groups. Thus a q 5 min S during IA at 35°C preserved DC during IA and R without impairing recovery of contractility. A q 30 min S, despite hypothermia, was less protective of DC during IA, and did not preserve DC during subsequent R.

Effect of Verapamil on Left Ventricular Relaxation and Filling in Hypertrophic Cardiomyopathy.

Peter Hanrath, MD; Detlef Mathey, MD; Peter Kremer, MD; Frank Sonntag, MD; Walter Bleifeld, MD, FACC.
Department of Cardiology, University Hospital Hamburg-Eppendorf, W.-Germany.

Hypertrophic cardiomyopathy (HCM) is often associated with an abnormal prolonged left ventricular isovolumic relaxation time (IVR). In order to examine the effect of Verapamil (V) on left ventricular (LV) IVR – measured from A_2 to mitral cusp separation – simultaneous recordings of the echo- and phonocardiogram were performed in 11 patients (pts) with HCM with (n = 6) and without (n = 5) outflow obstruction. Combined echo- and phonocardiographic recordings were made before (C) and 10 minutes after intravenous (i.v.) injection of V (0.15 mg/kg body weight). From the digitized echo- and phonocardiograms the following LV-dimension and -time calculations were derived: time interval: beginning R-wave – aortic component of the 2nd heart sound ($R-A_2$), isovolumic relaxation time (IVR), dimension increase during IVR (ΔD_{IVR}), LV filling period corrected for cycle length (LVF %), dimension increase during LVF (ΔD_{LVF}), peak rate of posterior wall thinning ($\frac{d\,PW\,min}{dt}$), enddiastolic dimension (DD) and fractional shortening of LV dimension (FS).

$R-A_2$ (ms)	C V	365 ± 38 366 ± 39	LVF (%)	C V	44.2 ± 4.6 49.0 ± 5.3*
IVR (ms)	C V	93 ± 10 67 ± 15***	ΔD_{LVF} (mm)	C V	14.4 ± 2.4 16.4 ± 2.4*
ΔD_{IVR} (mm)	C V	3.8 ± 1.9 2.4 ± 1.4**	DD (mm)	C V	42 ± 4 44 ± 4**
$\frac{d\,PWmin}{dt}$ (mm/s)	C V	64 ± 30 89 ± 38***	FS (%)	C V	44 ± 7 43 ± 7

mean value ± 1 S.D. ***$p<0.0005$, **$p<0.005$, *$p<0.01$

Cycle length (869 ± 76 / 861 ± 81 ms) and systolic blood pressure (139 ± 21 / 135 ± 17 mmHg) were not different between C and V. These results show, that abnormal prolonged IVR in pts with HCM can be shortened by i.v. application of V and may improve LVF.

RELATIONSHIP OF ISCHEMIC CONTRACTURE TO HIGH ENERGY PHOSPHATE CONTENT AND MITOCHONDRIAL FUNCTION IN HYPERTROPHIED MYOCARDIUM

James D. Sink, MD, William D. Currie, Ph.D., Ronald C. Hill, MD, Craig O. Olsen, MD, Robert N. Jones, MD, Andrew S. Wechsler, MD, Duke and VA Medical Centers, Durham, North Carolina

Hypertrophied (H) myocardium appears more susceptible to ischemic injury, however, the biochemical response of H hearts to ischemia has not been fully elucidated. ATP, and CP (μmoles/gm dry weight) and mitochondrial function (respiratory control index, RCI), were determined in 75 normal (N) and 63 H isolated rat hearts following 15 minutes of Langendorf perfusion (control), at initiation of ischemic contracture, and at completion of contracture. Duration of ischemia prior to occurrence of these events was noted. H, produced by banding the ascending aorta was confirmed by left ventricular (mg)/body weight (gm) ratio (N 1.92 wet, 0.43 dry; H 2.69 wet, 0.59 dry). Results are below (*p<0.05 for N vs H):

		RCI	ATP	CP	Ischemia (min)
Control	N	6.6±0.4	29.2±1.1	33.9±2.4	
	H	8.1±0.5*	20.3±1.3*	28.3±2.4*	
Initiation	N	5.3±0.3	14.3±1.0	6.3±0.4	10.1±0.7
	H	7.1±0.8*	12.0±0.5*	2.4±0.1*	6.7±0.5*
Completion	N	3.4±0.2	4.6±0.7	5.2±0.5	19.9±0.7
	H	5.7±0.3*	2.0±0.2*	2.4±0.1*	23.1±1.0*

H hearts had accelerated initiation of contracture. Our study suggests that the increased susceptibility of H myocardium to contracture may result from the lower ATP stores present at onset of ischemia. The imbalance in ATP anerobic production and utilization present during the first moments of ischemia due to continued contractile activity may also be greater in the H heart resulting in a more precipitous decline in already decreased energy stores and a more rapid onset of contracture.

EFFECTS OF PULSATILE AND NONPULSATILE REPERFUSION ON THE POST-ISCHEMIC MYOCARDIUM

Frederick H. Levine, MD; Geir J. Grotte, MBBS; John T. Fallon, MD, PhD; W. Gerald Austen, MD, FACC; Mortimer J. Buckley, MD, FACC, Massachusetts General Hospital, Boston, Ma 02114

Pulsatile perfusion has been reported to improve myocardial function, metabolism and blood flow distribution, and therefore to be of clinical value in myocardial protection. No studies have evaluated the clinically relevant effect of pulsatile reperfusion after a period of aortic cross-clamping. Twenty-two dogs were therefore studied during cardiopulmonary bypass with either a period of normothermic ischemia (N-10dogs-60min) or hypothermic potassium cardioplegia (KCP-12 dogs-90min) and divided equally into pulsatile (P) and non-pulsatile (NP) groups. After cross-clamp removal either P or NP reperfusion was carried out for 45 minutes with a beating vented heart. Left ventricular (LV) function was analyzed prior to ischemia and again after the reperfusion period by analysis of computer drawn Sarnoff curves. Microspheres were used to study regional myocardial blood flow and coronary venous samples were taken for lactate and oxygen utilization. LV biopsies were obtained for electron microscopy. Percent recovery of LV function in the N groups was P-57% and NP-62%, and in the KCP groups was P-92% and NP-89%. Total coronary blood flow and subendocardial perfusion were similar in both pulsatile and non-pulsatile groups. Lactate utilization and oxygen consumption were also unchanged with pulsatile perfusion. Electron microscopy demonstrated significant myocytic and capillary endothelial damage in the N groups but there was no alteration with pulsation. Pulsatile reperfusion offers no advantage over non-pulsatile reperfusion in the post-ischemic vented beating heart.

THE NO-REFLOW PHENOMENON: NOT A TIME-LIMITING FACTOR FOR REPERFUSION FOLLOWING CORONARY OCCLUSION

John E. Darsee, MD, Robert A. Kloner, MD, PhD. Peter B Brigham Hosp/Harvard Med Sch, Boston, MA

Following release of a coronary occlusion (occ) some tissue may not reperfuse ("no-reflow" phenomenon). To ascertain whether this is a critical factor determining the time beyond which revascularization can no longer salvage ischemic myocardium and to determine whether reperfusion damages tissue otherwise not destined to necrosis, 13 open-chest anesthetized dogs had either 2 hrs left anterior descending (LAD) occ and 4 hrs reflow (n=7) or 6 hrs of occ with reflow only to allow dye injection (<2 min;n=6). Prior to sacrifice, left atrial injections of thioflavin-S (1 cc/kg) were made with the LAD unclamped followed by methylene blue (3 cc/kg) with the LAD reclamped. Hearts were sliced into 5 mm transverse sections and areas not perfused by thioflavin-S (area of no reflow=A_{nr}), and by methylene blue (area-at-risk=A_r) were traced on clear plastic sheets, planimetered, and compared to the area of necrosis (A_n) determined by incubating the slices in triphenyl tetrazolium chloride. A_r was similar at 2 hrs (27±3%) and 6 hrs (29±2% of the left ventricle;p=NS). However, A_n/A_r was significantly smaller in dogs with 2 hrs of occ plus reflow (.39±.03) than in dogs with 6 hrs of occ (A_n/A_r=.96±.07, p<.001). The A_{nr}/A_r in 2 hr dogs was significnatly smaller than A_n/A_r (.11±.02 vs .39±.03, p<.01);A_{nr}/A_r was also smaller than A_n/A_r in 6 hr dogs (.46±.05 vs .96±.07, p<.01). In all dogs the A_{nr} was contained geographically within the A_n and was subendocardial. We conclude: 1) the A_{nr} does not determine critical time for salvageability by revascularization since A_{nr} always occurs within dead myocardium; and 2) reperfusion does not increase the quantity of ischemic tissue which becomes necrotic and in fact salvages substantial quantities of subepicardial tissue.

COMPARATIVE HEMODYNAMIC EFFECTS OF NITROGLYCERIN AND NITROPRUSSIDE DURING RECOVERY

Michael Todd, M.D., Phillip Morris, M.D., Daniel Philbin, M.D., FACC. Massachusetts General Hospital, Boston, Mass 02114

Both nitroglycerin (NG) and nitroprusside (NP) have been used extensively intraoperatively to control or reduce blood pressure with similar hemodynamic changes reported. This study was undertaken to determine the changes following discontinuation of these drugs. Ten dogs anesthetized with halothane were studied. Five each received either NG or NP to reduce $\overline{BP}$ to 70% of control for 30 min. During recovery measurements were made at 5,15,30 and 60 min of $\overline{BP}$,CVP,$\overline{PA}$,PCW,heart rate and CO. There was no significant change in HR in either group. Neither group had returned to control $\overline{BP}$ at 60 min but the NP group was higher (84±4 vs 72±4 mmHg). In the NG group $\overline{PA}$ (12.6±0.3 to 12.1±0.6 mmHg) PCW(5.5±0.7 to 4.56±0.5 mmHg) and CVP(2.8±0.4 to 2.7±0.6mmHg) were close to control at 5 min. In contrast, in the NP group the PA rebounded above control values (13.1±1.6 to 14.7±1.8-(5min) to 15.9±1.9 mmHg (15min) and remained elevated at 60 min (16.9±1.5 p<0.05). The CVP followed a similar pattern (2.29±1 to 3.15±0.1 mmHg at 5 min - p<0.05). These data demonstrate that while the hypotension produced by NG and NP have similar hemodynamic effects, NG action is more prolonged. Discontinuation of NP is associated with a more rapid rise in BP and an apparent rebound effect on the PA rising above control. This suggests reflex pulmonary vasoconstriction following abrupt cessation of NP which may be clinically significant in patients with pre-existing pulmonary hypertension or pre-existing right ventricular dysfunction.

EFFECTS OF INTRA-AORTIC BALLOON PUMPING ON REGIONAL AND TOTAL CORONARY FLOW IN PATIENTS WITH CORONARY DISEASE.
James L. Whittle, MD; Robert L. Feldman, MD; Carl J. Pepine, MD, FACC; Wilmer W. Nichols, Ph.D., FACC; John Selby, MD, FACC; Thomas Kelly, MD; C. Richard Conti, MD, FACC; University of Florida, Gainesville, Florida.

To clarify coronary hemodynamic effects due to intra-aortic balloon pumping(IABP) we studied total and regional coronary hemodynamic responses in 12 pts with coronary artery(CA) disease. Measurements were made during and 5 min after IABP was turned off. The left ventricle(LV) was divided into anterior (supplied by the anterior descending) and inferior (supplied by the circumflex and/or right CA regions). These LV regions were considered ischemic (isch) when ST segment shifts were observed in either anterior or inferior ECG leads during angina. All indentified isch regions were supplied by CA's with >90% diameter narrowing. Total anterior and inferior flow(F) and oxygen delivery($\dot{V}O_2$) were measured by coronary sinus(CS) and great cardiac vein(GCV) sampling using continuous regional thermodilution.
RESULTS: Heart rate and mean aortic pressure were similar during and off IABP. CSF was higher during IABP compared to off (157±21 to 142±20 ml/min, $p<0.05$). Isch region F was higher during IABP than off IABP (61±8 to 50±7 ml/min, $p<0.05$) while non-isch region F was unchanged (96±18 to 92±18 ml/min, p=NS). Total LV$\dot{V}O_2$ was similar during and off IABP (12.8±0.9 to 12.4±1.9 ml/min, p=NS). However, isch region $\dot{V}O_2$ was greater during IABP compared to off IABP (5.1±0.7 to 3.6±0.6 ml/min, $p<0.01$). Non-isch region $\dot{V}O_2$ was similar during and off IABP (7.7±1.2 to 8.8±1.1 ml/min, p=NS).
CONCLUSIONS: In selected pts with coronary disease, IABP increases blood flow to isch LV regions. This beneficial effect has the potential to increase regional oxygen delivery.

PERCUTANEOUS INTRA-AORTIC BALLOON PUMPING
David Bregman, M.D., FACC; Melvin B. Weiss, M.D., FACC; William J. Casarella, M.D., Columbia University, New York, New York

A 40cc percutaneous intra-aortic balloon (PIAB) has been developed which obviates the need for the usual surgical procedure to insert an intra-aortic balloon pump. The balloon can be tightly wrapped around a central wire within the balloon membrane so that it can be inserted by the standard Seldinger technique through a 12 French angiographic sheath. Insertion and removal are rapid and the resultant hemodynamics are similar to standard intra-aortic balloon pumping.
The PIAB has been employed in 9 patients (7 males, 2 females) at the Columbia Presbyterian Medical Center without complication. The average time for balloon insertion was between 3 and 4 minutes.
The clinical series includes 2 patients with crescendo angina refractory to medical therapy and 2 patients with postinfarction angina. These 4 patients underwent successful surgery, and all 4 patients survived and were discharged. PIAB was utilized to support an additional patient while undergoing treatment for septic shock. One patient underwent intraoperative PIAB for weaning from cardiopulmonary bypass who expired in the operating room. Three patients were treated in the recovery room for low cardiac output syndrome after open heart surgery and 2 of these 3 patients survived.
In the 7 survivors the balloon was removed at the bedside with 30 minutes of external pressure on the femoral artery. No complications ensued and all patients had good distal pulses.
Percutaneous intra-aortic balloon pumping appears to be a practical alternative to standard intra-aortic balloon pumping in patients who require either pre-, intra-, or postoperative counterpulsation.

THE HEART IN POLYARTERITIS NODOSA: A CLINICO-PATHOLOGIC STUDY OF 36 PATIENTS
Margaret L. Schrader; Bernadine H. Bulkley, MD, FACC. The Johns Hopkins Medical Institutions, Baltimore, Maryland.

Although polyarteritis nodosa (PAN) is known to affect the heart, there is little recent information on its cardiac pathology in the light of current therapies. We studied 36 autopsied patients with PAN that came to autopsy at this institution since 1935. Excluded were those with acute rheumatic fever, other collagen vascular diseases or arteritis of large vessels. Included were cases with healed or active lesions of small or medium sized vessels in at least two organs other than heart. The patients ranged in age from 11 months to 76 years, and 46% were women. Systemic hypertension was present in 72% of patients and congestive heart failure in 61% and was not less in recent or steroid-treated cases. At autopsy 24 (67%) hearts were hypertrophied; 10 (28%) had fibrous or fibrofibrinous pericarditis. Coronary arteritis, present in 18 (50%) patients, was healed in 6, subacute in 5, and acute in 7. Of these patients, 16 (89%) had focal myocardial necrosis and/or fibrosis; in 3 (17%) grossly evident myocardial infarction was present. Although the incidence of coronary involvement was not significantly different, active arteritis was evident most frequently in patients dying before 1952 (29%) and was least frequent in those treated with corticosteroids (8%).

The findings suggest that clinically significant cardiac abnormalities in PAN are common but are now mostly due to hypertension and renal failure. Coronary arteritis, although evident in half of patients, is now mostly healed or mild. Thus, although not diminishing and possibly aggravating, the secondary consequences of PAN on the heart, corticosteroid therapy appears to have altered the extent and quality of its coronary arteritis.

THE HEART IN PANCREATITIS: A COMBINED CLINICO-PATHOLOGIC STUDY OF 128 CASES
John R. Darsee, MD, Ruth E. Fincher, MD, Michael Fincher, MD, Candace L. Miklozek, MD, Ayten O. Someren, MD, J. Willis Hurst, MD, FACC. Emory University School of Medicine, Atlanta, Georgia

Since pancreatitis is thought to mimic electrocardiographic (ECG) features of acute myocardial infarction, produce cardiac dysfunction, pericarditis, and bizarre dysrhythmias, we characterized the cardiac features of 128 cases of pancreatitis: 42 clinical patients (P) studied prospectively and 86 clinical and necropsy cases studied retrospectively (22 also had hypertension and 14 had diabetes); 42 alcoholic patients and 86 disease-matched necropsy cases without pancreatitis served as controls (C). In clinical P, there was hypocalcemia-related QT prolongation in 8 (controls=6), transient atrial fibrillation in 4 (C=6), new T-wave inversion in 6 (C=5), and a transient moderate-sized pericardial effusion by echocardiography in 5 (C=7). Necropsy P and C showed a similar frequency of patchy interstitial myocardial fibrosis (P=36%, C=39%) associated with ECG conduction disturbances, heart block or T-wave inversion, pericardial effusions (10-300cc) (P=31%; C=27%), and fibrinous pericarditis (P=8%; C=5%) in uremic patients only; "pathological" Q waves on the ECG were always associated with significant (>75% cross-section) extramural coronary atherosclerosis (P=10%; C=12%). Although isolated case reports suggest that distinct cardiovascular manifestations of pancreatitis exist, this study of 128 cases supports the view that: 1) ECG abnormalities, pericarditis, and pericardial effusions are not caused by pancreatitis, but more likely by alcoholism, hypertension, uremia, and other coincident disorders; and 2) electrocardiographic signs of myocardial ischemia or infarction are due to coronary atherosclerosis and not to pancreatitis.

THE ANTHRACYCLINE HEART: ANALYSIS OF 69 PATIENTS TREATED WITH EITHER ADRIAMYCIN OR DAUNORUBICIN SHOWING A LACK OF CORRELATION BETWEEN CLINICAL AND MORPHOLOGIC FINDINGS

Jeffrey M. Isner, MD, FACC, Steven R. Cohen, Victor J. Ferrans, MD, Bruce G. Witkind, Renu Virmani, MD, John S. Gottdiener, MD, William C. Roberts, MD, FACC, National Heart, Lung, and Blood Institute, Bethesda, Maryland

Clinical cardiac toxicity (T) due to the anthracycline (A) drugs, adriamycin and daunorubicin, has been well documented. Little information is available, however, on either the necropsy findings of patients (pts) treated with these drugs or the relationship of clinical to morphologic signs of T. We studied 91 pts (ages 5-70 yrs, avg 45) who died after A therapy; 22 were excluded because of severe anemia, renal failure, non-A drug T, sepsis or because clinical evidence of T was equivocal. Of the remaining 69 pts, clinical evidence of AT was present in 23 and absent in 46. Of the 23 (33%) pts with unequivocal clinical AT, 10 (43%) had histologic findings (vacuolization, myofibrillar loss, interstitial fibrosis) of AT, while 13 had none. Of 46 (67%) pts without clinical signs of AT, 21 (46%) had histologic findings suggestive of AT. Gross examination of the hearts in the 23 pts with clinical AT disclosed 7 (31%) in whom cardiac dilatation was not present and in each the interval from onset of T to death was < 4 wks. Of the 31 pts with histologic signs of AT (with or without clinical AT), the left ventricle was involved in 90%, ventricular septum in 72%, and right ventricle in 56%. The presence of histologic abnormalities at necropsy was unrelated to the total dose or duration of A therapy, the interval from last dose to death, or the interval from onset of clinical T to death. Thus, a poor correlation exists between clinical and histologic signs of AT: pts with clinical signs of AT may have no histologic evidence of AT, and pts without clinical signs of AT may have extensive histologic abnormalities.

DIAGNOSIS OF CHAGAS CARDIOMYOPATHY BY THALLIUM 201 PERFUSION IMAGING.

Nusen Beer, Yuly Kertsnuz, Henry Collet, Hospital General del Oeste, Caracas, Venezuela.

Chagas disease affects early in life a large amount of the population in the rural area of several countries in South America (Venezuela, Brazil, Argentina). With the advances in medical and surgical therapy an early diagnosis is essential. In the early stages the disease affects the apex of the heart. With progression of the disease process other areas of the heart are involved. Myocardial perfusion images were performed in 15 patients with proven diagnosis of Chagas disease. Following the injection of 1.5-2.0 Mci of Thallium 201 at rest, imaging was performed in the left anterior oblique 45° and anterior posterior views. Coronary arteriography were performed in all the patients to exclude coronary artery disease. All patients had positive serology for Chagas.
Results: Apical lesions in 14 patients, septal lesions in 9 patients, posterolateral wall in 14 patients and inferior wall in 5 patients. These findings indicate: (a) There is a good correlation with previous pathology findings that demonstrated early lesions were located at the apex of the heart. (b) Chagas disease is a segmental disease affecting one or multiple segments of the myocardium. (c) Thallium 201 could identify the apical lesion in 14 of the 15 patients, and was able to identify other areas of the myocardium involved in the disease process, and (d) Thallium 201 imaging could be used as a non invasive technique for the early diagnosis of myocardial involvement and effects of therapy.

HEREDITARY PROGRESSIVE CARDIAC CONDUCTION AND MUSCLE DISEASE: CLINICAL STAGING

Harry L. Graber, MD; Joseph M. Ryan, MD, FACC; Nobuhisa Baba, MD and Charles F. Wooley, MD, FACC; The Ohio State University College of Medicine, Columbus, Ohio.

Familial cardiomyopathy and hereditable disorders of the cardiac conduction system (CCS) are incompletely defined. Ten family members (FM) with progressive CCS disease eventually developed congestive cardiomyopathy (COCM). All had pacemaker therapy. Catheterization (3), electrophysiologic studies (3), myocardial biopsy (3), and CCS autopsy study (1) defined CCS disease and diffuse atrial, ventricular fibrosis.

FM were traced from 1803-1979. Five FM of generation (G) 3,4 had slow heart rate, death by age 50; 10 FM of G 4,5 had heart block, 7 developed COCM, 4 are dead; 5 FM of G 5,6 have prolonged PR interval, with symptoms; 11 FM of G 5,6 have symptoms, PACs, abnormal P waves, bradycardia; 10 FM of G 5,6 have sinus bradycardia, no symptoms. Inheritance is autosomal dominant.

Clinical staging of FM suggests: Stage I - occurs in first and second decade with PACs, bradycardia and normal heart size; Stage II - with normal heart size, development of A-V block by third decade; Stage III - with advanced A-V block by fourth-fifth decade; Stage IV - with atrial arrhythmias, progressive COCM preceding death.

These data 1) document hereditable heart disease, distinctive clinical stages with early CCS involvement, progression to A-V block and chronic atrial arrhythmias, pacemaker therapy and COCM; 2) demonstrate a firm basis for the concept of hereditary COCM; 3) support the concept that genetic factors are involved in development of cardiac muscle, CCS fibrosis of adult onset. The diffuse nature of the process suggests the basic defect may be a hereditable cardiac membrane defect.

PATHOGENESIS OF MITRAL VALVE PROLAPSE (MVP) SYNDROME IN CHILDREN WITH DUCHENNE'S MUSCULAR DYSTROPHY: AN ULTRASTRUCTURAL AND HISTOLOGIC BASIS.

Shyamal K. Sanyal, F.A.C.C.*, Warren W. Johnson, M.D. St. Jude Children's Research Hospital, Memphis, TN.

We have previously reported a high prevalence of MVP syndrome in children with Duchenne's muscular dystrophy (DMD). The objective of this study was to determine if the valve disorder in patients with DMD arose from cardiomyopathy due to the primary disease or from dystrophic changes in the mitral valve itself. In 3 male children with Duchenne's muscular dystrophy, 13-15 years of age, who met accepted clinical, phono- and echocardiographic evidence of MVP syndrome the hearts were perfused within 1-2 hours of death, for 4 hours with 2.5% glutaraldehyde, 0.1M sodium cacodylate, pH 7.2, temp. 4°C. Gross, histologic and ultrastructural features of the following were noted: mitral valve anulus; anterior and posterior leaflets; origin, distribution pattern, length and thickness of chordae tendineae; right and left ventricular myocardium; anterior and posterior papillary muscles. For comparison, hearts from 3 age and sex matched, healthy normal children who died from accidents, were similarly studied. Mitral valves in DMD patients were entirely normal. The leaflets were neither redundant nor showed myxoid degeneration or accumulation of "granular cells". There were no changes in anulus or in number, origin, distribution, length, thickness, histologic and ultrastructural features of chordae tendineae. By contrast, myocardium in DMD patients showed gross cellular and subcellular alterations. Multifocal areas of myofiber degeneration with fibrosis and loss of contractile elements - thick as well as thin myofilaments - giving a "moth-eaten" appearance to the myofiber, were the predominant histologic and ultrastructural findings. These changes were most extensive in posterior papillary muscle and posterobasal segments of the left ventricle and in decreasing order of severity, in free wall of the left and right ventricle, interventricular septum and anterior papillary muscle. Observations of this study, therefore, confirm our earlier speculation that MVP syndrome in children with DMD is an expression of cardiomyopathy involving papillary muscles and ventricular myocardium rather than due to dystrophic changes in the mitral valve leaflets, anulus or chordae tendineae.

METHODS FOR ASSESSING VENTRICULAR FUNCTION
10:30-12:00

QUANTIFICATION OF LEFT VENTRICULAR VOLUME BY EQUILIBRIUM RADIOVENTRICULOGRAPHY

Michel H. Bourguignon, MD; J.Gregory Schindeldecker, CNMT; Robert D.Burow, BS; Edwaldo E.Camargo, MD; Lewis C.Becker, MD; Henry N.Wagner, Jr, MD. The Johns Hopkins Medical Institutions, Baltimore, MD.

We have developed a simple method for measuring LV volume based on semi-automated analysis of 40°LAO images obtained with the scintillation camera after equilibrium of an intravenous injection of Tc-99m red blood cells. The essence of the method is the use of the dimensions and radioactivity within a segment of aorta to convert observed LV counting rates to volume. We made 4 assumptions: (1)The edges of the aorta can be delineated as the lines where the second derivative of a cross sectional profile equals zero. (2)Ventricular and aortic arch counts undergo the same attenuation because of their anatomical proximity. (3)An aortic region of interest is selected that has the shape of a right cyclinder parallel to the camera face. (4)We measure the activity within two regions whose shape is known, one in the middle, the other at the edge of the aortic arch. Subtraction of these activities and volumes gives a volume/activity ratio that does not require measurement of background. The equation used is:EDV=(AV/AC)EDC, where EDV and EDC are left ventricular end diastolic volume and counts, AV and AC are aortic volume and counts. In initial validation, 19 patients were evaluated by equilibrium radio- and contrast ventriculography, the latter analyzed by planimetry. It was possible to identify the edges of the aortic arch by the 2nd derivative program in 12/19 patients. In these 12 patients, the radionuclide method yielded an end diastolic volume that correlated well with contrast ventriculography (r=0.95, Y=1.03 X + 3 ml). In addition to its simplicity and objectivity, a major advantage of this method of determining ventricular volume is that it does not require a blood sample.

COMPUTERIZED ANALYSIS OF BIPLANE LEFT VENTRICULOGRAPHY: INTRA-METHOD VARIATION IN THE ABILITY TO IDENTIFY AND QUANTIFY REGIONAL WALL MOTION ABNORMALITIES.

John D. Slack, MD; John K. Landon, PhD; Henry G. Hanley, MD; James S. Cole, MD, FACC, Veterans Administration and University of Kentucky Medical Centers, Lexington, KY.

Accurate separation of normal from abnormal regional wall motion (RWM) is possible using several methods of RWM analysis (A). The ability of each method to discriminate between hypokinetic and akinetic-dyskinetic (A-D) motion in an area of RWM abnormality (Abn) has not been evaluated. Therefore the ability of 6 commonly used methods of computerized RWMA to identify RWM Abn as well as to quantify that RWM Abn as A-D was tested in 58 patients undergoing calibrated biplane (30° RAO-60° LAO) left ventriculography (angio) who had clinical and electrocardiographic (ECG) evidence of healed transmural myocardial infarction (MI). The 6 methods of RWMA tested were: [I: 30° radial (rad) chords (C), II: 30° rad triangles (tri), III: 60° rad tri, IV: 90° rad tri, V: hemiC, VI: rectangular areas]. Four ECG/angio sites were analyzed: Anterior, Inferior, Posterolateral and Septal. RESULTS: ECG identified 108 MI regions in the 58 patients, and these were presumed A-D to allow statistical analysis.

Method	I	II	III	IV	V	VI
%RWM Abn	81.5	75.9**	67.0*	80.6	66.7*	82.4
% A-D	60.2	55.6	24.1*	36.1*	57.4	25.0*

(*$p<.001$), (**$p=.05$).

The ability of Method I to detect both RWM Abn as well as RWM A-D was compared to each of the other methods, and it was found significantly better where indicated (*). CONCLUSION: Methods I, II, IV and VI are equally sensitive in identifying regional wall motion abnormality. Method I, however, is most capable of both identifying a regional wall motion abnormality and quantifying that region as A-D in areas of transmural myocardial infarction.

RELATIONSHIP BETWEEN RIGHT ANTERIOR OBLIQUE CINE ANGIOGRAPHIC AND M-MODE ECHOGRAPHIC LEFT VENTRICULAR DIMENSIONS

Richard P. Lewis, M.D.,FACC; Paul D. Ruff, M.D.; Harisios Boudoulas, M.D.,FACC; Phillip K. Fulkerson, M.D., The Ohio State University College of Medicine, Columbus, Ohio.

Previous studies have indicated a high correlation between angiographic fractional minor diameter (D) change (%ΔD) and LV ejection fraction (EF) where D is obtained by the area-length method. This is the basis for using %ΔD from M-mode Echo as a measure of LV function. We studied LV dimensions in 90 adult patients (pts) by RAO cine (corrected by method of Kasser) and M-mode Echo employing standard technique. There were 20 normals, 30 with primary myocardial disease, and 40 with mitral and/or aortic regurgitation. None had localized contraction abnormalities. As volume increased, the LV became more spherical (decrease in ratio of length to D or L/D) regardless of the etiology. For angiographic end diastolic D (EDD) of <5.5cm the L/D was 1.7 $\pm$ .1, for 5.5 -7.5cm the L/D was 1.6 $\pm$ .2, and for >7.5cm the L/D was 1.4 $\pm$ .2 ($p<.05$). Similarly for end systolic D (ESD) of <4cm the L/D was 2.2 $\pm$.3, for 4-6cm the L/D was 1.8 $\pm$ .2, and for >6cm the L/D was 1.5 $\pm$.2 ($p<.05$).

Echo EDD was consistently smaller than angio EDD and the difference was magnified at larger EDD ($p<.01$). The difference was .46 $\pm$ .2cm for EDD <5cm, .80 $\pm$ .2cm for EDD of 5.5 -7.5cm, and 1.36 $\pm$ .2cm ($p<.001$) for EDD >7.5cm. Similar significant differences were found for ESD. This data indicates that M-mode Echo does not measure calculated angio D. The phenomenon is exaggerated by the changes in LV shape which occur with dilatation. The result is a relatively poor correlation of Echo %ΔD and angio EF (r =0.69), compared to r =.98 for angio %ΔD and EF. Therefore, we feel that the current M-mode Echo approach to assessing LV function should be re-examined.

CONTRIBUTION OF INTERVENTRICULAR SEPTAL WALL MOTION TO RIGHT AND LEFT VENTRICULAR FUNCTION: VISUALIZATION BY BIVENTRICULAR ANGIOGRAPHY

Vidya S. Banka, MD, FACC; Jai B. Agarwal, MD; Monty M. Bodenheimer, MD, FACC; Richard H. Helfant, MD, FACC, Presbyterian-University of Pennsylvania Medical Center, Philadelphia, Pennsylvania.

The interventricular septum (IVS) has conventionally been regarded as a functional part of the left ventricle (LV). To determine its normal range of motion, simultaneous biventricular cineangiograms (60 frames/sec) were performed (60° left anterior oblique) in 9 subjects without coronary or other heart disease. Arrhythmias were avoided by using a specially designed right ventricular (RV) angiographic catheter. IVS motion was studied qualitatively by three observers and quantitatively by superimposing end-systolic and diastolic frames using intra and extracardiac reference points. Two transverse chords which trisected the end-systolic length of the IVS were drawn to quantitate IVS, LV and RV free wall motion. Qualitatively, the IVS thickened towards both RV and LV cavities resulting from shortening on its longitudinal axis. LV motion was 43.3$\pm$3.7% on the transverse axis of which 33.3$\pm$3.2 was contributed by LV free wall and 9.0$\pm$ 1.1% by IVS. RV transverse axis motion was 40.7$\pm$7.1%, the RV free wall contributing 30.5$\pm$4.3% and IVS 10.2$\pm$ 3.6%. There was no difference between IVS motion toward LV or RV. The IVS longitudinal axis shortened by 17.4$\pm$ 2.8% ($p< 0.001$). Systolic IVS thickness symmetrically increased by 75.2$\pm$12.4% (from 7.4$\pm$0.5mm to 12.5$\pm$0.4 mm) ($p< 0.001$). In summary, the interventricular septum thickens on its transverse axis and shortens on its longitudinal axis contributing equally to the right and left ventricular function.

ASSESSMENT OF LEFT VENTRICULAR FUNCTION BY DETERMINATION OF MAXIMUM ACCELERATION OF BLOOD FLOW IN THE AORTA USING CONTINUOUS DOPPLER ULTRASOUND

P.A.N. Chandraratna, MD, FACC; B. Silveira; W. S. Aronow, MD, FACC, Long Beach Veterans Administration Medical Center, Long Beach, California

Using catheter tip velocity probes placed in the ascending aorta, previous investigators have demonstrated that maximum acceleration of blood flow in the aorta is a sensitive index of left ventricular contractility. This investigation was designed to determine whether maximum acceleration of blood flow in the aorta determined non-invasively by continuous Doppler ultrasound would be of value in determining left ventricular function. A calibrated continuous Doppler ultrasound probe was placed in the suprasternal notch and angulated posteriorly, inferiorly, and slightly laterally so that the ultrasound beam was more or less parallel to the direction of blood flow in the arch of the aorta. The velocity signal thus obtained was recorded at 100 mm/sec. The maximum acceleration of blood flow in the aorta (dv/dt) was determined by measuring the slope of the steepest part of the velocity curve. Ejection fraction determined by left ventricular cineangiography was used as an invasive parameter of left ventricular function. Twenty-eight patients with coronary artery were studied. The maximum dv/dt correlated well ($r = 0.83$) with ejection fraction. The maximum dv/dt ranged from 91 to 192 cm/sec^2. Eleven of 12 patients (92%) with a maximum dv/dt of <116 cm/sec^2 had an ejection fraction of <50%; and 16 of 16 patients (100%) with a dv/dt of >116 cm/sec^2 had an ejection fraction >50%. We conclude that noninvasively determined maximum acceleration of blood flow in the aorta, is a useful parameter of left ventricular function, and that this technique is of value in detecting impaired left ventricular performance.

VENTRICULAR PHASE ANALYSIS OF RADIONUCLIDE GATED STUDIES

Dan Pavel, M.D.; Steven Swiryn, M.D.; Wilfred Lam, M.D.; Ernest Byrom, Ph.D.; Amjad Sheikh, M.D.; Kenneth Rosen, M.D., Univ. of Illinois, Chicago, Il.

Phase analysis has been applied to 55 gated studies (GS). The procedure is based on a Fourier analysis of the variation of counts in each pixel over the 64 images representing the cardiac cycle. This leads to 2 functional images: the amplitude and the phase images (Phi). The phase lag can be quantified in degrees using color scales which cover a 360° span. The present data are based on 15 patients in whom contrast angiography (CA) was performed. Only LAO views were correlated because not all patients had GS in two views, and only the free borders were considered (inferior and postero-lat. wall). Results

C.A. Code	Phi / W.M.	10-20°	30-60°	60-110°	150-180°	Total
1	Normal	14	3	0	0	17
2	Hypokinesia	0	3	3	0	6
3	Akinesia	0	0	4	1	5
4	Dyskinesia	0	0	0	2	2

The Fisher's exact test shows a strong association when normal versus abnormal segments are considered ($p<.0001$). The correlation coefficient calculated by assigning a code to the 4 categories is 0.89 ($p<.01$). 1) Regional wall motion abnormalities (RWMA) appear out of phase with the rest of the ventricle. 2) On the 30 segments studied the RWMA was easily quantified: the higher the phase lag, the more accentuated the abnormality. 3) The delineation of abnormal areas is sharp and reproducible and can easily be used for quantitative evaluation of the surface involved. Conclusion: This method allows quantification of free border RWMA and is a valuable tool for the qualitative and quantitative assessment of ventricular function in general.

PM
CORONARY ARTERY DISEASE: DIAGNOSTIC METHODS
2:00-5:30

RIGHT VENTRICULAR VOLUME: ANALYSIS BY EQUILIBRIUM RADIONUCLIDE ANGIOGRAPHY IN NORMAL SUBJECTS AND PATIENTS WITH CORONARY DISEASE.

Robert Slutsky, MD; Joel Karliner, MD, FACC; William Ashburn, MD, University of California, San Diego.

To assess a new method for the noninvasive evaluation of right ventricular (RV) volume, we analyzed 10 normal subjects group (I) and 30 patients (pts) with coronary artery disease (CAD) by equilibrium radionuclide angiography. RV end diastolic volume (EDV) in non-geometric units was developed from the RV time-activity curve obtained from fixed RV and background regions-of-interest. Volume was obtained from ED counts and corrected for plasma radioactivity, frame-time and the number of processed cardiac cycles. The 30 CAD pts were divided into 2 separate groups; 20 with RVEDP $<$ 10 mmHg (II) and 10 with RVEDP $\geq$ 10 mmHg (III).

	RVEF	RVEDVI	RVEDP mmHg	PAP, mmHg
I	0.53 ± .09	5.14 ± .59	--------	--------
II	0.54 ± .16	5.20 ± 1.05	6.5 ± 2	13.0 ± 4.6
III	0.41 ± .12*	8.62 ± 1.99*	12.9 ± 2.9*	28.7 ± 11.1**

*$p<.01$ vs I + II **$p<.01$ vs II PAP = pulmonary artery mean pressure. All results are mean ± 1 SD.

Only 1 of 20 (5%) pts in Group II had a depressed RVEF and 2 (10%) had an increased RVEDVI. Nine of 10 (90%) patients in III had an increased RVEDVI, while only 4 of 10 (40%) had a depressed RVEF. We conclude that RV dysfunction occurs in association with increases in RVEDP in pts with CAD. The data suggest that RV dilatation occurs prior to depression of RVEF at rest. Equilibrium radionuclide angiography may be used to evaluate changes in RV size, which may be an early sign of RV disease in patients with coronary artery disease.

THALLIUM-201 EXERCISE SCINTIGRAPHY FOR DETECTION OF MULTIVESSEL DISEASE IN PATIENTS WITH PRIOR INFERIOR MYOCARDIAL INFARCTION

Virinderjit S. Bamrah, MD, FACC; Michael H. Keelan, Jr., MD, FACC; Jagmeet S. Soin, MD; Ronald D. Siegel, MD; Josep G. Llaurado, MD; Donald D. Tresch, MD, FACC; Felix E. Tristani, MD, FACC; Harold L. Brooks, MD, FACC: Medical College of Wisconsin and Veterans Administration Medical Center, Milwaukee, Wis.

In the presence of prior inferior myocardial infarction (IMI) graded exercise electrocardiography (GXT) has variable sensitivity (SENS) in identifying significant (≥70%) obstructive multivessel disease (MVD). Thallium-201 exercise scintigraphy (TLX) reportedly has more SENS than GXT and should be a reliable technique for evaluation of post MI patients (pts). Eighty pts with prior IMI underwent TLX. Multiple view scintigraphy was performed 10-15 min and 4 hrs after injecting 1.5 mCi of Tl at peak exercise. Scans and coronary angiograms were reviewed independently by two observers. Sixty-two pts had MVD (3V-32 pts; 2V-30 pts). All 62 pts showed resting perfusion defects (DEF) confirming previous IMI. New DEF were detected in 30 pts (48%). Pts with 3V disease showed fewer new DEF (11/32 pts) than pts with 2V disease (19/30 pts). GXT alone suggested MVD in 56% (35/62 pts) increasing the total SENS for MVD to 68%. While 40 pts showed significant disease in the left anterior descending (LAD), new DEF in the LAD distribution developed in only 15/40 (38%) pts. We conclude that TLX does not reliably identify MVD in pts with previous IMI. Lack of SENS also precludes reliable detection of LAD disease in this group. These surprising results may relate to: a) early redistribution of Tl, b) global ischemia, c) large fixed defects limiting visual interpretation of moderately hypoperfused zones, d) overlap of perfusion zones due to variation in coronary anatomy and collateral flow.

NITROGLYCERINE VS POST-EXTRASYSTOLIC POTENTIATION IN THE ASSESSMENT OF THE ACUTELY ISCHAEMIC LEFT VENTRICLE

Rudolph Canepa-Anson, Charles D. Ilsley, David W. Baron, Anthony F. Rickards. National Heart Hospital, London, U.K.

Nitroglycerine (NG) and Post-extrasystolic Potentiation (PESP) may be used to identify reversible impairment of left ventricular (LV) function in ischaemic heart disease. Twenty one pts. were studied with two consecutive LV angiograms after rapid atrial pacing and NG. Each LV angiogram included a controlled ventricular ectopic beat (coupling interval 430 msec, atrial paced rate 100) to give 4 beats for analysis. 14 pts. (group A) developed angina and an acutely ischaemic LV. Seven pts. (group B) did not get angina and LV function remained normal. Ejection fraction measurements tabulated below showed that NG had a greater effect on the ischaemic LV and no effect in group B.

	Post pacing	PESP	NG	NG PESP
Group A	38.6(3.7)	**48.4(3.4)	* 55.9(2.8)	**67.0(2.3)
Group B	65.3(2.7)	* 75.4(2.4)	68.4(4.8)	* 76.4(3.5)

EJECTION FRACTION %(SEM), *=p .01, **=p .0005

Radial analysis of segmental wall motion confirmed the advantage of NG over PESP in the ischaemic LV.

It was concluded that: 1) NG is more effective than PESP in increasing inward systolic wall motion, and therefore in assessing the potential reversibility of abnormal LV function, in the acutely ischaemic left ventricle; 2) PESP increases systolic wall motion in both ischaemic and normal LVs whereas the effect of NG is maximal in the ischaemic areas.

DETECTION AND LOCALIZATION OF ≥40% CORONARY STENOSIS IN PATIENTS: COMPARISON OF EXERCISE AND DIPYRIDAMOLE THALLIUM-201 MYOCARDIAL IMAGING.

Martin A Josephson MD, B Greg Brown MD PhD, Harvey S Hecht MD FACC, James Hopkins BS, Cynthia D Pierce BS, Robert B Petersen PhD, Wadsworth VA Hosp, UCLA, CA.

Twenty-five unselected patients with ischemic heart disease were studied prospectively to determine the value of two different methods for isotopic detection and localization of coronary stenosis (CS). All received i.v. dipyridamole (DP) 0.56 mg/kg over 4 minutes; 6 were not able to perform maximal treadmill exercise (ETT). Thallium (Tl)-201 (1.5 mCi) was injected one minute before peak exercise or one minute after DP infusion. Imaging was performed immediately and 4 to 5 hours later (redistribution). The analysis incorporated: 1) A blinded consensus image reading by 3 experienced observers. 2) A prospective strategy for characterizing imaging information and for localizing each defect to one (or 2 if overlapping) of 6 major arterial distributions (AD). 3) A computer-based measurement of % stenosis (%S), minimum lumen area (A_{min}), and stenosis flow resistance (R) from high quality angiograms. Results: The distribution of CS severity was uniform. Coronary stenoses of ≥40% were usually absent from the appropriate AD with negative (N) and present with positive (P) Tl-201 images for both ETT ($p<.001$) and DP ($p<.001$). For all AD the relative value of imaging in detecting and localizing a ≥40% CS is:

	Sensitivity (TP/TP+FN)	Specificity (TN/TN+FP)	Predictive Accuracy (TP/TP+FP)
ETT	36/44=82%	32/44=73%	36/48=75%
DP	49/56=88%	34/45=76%	49/60=82%

Analyses based on A_{min} and R slightly improved the value of both methods (p=NS). In conclusion, both exercise and DP Tl-201 myocardial imaging proved surprisingly reliable in detecting and localizing CS≥40%; DP, which could be used more frequently in these patients, appeared somewhat more useful (p=NS). Thus, these methods are of potential value in screening for sub-clinical coronary disease.

INFARCTION SIZING AND MYOCARDIAL PERFUSION MEASUREMENTS USING RUBIDIUM-82 AND POSITRON EMISSION TOMOGRAPHY

Thomas F. Budinger, M.D., Ph.D.; Yukio Yano, B.S.; Stephen E. Derenzo, Ph.D.; Ronald H. Huesman, Ph.D.; Chi-Kwan Yen, M.D.; Brian R. Moyer, B.S.; Lon G. Sherman, M.D.; Donner Laboratory, University of California, CA

Rb-82 (positron emitter of 1.25 min half-life) has unique potentials for sequential evaluation of infarction size and for quantitation of flow times extraction when used with a dynamic positron emission tomograph. Validation of these potentials involve studies with dogs and coronary artery disease patients using Rb-82 from a table top generator containing Sr-82 ($T_{\frac{1}{2}}$ = 25 days) and the Donner 280-crystal positron emission tomograph.

Infarct sizing studies in dogs comprise imaging before and after ligation of branches of coronary arteries. Infarcts as small as 0.7 cc can be visualized. In 15 patient studies, 20 mCi (1.2 millirads/mCi) or more was injected. Uptake defects in transverse section images correlated well with EKG and catheterization findings.

Perfusion studies involve sequential transverse section imaging to obtain myocardial uptake curves and the arterial blood input function. A second method involves constant infusion of Rb-82 at approximately 2 mCi/min to give equilibrium images from which specific volume flow is estimated by the ratio of the uptake in the myocardium to the uptake in the left ventricular cavity. Validation studies using flow manipulation by Intensain and microspheres demonstrated that Rb follows flow sufficiently well to compete with Th-201, N-13, ammonia, K-38, for early detection of coronary artery disease. In man, there was a 1.7 times increase in uptake in myocardium at exercise. The short half-life, low whole body dose, and immediate availability give Rb-82 unique potentials for physiological and clinical studies.

SPECIFICITY, SENSITIVITY AND ACCURACY OF THE NITROGLYCERIN VENTRICULOGRAM AS A PREDICTOR OF SURGICALLY REVERSIBLE WALL MOTION ABNORMALITIES

Michael Stadius, MD; John H. McAnulty, MD, FACC; Joshua Cutler, MD; Joseph Rosch, MD; Shahbudin H. Rahimtoola, MD, FACC, University of Oregon Health Science Center, Portland, Ore.

The response of left ventricular (LV) segmental wall motion to nitroglycerin (NTG) was evaluated as a means of identifying wall motion abnormalities (WMA) that might be improved with coronary artery bypass surgery (CABS). Of many patients (pts) prospectively studied, 19 had satisfactory LV angiograms before and after NTG prior to CABS, and without NTG at an average of 8 months after surgery. Of 40 segments with WMA identified preoperatively, 18 (Group A) were in a segment of a preop myocardial infarction (MI) (12 segments), in the region of a periop MI (2 segments) or in the region supplied by a graft which became occluded (6 segments). In these 18, NTG correctly predicted the response of WMA to CABS in 12/18 (67% accuracy). The specificity of the response to NTG in this group was 80% with a sensitivity of 50%.

Twenty-two WMA (Group B) were not associated with the complications listed above. Thirteen improved after NTG. Eleven of these 13 WMA (85%) also improved with CABS. Although 9/22 WMA did not improve with NTG, 4 improved with CABS. Thus, in this group, the specificity of the response to NTG was 67%, the sensitivity 73% and the accuracy 73%. When all 40 WMA were evaluated, specificity of the NTG ventriculogram in predicting reversible WMA with CABS was 76%, the sensitivity 65%, and the accuracy 70%.

In ideal conditions of no pre- or periop MI and no graft occlusion, improvement of WMA with NTG was associated with improvement in the same WMA with CABS in 85%. However, since the accuracy values are only 67-73%, depending on how the segmental WMA are grouped, there are clear limitations to the value of the NTG ventriculogram in predicting reversible abnormalities with CABS.

PREDICTIVE ACCURACY OF CORONARY ARTERY CALCIFICATION AND POSITIVE EXERCISE TEST IN ASYMPTOMATIC NON-HYPERLIPIDEMIC MEN FOR CORONARY ARTERY DISEASE.

Rene A. Langou, MD, FACC; Michael J. Kelley, MD, FACC; Edwin K. Huang, MD; Lawrence S. Cohen, MD., FACC, Yale University School of Medicine, New Haven, CT.

To determine the predictive accuracy (PA) of fluoroscopically detected coronary artery calcification (CAC) and a positive submaximal exercise test (ET), 129 asymptomatic men were screened and 13 had both CAC and positive ET (>1.5 mm ST segment depression). These 13 men were studied at coronary arteriography (ART). They had a mean age of 44 years (range 41 to 56 years); 3 had hyperlipidemia, none had history or symptoms of heart disease and all had normal resting ECG's at entry.

CAC was detected in 1 artery in 10, in 2 arteries in 2, and in 3 arteries in 1 man. Coronary artery disease (CAD) was considered clinically significant if there was >50% narrowing in any major coronary branch. ART revealed 12 men with clinically significant CAD (single CAD in 4, double in 5 and triple in 3 men) and 1 with minor CAD (single CAD). The PA was 100% for minor CAD, 92% for clinically significant CAD. Correlation was found between the location of CAC and CAD but the absence of CAC did not rule out the presence of CAD at ART. Furthermore, CAC did not indicate the location of the highest stenotic lesions seen at ART. Followup for the 13 pts was 40 mos.; 3 pts developed typical angina and 1 pt developed a transmural myocardial infarction.

Thus, this study suggests that 1) the PA of CAC and a positive ET, in the middle aged non-hyperlipidemic asymptomatic male, is very high; 100% for CAD and 92% for clinically significant CAD; 2) that CAC and a positive ET, predicts an early appearance of symptoms; angina or myocardial infarction, in previously asymptomatic men.

DOES LOCATION OR LATE DISAPPEARANCE OF Q WAVES AFTER MYOCARDIAL INFARCTION AFFECT PROGNOSIS?

Jorge C. Rios, M.D., Alan G. Wasserman, M.D., George B. Bren, M.D., Allan M. Ross, M.D., FACC, for the Aspirin Myocardial Infarction Research Group, George Washington University Medical Center, Washington, D.C.

Absence or disappearance of diagnostic Q waves following a myocardial infarction (MI) and the location of the infarction by Q wave distribution have been thought to carry prognostic implications. To test that hypothesis we examined the records of all patients participating in a clinical trial (Aspirin Myocardial Infarction Study: AMIS), ages 30-69 years (m=52.7) who had a myocardial infarction within 1 year preceeding entry into the study. There were 1464 such patients which constitutes this study group. Follow up was 28-42 months (m=32) during which time 120 (8.2%) patients had died. Thus the annualized mortality is 3.1% (treatment and control groups pooled).

Total mortality in patients with a single electrocardiographically defined infarct location was: Antero-lateral 7/73 (9.6% total, annualized to 3.6% per year); Inferior 37/517 (7.2% total, 2.7% per year; and Antero-septal 13/189 (6.9% total, 2.6% per year). There was no significant difference in mortality rate between any of these groups.

When patients with residual Q waves at randomization (1200) were compared to those whose Q waves completely resolved (264) there was no significant mortality difference after 32 months (102/1200 vs 18/264). Yearly mortality 3.2% vs 2.5% respectively ($p>0.05$).

CONCLUSION: Neither loss of Q wave nor location of MI by Q wave distribution influences the annualized mortality (3.1%) for patients having survived the acute phase of a myocardial infarction.

REPRODUCIBILITY OF EXERCISE TESTING AT TWO AND SIX WEEKS POST MYOCARDIAL INFARCTION

Mark Starling, MD; Gemma Kennedy, RN; Michael Crawford, MD, FACC; Robert O'Rourke, MD, FACC, University of Texas Health Science Center and Veterans Administration Hospital, San Antonio, Texas.

Although the safety of pre-discharge (DC) ECG exercise testing in post myocardial infarction (pMI) patients (pts) and the grave prognostic significance of exercise ST segment depression (ST↓) has been demonstrated, little evidence exists concerning the reproducibility of abnormalities detected pre-DC compared to exercise testing done post-DC. Therefore, we studied 46 pMI pts by a modified Naughton treadmill exercise test (TT) prior to hospital DC and at 6 wks pMI. ST↓ during TT occurred in 12 pts pre-DC and in 11 of them at 6 wks. In these 11 pts, there was no difference between 2 and 6 wks in maximum heart rate [114±16 (SD) vs 117±12 beats/min], rate pressure product (RPP, 18.3±3.8 vs 18.0±3.7 X 10^3) and the duration of TT (5.7±3.9 vs 5.5±2.5 min). The 1 pt without ST↓ at 6 wks was put on propranolol after his 2 wk TT. Also, 2 additional pts had new ST↓ on TT at 6 wks. ST segment elevation (ST↑) on TT was seen in 17 pts pre-DC but at 6 wks was no longer present in 9 of these pts. No new pts showed ST↑ at 6 wks. Angina pectoris (AP) was provoked on TT in 8 pts pre-DC and reoccurred in 5 of them at 6 wks. Additionally, 6 pts had new AP on TT at 6 wks. In these 6 pts there was no change in the duration of TT at 2 and 6 wks, however, heart rate (120±19 vs 125±14 beats/min) and RPP (18.1±4.3 vs 20.5±9.8 X 10^3) tended to increase at 6 wks. No abnormality was detected in 13 pts pre-DC and 11 of them continued to have a normal TT at 6 wks. In comparing pre-DC to 6 wks pMI, we conclude: 1) ST↓ is a relatively consistent and reproducible finding at 2 and 6 wks pMI; 2) ST↑ often disappears by 6 wks pMI; and 3) more pts with angina pectoris are identified at 6 wks.

AN IMPROVED, RAPID RADIOIMMUNOASSAY FOR INDIVIDUAL HUMAN CK ISOENZYMES

Robert Roberts, MD, FACC; Ceil Herman PhD, Washington University, St. Louis, Missouri

The radioimmunoassay (RIA) we previously developed for MB CK employed an antibody to BB CK which cross-reacts with MB and required 6 hr of incubation for sample analysis. MB CK antiserum would have been preferable but purification of MB free of albumin was not then achievable. In this study, we developed a new procedure that permits assay of MB CK within minutes based on the use of purified MB rather than BB as the inhibiting moiety. MB CK was isolated from human myocardium by homogenization (Tris HCL, 50 mM, pH 7.4), and ethanol extraction (50 and 70%) and separated from MM CK by anion-exchange chromatography on Sephadex DEAE A-50. Albumin was removed by affinity chromatography (affigel-blue) with 250 mM NaCl elution (pH 8.0). The purified MB CK migrated as a single protein band on SDS gel and did not react to albumin antiserum. MB CK antiserum raised in rabbits exhibited a titre of 1:10,000. With the use of MB CK antiserum and the use of a second antibody technique, rather than $(NH_4)_2SO_4$, free and bound ^{125}I-CK can be separated within 10 minutes. MM CK present in 500-fold excess of MB exhibited no inhibition. Plasma MB CK activity in normal subjects (n=200) detectable with the new assay ranged from .5 to 6.5 IU/L with similar values in patients with angina without infarction (n=120) of .2 to 6 IU/L. In contrast, patients with myocardial infarction (n=230) exhibited mean peak plasma MB CK of 230 ± 172 IU/L with initial elevations occurring 2-4 hr after onset of symptoms. Thus, the assay of MB CK employing purified MB CK and MB CK antiserum is sensitive, specific and more rapid than the previously available procedure.

HETEROGENEITY OF MYOCARDIAL METABOLISM: EVIDENCE OF LACTATE PRODUCTION DURING NET CHEMICAL EXTRACTION IN MAN.

Edward W. Gertz, MD; Judith A. Wisneski, MD; Richard Neese, PhD; Whai-Jen Soo, PhD; J. David Bristow, MD, FACC. Veterans Administration Medical Center, University of California, San Francisco, CA.

Myocardial blood flow has been recognized to be heterogeneous in patients with CAD. Myocardial metabolism could also be heterogeneous which traditional arterial (A)-coronary sinus (CS) sampling methods would fail to demonstrate. This study was performed to investigate the possibility of heterogeneity of lactate metabolism. Ten patients (pts) with significant CAD in the LAD and/or LCX arteries were studied. ^{14}C-1-lactate was injected intravenously as a constant infusion after a priming dose. Mid-CS and A blood samples were obtained at rest and analyzed for chemical lactate and ^{14}C-lactate. No evidence of ischemia by symptoms or EKG was present during the study.

The mean lactate extraction by chemical analysis was 26.6% (11.6-45.9). By radioisotope analysis, the mean lactate extraction was 45.5% (25.5-62.6). This would indicate that while there was global net extraction of lactate, certain areas were producing lactate. Comparing chemical and isotope lactate extractions, the quantity of lactate produced can be calculated. Six pts with significant left main and/or both LAD & LCX lesions produced 0.141 μM/ml lactate (0.070-0.188). Four pts with only LAD or LCX lesions produced 0.074 μM/ml lactate (0.049-0.087).

Using a tracer method myocardial lactate metabolism was demonstrated to be heterogeneous in pts with CAD at rest. A significant amount of lactate can be produced by the myocardium at a time when chemical A-CS analysis indicates myocardial extraction. It appears that the degree of heterogeneity is related to the severity of the CAD.

ECHOCARDIOGRAPHY
2:00-5:30

TWO-DIMENSIONAL ECHOCARDIOGRAPHIC RECOGNITION OF THE DESCENDING THORACIC AORTA: VALUE IN DIFFERENTIATING PERICARDIAL FROM PLEURAL EFFUSIONS

William S. Haaz, MD, Gary S. Mintz, MD, Morris N. Kotler, MD, FACC, Wayne R. Parry, Hahnemann Medical College and Hospital, Philadelphia, Pennsylvania

M-mode echocardiography (MME) is not always reliable in differentiating pericardial (PE) from pleural (PLE) effusions, especially when a large posterior PE exists in the absence of anterior pericardial fluid. We evaluated the utility of two-dimensional echocardiography (2DE) in differentiating PE from PLE by using the descending thoracic aorta (DTA) as a marker of the pericardial-pleural interface. 76 patients (PTS) were studied by 2DE. In the 2DE long axis view, the DTA is a circular echo-free structure posterior to the atrioventricular groove; in the 2DE short axis view, the DTA is a circular or oval echo-free structure behind the left ventricular posterior wall (LVPW). 16 PTS with PE only had an echo-free space between the LVPW and the DTA. All 16 PTS had confirmation by surgery, pericardiocenteis, or autopsy. 9 PTS with an isolated left PLE only had an echo-free space posterior to the DTA. All 9 PTS had confirmation by chest x-ray or autopsy. 10 PTS with both PE and PLE had echo-free spaces both between the LVPW and DTA and also posterior to the DTA. All 10 PTS had anatomical confirmation. 41 PTS served as a control, and none had echo-free spaces either anterior or posterior to the DTA. In each instance, PE or PLE was not present at surgery.
Thus, in conclusion, visualization of the DTA by 2DE is a useful marker of the pericardial-pleural interface and allows differentiation of PE from PLE.

CHRONOTROPIC INCOMPETENCE IN STRESS TESTING IN PATIENTS WITH CORONARY ARTERY DISEASE.

Carey M. Marder, M.D., Robert D. Wiens, M.D., FACC, Robert G. Evans, Hiltrud S. Mueller, M.D., FACC. St. Louis University School of Medicine, St. Louis, Missouri 63104

Treadmill stress tests were performed on 171 patients (pts) with angiographically documented coronary artery disease (CAD) to determine the prevelance of chronotropic incompetence (CI). CI is defined as a maximum heart rate (HR) greater than 2 standard deviations below the mean for 141 pts with normal coronary arteriograms. Pts receiving propranolol are excluded. Of the normal pts, only 2 are classified as CI, indicating that CI is 99% specific for CAD. The incidence of CI in pts with single (SVD), double (DVD) and triple (TVD) vessel disease is reported below.

	# Pts Total	# Pts with CI	% Pts	p<
SVD	41	5	12	.05
DVD	60	5	8	.05
TVD	70	6	9	.05

The incidence of CI in all disease groups is significantly greater than normal, however the proportion of pts with CI is not related to the severity of the disease. In those pts with CI, 37% of the recorded HRs in SVD, 45% in DVD and 63% in TVD fall below the lower 95% confidence limit indicating that the more severe the CAD the fewer normal HRs at each recording period. Of the 16 pts with CI, 13 had inconclusive stress tests due to failure to reach maximum HR, indicating that in these pts, CI might be useful in the diagnosis of CAD.

Conclusions: 1. CI occurs in approximately 10% of pts with CAD and is as frequent in SVD as TVD. 2. The more severe the CAD the greater the number of abnormal HRs. 3. Pts with CI should be further evaluated for CAD.

CONTRAST ECHOCARDIOGRAPHY: TRANSMISSION OF ECHOES TO THE LEFT HEART ACROSS THE PULMONARY VASCULAR BED.

Attilio Reale, MD, FACC, University of Rome, Rome, Italy

All available reports on contrast echocardiography indicate that the echoproducing quality of the various agents used is lost during their first passage through either the pulmonary or systemic capillary bed. The purpose of this study was to investigate the possibility of transmitting echoes to the left side of the heart across the pulmonary vascular bed with the use of venous catheterization. A balloon-tipped catheter was wedged under fluoroscopic control in a pulmonary arterial branch. When a satisfactory M-mode or two-dimensional echocardiographic display was obtained, the balloon was inflated, an echo-producing substance injected through the end-hole and the balloon thereafter rapidly deflated. Agents used were: indocyanine green (5-10 mg), saline (5 ml) or CO2 (0.5-1 ml). Observations were performed in 16 patients (p.) (Gr.I) with acquired valvular, ischemic or congenital heart disease without any oxymetric or angiographic evidence of septal defects or aorto-pulmonary communications, and in 14 p. (Gr.II) with atrial or ventricular septal defects or patent ductus arteriosus and documented left-to-right shunts (calculated Qp/Qs ratio ranging from 1/1 to 4.3/1). Echoes of variable density consistently appeared in the left heart. In the p. of Gr.I transmitted echoes were confined to the left heart cavities and aorta, in those of Gr.II echoes also appeared in the right atrium, right ventricle or pulmonary artery, depending on the site of the left-to-right shunt. There were no false negatives nor false positives. No complications or side-effects were observed. The presumable mechanism of transmission is achievement of a high concentration of echoes and/or bypassing of pulmonary capillaries through physiologic intrapulmonary shunts.

CONTRAST TWO-DIMENSIONAL ECHOCARDIOGRAPHY IN INTER-ATRIAL SHUNTS.

Brian W. Gilbert, MD, FACC; Milutin Drobac, MD; Harry Rakowski, MD, Toronto General Hospital, Toronto, Ontario, Canada.

To examine the reliability of contrast two-dimensional echocardiography (2DE) in the detection of inter-atrial shunting (IAS), we studied 30 patients (pts): 23 pts with secundum atrial septal defect (ASD) and 7 with pulmonary hypertension (PH) and IAS. Normal saline (10 cc) was injected into a peripheral vein and microbubbles were visualized in the right heart.

Twenty-two of 23 ASD pts demonstrated (I)positive (+ve) left atrial (LA) contrast (microbubbles moving from right atrium (RA) to LA) and/or (II)negative (-ve) RA contrast (microbubble-free blood moving from LA to RA). Twelve of 23 ASD pts showed both +ve LA and -ve RA contrast. In these pts, the shunt ranged from 1.9 to 4.0/1.0. Four of 23 ASD pts demonstrated only -ve RA contrast (shunt 2.0-2.6/1.0). In 6/23 ASD pts, only +ve LA contrast was visualized (shunt 1.7-3.8/1.0). In 1/23 pts with clinical ASD, no +ve LA or -ve RA contrast could be seen. This pt was found to have anomalous pulmonary venous drainage at surgery.

In the 7 pts with pulmonary hypertension and IAS, all (7/7) had +ve LA contrast but none (0/7) displayed -ve RA contrast. Six of 7 pts had contrast 2DE evidence for tricuspid regurgitation.

We conclude that 1)all pts with IAS have either +ve LA or -ve RA contrast and approximately 50% have both. Shunt size cannot be predicted by +ve LA or -ve RA contrast alone or in combination. 2)in pts with PH and IAS, only +ve LA contrast is seen. 3)if a pt has clinical evidence for an IAS but no evidence of +ve LA or -ve RA contrast, anomalous pulmonary venous drainage should be suspected.

DEFINITIVE NONINVASIVE ASSESSMENT OF VALVULAR HEART DISEASE: SURGERY WITHOUT CATHETERIZATION

Kenneth M. Borow, MD; Joshua Wynne, MD, FACC; Laurence J. Sloss, MD; Lawrence H. Cohn, MD, FACC; John J. Collins, Jr., MD, FACC, Harvard Medical School and Peter Bent Brigham Hospital, Boston, MA

Over the past 4 years, 33 patients (pts) ages 16 to 84 years underwent valve surgery at our institution based solely on clinical and noninvasive cardiac evaluation without pre-operative cardiac catheterization (cath). Pts with angina pectoris or other clinical evidence of coronary artery disease were excluded from the study. All pts had combined M-mode echocardiographic and phonocardiographic evaluations of valvular and left ventricular morphology and function. In 27/33 pts, marked clinical deterioration had occurred within 6 months prior to surgery. Twenty-six pts had no history of prior valve surgery (group I) while 7 pts had previous valve replacements or mitral commissurotomy (group II). Twenty-four (92%) group I and 4 (57%) group II pts were functional class III or IV at time of surgery. In all pts, the noninvasive evaluation was considered to be sufficiently diagnostic of valvular heart disease (8 aortic stenosis, 4 aortic regurgitation, 6 mitral stenosis, 8 mitral regurgitation, 1 mitral stenosis/mitral regurgitation, 6 prosthetic valve dysfunction) to allow surgery without preoperative cath. In all 33 pts, the noninvasive diagnosis was corroborated at operation without unexpected findings. Twenty-seven of 33 pts survived the peri-operative period and left the hospital clinically improved. There were no deaths related to incomplete or incorrect diagnosis. Thus, in selected pts, appropriate and successful valve surgery may be performed solely on the basis of combined clinical and noninvasive evaluation without the need for cardiac cath.

IDENTIFICATION OF PROMINENT EUSTACHIAN VALVES BY M-MODE AND TWO-DIMENSIONAL ECHOCARDIOGRAPHY: DIFFERENTIATION FROM RIGHT ATRIAL MASSES

William J. Bommer, MD, FACC; Oi Ling Kwan, BS; Dean T. Mason, MD, FACC; Anthony N. DeMaria, MD, FACC, University of California, Davis, California.

No data have been reported regarding the ability of echocardiography to visualize the Eustachian valve (EV). Therefore we studied 6 patients with abnormal right atrial echoes suspected of representing congenitally prominent EV. In all 6 patients (pts) abnormal echoes were identified during routine M-mode (5/6) or two-dimensional echocardiographic (2DE) (6/6) scans of the tricuspid valve (TV) and right atrium (RA). Abnormalities on M-mode consisted of rapidly moving 1-2 mm thick echoes located in the mid RA behind the TV. These abnormal echoes showed anterior movement (mean amplitude = 2 cm) and coarse flutter, in both systole and diastole. On 2DE an abnormal rapidly moving linear echo could be seen in all patients with the transducer in a parasternal position directed toward the RA in a plane oblique to the right ventricular long axis. Continuity of the linear echo with the junction of the inferior vena cava (IVC) and RA was demonstrated by 2DE and confirmed during IVC echo contrast injections. Additional confirmation was obtained in all 3 patients in whom angiography or autopsy was performed. M-mode and 2DE findings in patients with prominent EV were compared with echograms from patients with other RA masses documented at catheterization or surgery. Although the abnormal M-mode findings were not specific for EV, the 2DE easily distinguished EV from RA catheters (5/5), RA vegetations (4/4) and RA tumors (2/2), by demonstrating the origin and the spacial configuration of the RA masses. Thus prominent EV can readily be recorded on M-mode and 2DE. Two-dimensional echo reliably distinguishes prominent EV from other RA masses.

LEFT VENTRICULAR MICROCAVITATIONS IN PATIENTS WITH BEALL VALVES

Lehman K. Preis, MD; John P. Hess, MD; Joseph L. Austin, MD; George B. Craddock, MD; Lockhart B. McGuire, MD; Randolph P. Martin, MD, University of Virginia, Charlottesville, VA.

In vitro studies have suggested that the release of gases from hemolyzing red cells can be detected as microcavitation (MC) by echo. Twenty-seven patients (pts) with Beall prosthesis (BP) were evaluated by two-dimensional echo (2DE), combined echo-phono, and serum LDH levels to assess the ability of 2DE to detect MC, and to correlate this finding with possible prosthetic dysfunction and/or red cell hemolysis. Pts with bioprosthetic, Kay-Shiley, and Starr-Edwards (SE) valves in the mitral position were similarly evaluated. The findings for MC and LDH levels in pts with BP are as follows:

	MC in Ventricle		LDH (IU)
	Left	Right	Mean (Range)
Mitral BP (n=17)	11/17		1454(456-2324)
Mitral BP & Aortic SE (n=7)	3/7		1962(1058-4350)
Mitral & Tricuspid BP (n=2)	2/2	0/2	1412(746,2078)
Tricuspid BP (n=1)	0/1	0/1	289

The apical four chamber view was most sensitive for detecting left ventricular (LV) MC. Only the pt with the isolated tricuspid BP failed to show an otherwise unexplained elevation of the serum LDH level. No MC or significant LDH elevations were observed in the control pts. Three of 12 pts with mitral BP who had 2DE and echo-phono showed MC despite a normal A2-opening click interval. To date, only 2 pts with mitral BP and MC have required valvular replacement. The remainder of pts with mitral BP are clinically stable despite ongoing hemolysis. Thus, spontaneous diastolic MC within the LV may represent hemolysis of red cells secondary to possible subclinical valvular dysfunction. MC may identify a subset of pts with metallic prosthetic valves who warrant close follow-ups.

DIFFERENTIATION OF A-MODE ULTRASOUND SIGNALS FROM NORMAL AND ISCHEMIC MYOCARDIUM BY MULTIVARIATE DISCRIMINANT ANALYSIS OF WAVEFORM PARAMETERS.

Thomas D. Franklin, Jr., PhD; John K. Cuddeback, PhD, MD; Narendra T. Sanghvi, MSEE; Arthur E. Weyman, MD, FACC; Kathleen S. Avery, BS; and Francis J. Fry, MS. Indiana University School of Medicine and the Indianapolis Center for Advanced Research, Inc., Indianapolis, Indiana

The major objective of this study was to evaluate capabilities of differentiating reflected ultrasound signals from normal and ischemic myocardium by extracting a set of features which could be used in a statistical decision algorithm. Pulse-echo techniques were applied to collect A-mode waveforms of the entire transmural myocardium at selected times in the cardiac cycle. In opened-chest canine experiments, waveforms were digitized before, and at 1,2 and 4 hrs. after coronary artery ligation. A wideband (1-8 MHz), focused transceiver was positioned in a small water bag coupled to the antero-lateral aspect of the heart. Each waveform was EKG gated and processed into normalized amplitude, rectified, and power spectrum transformations. Thirteen features were extracted from each transformed wave at selected windows in range (usually subepi and subendo). In 6 acute canine experiments, over 6,000 waveforms have been analyzed. The multivariate discriminate analysis usually selected 5-7 of the 13 features to provide the best discriminant function. The classification success has been best using the rectified transformation with 94.5% (2051/2170) of the unknown waveforms identified correctly. The power spectrum gave 92.6% (2038/2201) and the amplitude gave 91.4% (2010/2199). The overall success using all three transformations was 92.8% (6099/6570). In conclusion we feel that sufficient changes occurred in the reflected waveform pattern to provide capabilities for differentiation of ischemic and normal myocardium as early as 1 hour after coronary artery occlusion.

COMPARATIVE EFFICACY OF CROSS-SECTIONAL ECHOCARDIOGRAPHY AND GATED EQUILIBRIUM RADIONUCLIDE ANGIOGRAPHY FOR ASSESSING LEFT VENTRICULAR SIZE AND PERFORMANCE

Mark Starling, MD; Michael Crawford, MD, FACC; Bernard Levi, MD; Sherman Sorensen, MD; Kent Richards, MD, FACC; Robert O'Rourke, MD, FACC, University of Texas Health Science Center and Veterans Administration Hospital, San Antonio, Texas.

Both cross-sectional echocardiographic (CSE) and gated equilibrium radionuclide angiographic (RNA) estimates of left ventricular (LV) ejection fraction (EF) have compared favorably to angiographic (ANG) LV-EF. However, no study has compared the efficacy of these two non-invasive techniques for assessing the ANG-EF in the same patients (pts). Accordingly, in 37 pts undergoing biplane LV cine-ANG (Dodge formula), we measured LV end-diastolic volume (EDV) and end-systolic volume (ESV) on phased array CSE images from 2 orthagonal apical views using a microprocessor controlled video light pen system programmed for Simpson's rule. RNA-EF was calculated using an R-wave synchronized Gamma camera-computer system that evaluated equilibrium LV time activity curve count information. EDV by CSE was significantly smaller than that by ANG (145±52 vs 178±64 ml, $p<.001$), but the correlation between the values was excellent ($r=.90$). Similar results were obtained for ESV (74±48 vs 85±59 ml, $p<.001$, $r=.96$). EF by CSE was significantly less than that by ANG (52±16 vs 55±17%, $p<.005$) but no different from that by RNA (52±17). However, the correlation between ANG and CSE-EF was better ($r=.94$) than ANG vs RNA-EF ($r=.80$). Using 51% as the lower limit of a normal ANG-EF both CSE and RNA misclassified 3 pts (8%). We conclude that: 1) CSE underestimates LV EDV, ESV and EF by ANG but they correlate closely; 2) RNA gives similar results for EF but they correlate less closely than CSE to ANG; 3) both non-invasive techniques correctly classify >90% of pts with normal or abnormal EF.

COMPUTERIZED IMAGE PROCESSING IN CROSS-SECTIONAL ECHOCARDIOGRAPHY

David J. Skorton, MD; Charles A. McNary, PhD; John S. Child, MD, FACC; Pravin M. Shah, MD, FACC, University of California at Los Angeles, Los Angeles, California

Quantitative, non-invasive measurement of cardiac structure is the goal of our program of computerized image processing of cross- sectional echocardiograms (CSE). The rationale is to couple current transducer technology with digital image processing techniques. The approach includes digitization of the CSE images, spatial and temporal registration of individual frames, multiple image averaging, analysis of grey-level (GL) histograms for threshold selection, and echo intensity thresholding for region and boundary (endocardial) definition. Our study used ECG-gated echo frames photographed from phased array and mechanical sector scanner displays. The frames were digitized and time-averaged to improve signal-to-noise ratios (two or more unprocessed frames were averaged for each processed image). GL histograms were generated, exhibiting a multimodal distribution, with modes corresponding to the left ventricular cavity and various tissue regions. A global GL threshold was chosen to separate high from low acoustic scattering regions (tissue from cavity). Endocardium was defined as the interface between tissue and cavity, and close agreement was found for the position of the endocardial outline when compared to that obtained with an independent, GL gradient, edge extraction algorithm. The processed endocardial outlines were validated by comparison to the unprocessed CSE frames and by comparison to left ventricular minor axis dimensions on the standard M-mode echocardiogram.

We conclude that application of digital computer image processing algorithms to standard CSE can yield automated quantitative measurements of cardiac structures.

COMPARISON OF TWO-DIMENSIONAL ECHOCARDIOGRAPHY, GATED HEART POOL SCAN, AND LEFT VENTRICULOGRAPHY IN THE DETECTION OF REGIONAL WALL MOTION ABNORMALITIES.

R. Brad Stamm, MD; Denny Watson, PhD; George Taylor, MD; George Beller, MD, FACC; Randolph P. Martin, MD, University of Virginia, Charlottesville, VA.

In order to compare the detection of wall motion abnormalities (WMA) by two-dimensional echo (2DE) and multiple gated heart pool scan (MUGA), 9 coronary and 5 noncoronary patients were evaluated with 2DE, MUGA, and left ventriculogram (LVG). The heart was divided into 7 segments: anterior base, anterior, apex, distal inferior, proximal inferior, septal, and lateral. The analysis was repeated upon 5 segments by combining the two anterior segments and two inferior segments into one segment each. In patients with RAO-LVG only septal and lateral segments were excluded. One 2DE was inadequate for evaluation and one MUGA was eliminated due to excessive time between studies. Comparison of 2DE and MUGA with LVG revealed;

	Segs	Normal/ LVG Normal	Hypokinetic/ LVG Hypokin	A-Dyskinetic/ LVG A-Dyskin
2DE	7	17/21 (81%)	23/26 (88%)	13/14 (93%)
	5	6/8 (75%)	14/15 (93%)	14/14 (100%)
MUGA	7	21/21 (100%)	17/26 (65%)	8/12 (67%)
	5	8/8 (100%)	12/13 (92%)	10/12 (83%)

Four WMA were seen on 2DE, but not on LVG. Most of the discrepancy between WMA as seen by 2DE and LVG occurred at the anterior base, while MUGA and LVG differences most often occurred inferiorly. We conclude: 1) When 5 segments are analyzed for WMA, 2DE and MUGAs are both able to detect WMA as seen on LVG. 2) 2DE appears to give better localization of wall motion abnormalities as seen by the comparison of the 7 segment analysis with LVG. Hence, 2DE appears to be a reliable method to detect segmental and subsegmental WMA.

SUBCLINICAL ABNORMALITIES OF LEFT VENTRICULAR FUNCTION IN CORONARY PATIENTS DETECTED BY 2-D ECHO. James Adams, MD; Shahbudin Rahimtoola, MD; Nelson Schiller, MD; J. David Bristow, MD. VA Medical Center and University of California, San Francisco, CA.

To define subclinical abnormalities of left ventricular function (LVF), we compared short-axis 2-D echos taken in 8 healthy volunteers (NLS) and 6 patients (PTS) with angiographic findings of coronary disease and normal LVF. Measurements were made at rest and during handgrip exercise (HGE), before and after nitroglycerin. LV volumes were determined by sequential frame analysis of at least 2 beats in each state using a minicomputer lightpen and the area-length method. Total ejection fraction (EF) and mean Vcf ($\overline{Vcf}$) in circ/sec, EF and mean Vcf for the first third of systole ($EF_{\frac{1}{3}}$, $\overline{Vcf}_{\frac{1}{3}}$), as well as percent EF ejected in the first third of systole ($\%EF_{\frac{1}{3}} = EF_{\frac{1}{3}} \div EF \times 100$) were calculated. Heart rate and mean blood pressure were similar in each state in PTS and NLS. With HGE mean blood pressure increased 30±2 mmHg (mean±SE).

	EF	$\overline{Vcf}$	$EF_{\frac{1}{3}}$	$\%EF_{\frac{1}{3}}$	$\overline{Vcf}_{\frac{1}{3}}$
NLS	72±2	1.4±0.1	29±3	41±4	1.4±0.2
PTS	74±3	1.3±0.1	19±2*	26±3*	0.7±0.1+
NLS-HGE	67±2	1.4±0.1	25±2	37±3	1.2±0.1
PTS-HGE	73±3	1.4±0.2	20±2	28±3*	0.9±0.2
NLS-NTG	72±2	1.4±0.1	27±2	37±3	1.2±0.1
PTS-NTG	78±3	1.6±0.1	25±3	32±4	1.2±0.3

*p<.05; +p<.02

Total EF and $\overline{Vcf}$ were similar in each state for PTS and NLS. However, first third indices were significantly different at rest and with HGE. NTG reversed both resting and HGE abnormalities.

Our data show that by using 2-D echo subclinical abnormalities of LV function can be detected in coronary disease patients by examining the first third of systole; whereas these abnormalities are not evident when one looks at end-systolic indices. The reversal of these abnormalities with NTG suggests that they are related to myocardial ischemia.

EXERCISE CROSS SECTIONAL ECHOCARDIOGRAPHIC DIAGNOSIS OF CORONARY ARTERY DISEASE
Joel Morganroth, MD, FACC, Chin C. Chen, MD, Daniel David, MD, Henry S. Sawin, MD, Masahito Naito, MD, Connie Parrotto, Linda Meixell, Lankenau Hospital, Jefferson Medical College, Philadelphia, PA

Cross sectional echocardiography (CSE) both at rest and continuously during supine bicycle exercise was performed prospectively in 20 patients (PTS) undergoing coronary angiography. Regional wall motion (RWM) abnormalities were analyzed primarily in the short axis CSE view. Adequate endocardial echoes for analysis of studies during exercise were seen in 18/20 (90%) PTS. Ten of these 18 PTS were men, 6 had ECG evidence of prior myocardial infarction, and 16 had angina. Their mean age was 51 ± 11 years. The exercise test (ETT) was considered positive if either ST segment depression (≥ 1mm) or classic angina occurred. Normal rest CSE RWM remained normal on exercise CSE in 10 PTS and 7 had normal ETT. Seven (70%) had coronary artery disease (CAD) (4-3 vessel, 2-2 vessel, 1-1 vessel) and none of the 7 had had prior myocardial infarction or abnormal left ventricular cineangiography. New RWM abnormalities on exercise CSE compared to rest occurred in 8 PTS and all 8 had positive ETT. CAD was present in 7 (6-3 vessel, 1-2 vessel) and one PT had no CAD but occult cardiomyopathy. The location of new exercise RWM abnormalities correlated directly with the presence of high-grade obstruction in the coronary artery supplying that segment. RWM abnormality on resting CSE had a sensitivity for CAD of 29% and a specificty of 100% whereas exercise CSE RWM abnormalities increased this sensitivity to 50%. Thus, new exercise-induced RWM abnormalities identified by CSE is an insensitive marker for the presence of CAD but is highly specific for CAD or occult cardiomyopathy.

CHARACTERISTIC ALTERATION OF THE RETROGRADE ATRIAL ACTIVATION SEQUENCE IN PATIENTS WITH DUAL ATRIOVENTRICULAR NODAL PATHWAY CONDUCTION
Ruey J. Sung, MD, FACC; Harvey L. Waxman, MD, University of Miami School of Medicine, Miami, Florida

The sequence of retrograde atrial activation(RAA) due to atrioventricular(AV) nodal reentry is considered to be distinctly different from that due to ventriculo-atrial (VA) conduction by way of an accessory pathway(AP). This RAA sequence recorded during AV nodal reentry is usually related to retrograde fast AV nodal pathway conduction. No information, however, is available concerning the RAA sequence resulting from retrograde slow AV nodal pathway conduction. Using the technique of intracardiac electrical stimulation we studied six patients(pts) with dual AV nodal pathways. Electrograms of the high right atrium (HRA), low septal right atrium(LRA) and proximal coronary sinus(PCS) at the coronary ostium were simultaneously recorded at a paper speed of 150-250 mm/sec. All pts manifested discontinuous A_1-A_2, H_1-H_2 and/or V_1-V_2, A_1-A_2 curves suggestive of dual AV nodal pathway conduction. During programmed ventricular extrastimulation and incremental ventricular pacing, retrograde fast AV nodal pathway conduction, as expected, resulted in a LRA-PCS-HRA sequence of RAA. Nevertheless, this RAA sequence then either gradually or abruptly shifted to a PCS-LRA-HRA sequence consequent upon a change from retrograde fast to retrograde slow AV nodal pathway conduction in all pts. We conclude that:(1) anatomically the proximal common pathway is a broad area allowing the slow AV nodal pathway to have a retrograde exit posterior to that of the fast AV nodal pathway; (2) the RAA sequence resulting from retrograde slow AV nodal pathway conduction may thus mimic VA conduction by way of an AP; and (3) the RAA sequence recorded during tachyarrhythmias should be elucidated with caution.

CLINICAL INCIDENCE OF TACHYCARDIA AND EASE OF INITIATION DURING PROGRAMMED ELECTRICAL STIMULATION OF THE HEART
Hein Wellens,MD,FACC, Frits Bär,MD, David Ross,FRACP, Jerónimo Farré,MD, Edgard Vanagt,MD. Department of Cardiology, University of Limburg, Annadal Hospital, Maastricht, The Netherlands.

The relation between the clinical incidence of tachycardia (T) and ease of initiation (IN) of T during programmed electrical stimulation (PES) of the heart was prospectively analyzed in 100 consecutively studied patients (P) with T in whom T could be initiated by PES. 31 P had AV nodal (AVN) T; 17 P ventricular (V) T; 12 P atrial (At) T; and in 40 P an accessory pathway (AP) was used during circusmovement (CM) T. Incidence of T was classified as A > 3x/month; B 3x/month-3x/yr; C < 3x/yr. IN of T was classified as by 1) a single premature beat (PB); 2) incremental pacing; 3) 2 or more PB's; 4) after Atropine.

Results:

	A				B				C			
	AVNT	VT	AtT	CMT	AVNT	VT	AtT	CMT	AVNT	VT	AtT	CMT
1	11	11	4	20	3	1	2	12	1	2	-	8
2	2	-	2	-	2	-	1	-	-	-	-	-
3	-	2	1	-	-	-	-	-	-	-	1	-
4	8	-	-	-	3	-	-	-	-	-	-	-

In the 75 P where T could be initiated by a single PB there was no correlation between the width of the tachycardia zone and the clinical incidence of T.

Conclusions: 1) There is no correlation between clinical incidence and ease of initiation of T during PES; 2) In all P with CMT and AP, T could be initiated by a single PB, independent of incidence of T; 3) In P with AVNT incidence of T seems to be influenced by autonomic tone.

RECURRENT TACHYCARDIA ASSOCIATED WITH EBSTEIN'S ANOMALY, Warren M. Smith, MD; D. Woodrow Benson, MD; Augustus Grant, MD; John J. Gallagher, FACC; Duke University, Durham, North Carolina.

Nineteen patients with Ebstein's anomaly were evaluated because of recurrent tachycardia. There were 11 males and 8 females with an age range of 10-45 years (mean 25 years). Atrial fibrillation had occurred in 5 patients. Reciprocating tachycardia (RT) was documented in 18 patients, 17 of whom had an accessory atrioventricular pathway (AP). The location of the AP was posterior septal (PS) in 11 patients, and right posterolateral (RPL) in 10 patients, but never anterior or anteroseptal. Six patients had multiple APs. Four patients had both a RPS and a RPL AP, while a further three had a Mahaim fiber coexistent with at least one AP. In 1 patient a Mahaim fiber was solely responsible for RT. Ventricular tachycardia was spontaneously present in one patient and induced in two further patients during electrophysiologic study. The earliest ventriculo-atrial (VA min) conduction time during RT was measured in 16 patients. The range of VA min was 100 to 220 msec, with a mean of 176±35 msec. VA min was less than 135 msec in only one instance, a pediatric patient. Complete or incomplete RBBB in RT was present in 9 patients. Twelve patients underwent attempted section of the AP together with tricuspid valve replacement in 5, without mortality. The AP was successfully divided in 10/12 patients. One patient, in whom the AP permitted rapid anterograde conduction, conducted only retrograde post-operatively. At surgery, preexcitation was invariably localized to the atrialized ventricle. This correlated with the disposition of the delta waves on the scalar ECGs which suggested inferolateral preexcitation. The long VA conduction time appeared to consist both of late activation of the local ventricle in the region of the AP, with a further delay before excitation of adjacent atrium. The combination during RT of a long VA interval and RBBB should suggest the diagnosis of an AP and Ebstein's anomaly.

SIGNIFICANCE OF H-V INTERVAL IN 515 PATIENTS WITH CHRONIC BIFASCICULAR BLOCK

Kenneth M. Rosen, MD, FACC; Ramesh C. Dhingra, MD, FACC; Christopher R.C. Wyndham, MD, FACC; Prakash Deedwania, MD, FACC; Edwin Palileo, MD; Robert A. Bauernfeind, MD; Steven Swiryn, MD, University of Illinois, Chicago, Illinois.

In January 1975, we reported results of prospective follow-up (mean 538 ± 42 days) in 119 patients (pts) with chronic bifascicular block (BFB), concluding that BFB pts with normal and prolonged H-V (NHV and PHV) had similar incidence of A-V block and mortality. In this report, we update these findings in 515 pts with a follow-up of 21 days to 9.1 yrs (mean 3.9 ± 0.06 yrs). 324 pts (67%) had NHV and 191 (37%) had PHV ($\geq$ 55 msec). The NHV and PHV groups were similar in regard to age (NHV vs PHV): (61 ± 0.9 vs 62 ± 1 yrs) and sex (79% M, 21% F vs 82% M and 18% F). The following were more common ($p < 0.05$) in pts with PHV (number, and % of pts with finding in NHV vs PHV groups): angina (60, 19% vs 53, 28%) congestive failure (88, 27% vs 84, 44%), cardiomegaly (158, 49% vs 130, 68%), functional class II-IV (113, 35% vs 109, 57%), PVC's (60, 18% vs 52, 28%), and organic heart disease (OHD) (223, 69% vs 162, 85%). Spontaneous trifascicular block (TFB) developed in two (0.6%) pts with NHV and 9 (4.7%) pts with PHV ($p < 0.05$). Five year total cumulative and sudden death mortalities were respectively, 38% and 17% in NHV and 54% and 28% in PHV ($p < 0.05$ and < 0.05). In conclusion, PHV in pts with chronic BFB was associated with a greater incidence and severity of OHD, and higher total and sudden death mortalities. The risk of spontaneous TFB was small in both NHV and PHV pts, although significantly higher in the latter (eight times more frequent). Utilizing Bayes' theorem, it is clear that the sensitivity and specificity of PHV in predicting TFB, relates to the inherent risk of TFB in the BFB group being studied.

MECHANISMS OF TERMINATION OF ABERRANT CONDUCTION DUE TO RETROGRADE CONCEALED PENETRATION OF THE BUNDLE BRANCHES DURING CIRCUSMOVEMENT TACHYCARDIA UTILIZING AN ACCESSORY PATHWAY.

David Ross, FRACP, Edgard Vanagt, MD, Jerónimo Farré, MD, Frits Bär, MD, Isaac Wiener, MD, Hein Wellens, MD, FACC. Department of Cardiology, University of Limburg, Annadal Hospital, Maastricht, The Netherlands.

During circusmovement tachycardia (CMT) utilizing an accessory pathway (AP) abolition of bundle branch block (BBB) by a ventricular premature beat (PB) has been considered evidence for retrograde concealed penetration (RCP) of the bundle branches (BB). Analysis of aberrant conduction during CMT in 20 patients with left or septal AP revealed multiple mechanisms for termination of BBB by atrial (A) or ventricular (V) PB's. Mechanisms were: 1) Pre-excitation of the right BB during RBBB without affecting the tachycardia (T) interval resulting in earlier recovery of the right BB leading to disappearance of the RBBB; 2) Premature activation of the ventricle (by APB or VPB) leading to advancement of the next QRS of the T resulting in change of the critical time relations required for RCP; 3) Pre-excitation of any part of the CMT cycle by APB or VPB causing AV nodal delay with later activation of the ventricle allowing the re-entrant impulse to fall outside the refractory period of the retrogradely penetrated BB.

Conclusion: At least 3 different mechanisms can be demonstrated during termination of aberrant conduction by a single PB during tachycardia based upon RCP of the BB.

RIGHT VENTRICULAR FUNCTION AND ANGIOGRAPHY IN PATIENTS WITH RIGHT VENTRICULAR TACHYCARDIA WITHOUT ISCHEMIC HEART DISEASE

Raymond Pietras, MD, FACC; Robert A. Bauernfeind, MD; Wilfred Lam, MD; Christopher R.C. Wyndham, MD, FACC; Kenneth M. Rosen, MD, FACC, University of Illinois, Chicago, Illinois.

Surgical cure of right ventricular (RV) tachycardia (T) has been recently described in patients (pts) with "arrhythmogenic right ventricular dysplasia", a disease characterized by presence of RV wall motion abnormalities (WMA). To further delineate the pathophysiology of RVT, we evaluated RV function (F) and anatomy with catheterization and biplane angiography in 20 consecutive pts (mean age 32 ± 11 yrs) with recurrent RVT and no ischemic heart disease. RVT was diagnosed by ECG and endocardial mapping. Eight of the 20 pts had objective evidence of left ventricular disease (LVD) including four with mitral valve prolapse (MVP). Seven of eight (89%) of LVD pts had one or more abnormalities of RVF; ↓RV dp/dt (< 220 mmHg/sec) (4 pts), ↓RV ejection fraction (EF) ($< 43\%$) (4 pts), ↑RV end diastolic pressure (> 7 mmHg) (4 pts). Tricuspid prolapse (TVP) was noted in 2/4 pts with MVP. No localized RV WMA were seen. In the 12 pts with no LVD, only three (25%), had one or more abnormalities of RVF; ↓RV dp/dt (3 pts), and ↓RVEF (1 pt). None of these 12 pts had TVP or RV WMA. In conclusion, RVF is usually abnormal in pts with RVT complicating non-ischemic LVD, with TVP sometimes accompanying MVP. In RVT pts without LVD, RVF is usually normal and RV WMA are not noted. Localized RV WMA suggesting "arrhythmogenic RV dysplasia" were not seen in either group.

ROLE OF VENTRICULAR FRAGMENTATION IN DEFINING THE MECHANISM OF VENTRICULAR TACHYCARDIA IN MAN

Harvey L. Waxman, MD; Ruey J. Sung, MD, FACC, University of Miami School of Medicine, Miami, Florida

Ventricular fragmentation(VF)may be observed during experimental myocardial infarction in the canine heart.It is postulated that VF is a marker for conduction delay in the ischemic myocardium which is a requisite condition for development of reentrant ventricular tachycardia(VT). Recent studies using intracardiac recordings(ICR)suggest that VF can be detected in patients(pts)with chronic VT associated with cardiomyopathy(CM) or ischemic heart disease(HD)with ventricular aneurysm.Nevertheless,no systematic evaluation of VF has been performed in man.To define the role of VF in the genesis of VT,we studied 17 pts(12 without and 5 with VT)during ICR.Of these 17 pts,2 had CM,5 ischemic HD(3/5 had ventricular aneurysm),5 rheumatic HD,2 congenital HD,and the remaining 3 no apparent HD. The left ventricular electrogram(LVE) and right ventricular electrogram(RVE) were recorded at multiple sites with variable interelectrode distances(IED) and filter frequency settings(FFS).Following adjustment of ICR location, VF was observed in the RVE in 3 pts without VT and 1 pt with VT,but in the LVE in all 17 pts using IED of 1 cm or greater and FFS of 40-500 Hz or less.Incremental atrial pacing resulted in progressive prolongation of VF without leading to VT,and the initiation of VT required no antecedent prolongation of VF.Moreover, during VT,interruption of VF with ventricular extrastimulation could neither reset nor terminate VT.We conclude that:1)recordings of VF depend on ICR location,IED,and FFS;2)VF is most likely related to intracardiac catheter electrode movement associated with mechanical systole and diastole,and can thus be recorded in pts with or without VT;and 3)VF recorded using ICR probably has no significance in defining the mechanism of VT in man.

REPETITIVE VENTRICULAR RESPONSES IN PATIENTS WITH LIFE-THREATENING VENTRICULAR ARRHYTHMIAS

Jeremy N. Ruskin, MD, FACC; Hasan Garan, MD; Cardiac Unit Massachusetts General Hospital, Boston, Mass.

Electrophysiologic studies were performed in 22 patients (pts) with recurrent sustained ventricular tachycardia (VT) and in 14 patients with a history of recent out-of-hospital ventricular fibrillation (VF) unassociated with acute myocardial infarction. Programmed ventricular stimulation from the right ventricular apex included: premature stimulation during sinus rhythm and atrial pacing, premature stimulation during ventricular pacing, and brief bursts of rapid pacing. A repetitive ventricular response (RVR) was defined as two or more nonstimulated ventricular premature depolarizations in response to a single stimulated ventricular depolarization during sinus rhythm or atrial pacing. RVR was present in 18% (4 of 22) of the VT pts and 14% (2 of 14) of the VF pts. In contrast, premature ventricular stimulation during ventricular pacing and bursts of rapid ventricular pacing results in the initiation of VT or VF in 91% (20 of 22) of the VT pts and in 79% (11 of 14) of the VF pts. We conclude that (1) RVR is an insensitive index of chronic ventricular electrical instability in pts with documented VT or VF and (2) electrophysiologic evaluation in pts with prior VT or VF should include premature ventricular stimulation during ventricular pacing and bursts of rapid ventricular pacing.

NON CLINICAL POLYMORPHIC VENTRICULAR TACHYCARDIA INDUCED BY PROGRAMMED CARDIAC STIMULATION: INCIDENCE AND CLINICAL IMPLICATIONS.

C. Pratap Reddy, MD, FACC; John Sartini, MD, VA and University of Kentucky Medical Centers, Lexington, Kentucky.

Acute drug testing during programmed cardiac stimulation (PCS) is increasingly relied upon in designing the treatment of recurrent (R) ventricular (V) tachycardia (T). This approach to the treatment of RVT is based on the premise that PCS reliably reproduces the morphology and rate of spontaneous VT. In order to test this assumption, we analyzed the morphology and rate of VT induced by PCS in 20 patients (pts) with RVT who exhibited only one type of VT during spontaneous episodes. The induced VT was clinical, i.e. similar to spontaneous VT in 10 pts (Group A) and non clinical, i.e. different from spontaneous VT in 10 pts (Group B). During PCS 8/10 pts in Group B exhibited multiple morphologies (polymorphism). T morphology and rate could be changed by changing the basic cycle length (2 pts), the method of initiation of T (1 pt) and by introducing paced V beats during T (5 pts). The table shows clinical data for both groups.

	Group A	Group B	p value
Coronary artery disease	7 pts	8 pts	N.S.
V aneurysm	2 pts	1 pt	N.S.
Intraventricular conduction defects (IVCD)	4 pts	8 pts	<0.01
H-V interval (msec)	48±13	64±19	<0.001
Left V ejection fraction %	0.42±9	0.33±8	<0.01

CONCLUSIONS: 1) VT induced by PCS is non clinical in 50% of pts with RVT; 2) there is a frequent association of polymorphic VT with IVCD, prolonged H-V intervals and depressed V ejection fraction; 3) polymorphic VT is not peculiar to pts with V aneurysm and occurs in its absence. Our results may have important clinical implications in identifying pts with RVT suitable for specific modes of drug, pacemaker and surgical treatment.

ELECTROPHYSIOLOGIC FINDINGS IN PATIENTS SUFFERING CARDIAC ARREST

Mark E. Josephson, MD,FACC; Leonard N. Horowitz, MD,FACC; Allan M. Greenspan, MD; Scott R. Spielman, MD; John A. Kastor, MD,FACC, Hospital of the University of Pennsylvania, Philadelphia, Pa.

Fifty-two patients (pts) resuscitated from cardiac arrest (CA) underwent electrophysiological studies (EPS). There were 40 men and 12 women ranging in age from 21-75 years. The earliest documented arrhythmia at the time of initial or recurrent (15 pts) CA was ventricular fibrillation (VF, 30 pts), ventricular tachycardia (VT) degenerating to VF (VT/VF, 15 pts), and sustained VT (5 pts). In two pts no arrhythmia had been documented prior to defibrillation. EPS revealed normal sinus node function in 51/52 pts, A-H intervals ranging from 45-140 msec with a mean of 85.9 msec, and H-V intervals ranging from 35-100 msec with a mean of 57.6 msec. EPS revealed inducible arrhythmias (IA) in 33 pts (63%) and no inducible arrhythmia (NIA) in 17 pts (37%). Of 30 pts with documented VF, 13 had IA (VF in 4 pts, VT/VF in 5 pts, and VT in 4 pts). Of 20 pts with VT or VT/VF, 18 had IA (VT in 16 pts and VT/VF in 2 pts). VT and VT/VF were induced in the two pts with undocumented CA mechanism. Pts with IA had longer A-H intervals than those with NIA - 91.1 vs 76.6 ($p < .002$) and 61.4 vs 50.8 msec ($p < .007$) respectively. Prolonged H-V intervals (>55 msec) and intraventricular conduction defects were each observed in 18/33 (55%) pts with IA and were observed in 5/19 (26%) and 7/19 (37%) pts with NIA respectively. We conclude that: a) pts resuscitated from CA have a high incidence of IA; b) IA are more frequent if the mechanism of CA is VT or VT/VF; c) pts with IA have a high incidence of infra-nodal and intraventricular conduction defects which may predispose to VT, VT/VF and VT; and d) EPS may provide data upon which to base therapy in pts resuscitated from CA.

REPETITIVE BEATING AFTER SINGLE VENTRICULAR EXTRASTIMULI: INCIDENCE AND PROGNOSTIC SIGNIFICANCE IN PATIENTS WITH RECURRENT VENTRICULAR TACHYCARDIA

Jay W. Mason, MD, FACC, Stanford University, Stanford, CA.

We have tabulated the incidence of repetitive ventricular beating in 59 patients with recurrent ventricular tachycardia in response to programmed single ventricular extrastimuli delivered during spontaneous rhythm to clarify a controversy regarding frequency and prognostic significance of ventricular repetitions. The 44 males and 15 females had an average age of 51.7 (range 16-75) years. Thirty-four had ischemic heart disease, 28 with prior myocardial infarction; 25 had non-ischemic disease, (8 cardiomyopathies, 8 no identifiable heart disease, 6 valve disease and 3 QT prolongation syndrome.)

Repetitive beating occurred in only 9 (15%) of the patients. The repetitive response seemed to be clearly a result of bundle branch reentry in 4 subjects, and possibly due to other mechanisms in 5. There was no difference in the incidence of repetitive beating or in the type of repetitive response in patients with compared to patients without ischemic heart disease. During an average follow-up period of 13.6 months per patient, there were 8 sudden and 6 non-sudden deaths. Life table analysis revealed a significantly higher incidence of sudden death in patients with ischemic heart disease compared to subjects with non-ischemic cardiac disease. There was no significant difference in the incidence of sudden death in patients with compared to patients without repetitive beating.

We conclude that the repetitive response to single ventricular extrastimulation is infrequent in patients with recurrent ventricular tachycardia, and that repetitive beating is not a prognostic indicator or an indicator of vulnerability to ventricular tachycardia.

SENSITIVITY AND SPECIFICITY OF PROGRAMMED VENTRICULAR STIMULATION IN PATIENTS WITH VENTRICULAR TACHYCARDIA

Christine J. VandePol, MD; Ardeshir Farshidi, MD,FACC; Scott R. Spielman, MD; Allan M. Greenspan, MD; Leonard N. Horowitz, MD,FACC; John A. Kastor, MD,FACC; Mark E. Josephson, MD,FACC, Hospital of the University of Pennsylvania, Philadelphia, Pa.

Programmed ventricular stimulation (PVS) has been used to evaluate patients (pts) with suspected or documented ventricular tachycardia (VT), however its sensitivity and specificity has not been assessed in a large group of pts. PVS including single and double premature stimuli and rapid pacing was performed in 529 pts during electrophysiologic study. Symptomatic clinical VT had been documented in 86 pts. Clinical VT was sustained (VT-S) in 57 pts and nonsustained (VT-NS) in 29 pts. Of the pts with VT-S clinically, PVS induced VT-S in 52/57 (91%) pts and VT-NS in 2/57 (4%) pts. In 3/57 (5%) of these pts no VT was induced. Of the pts with VT-NS clinically, PVS induced VT-NS in 18/29 (62%) pts, in the remaining 11 pts (38%) no VT was induced. Thus, PVS is highly sensitive in identifying pts with VT-S and moderately sensitive for pts with VT-NS. In the 529 pts, VT was induced in 75 pts, 72 of whom had clinical VT. All 52 pts with induced VT-S had VT clinically and 20/23 (87%) pts with induced VT-NS had VT clinically. QRS morphology and axis and tachycardia cycle lengths of the induced and clinical VTs were similar in each pt. VT-NS was induced in 3/443 (0.7%) pts without clinically documented VT. Thus, PVS is highly specific for identifying pts with VT, either sustained or nonsustained. We conclude that VT resembling clinical VT can be induced by PVS in almost all pts with VT-S clinically, in many pts with symptomatic VT-NS clinically, and rarely in pts without previously documented VT. Moreover, induction of VT by PVS predicts its clinical occurrence.

DETERMINATION OF ABSOLUTE LEFT VENTRICULAR VOLUME FROM GATED BLOOD POOL IMAGING WITH AN ATTENUATION CORRECTED COUNT RATE METHOD

Jonathan M. Links, BA; Lewis C. Becker, MD, FACC; J. Gregory Schindledecker, CNMT; Pablo Guzman, MD; Robert D. Burow, BS; Edward L. Nickoloff, ScD; Philip O. Alderson, MD; and Henry N. Wagner, Jr., MD. The Johns Hopkins Medical Institutions, Baltimore, Maryland.

A new method for determination of absolute left ventricular volume (LVV) was studied in 22 pts who had gated blood pool (GBP) imaging within 24 hrs of single plane (RAO) contrast ventriculography (CV). LAO 40° and anterior views were acquired. A radioactive marker was placed on the skin over the LV in the LAO view, and imaged during the anterior view. A blood sample was withdrawn during the LAO view, and counted on the collimator face after completion of both views. LVV at end-diastole (ED) was given by the ratio of the attenuation corrected LVED count rate in the LAO view to the count rate per ml from the blood sample. The LVED count rate was given by dividing the total background corrected counts in the LVED region of interest by the time per ED frame times the number of cardiac cycles acquired. Attenuation correction was made by dividing the LVED count rate by e^{-ud} (u=u of water, d=distance from skin marker to center of LV in anterior view divided by sin 40° to yield depth of LV in LAO view). This LVEDV was used to calibrate the LV time-activity curve, yielding LVV throughout the cardiac cycle. The correlation between GBP and CV EDV was 0.96 (GBP=1.06CV - 12 ml); between GBP and CV ESV was 0.96 (GBP=1.19CV - 13 ml). This method permits determination of absolute LVV without geometric assumptions or the use of a regression equation.

VIEWER SPECIFIED PROJECTION: A NEW METHOD OF COMPUTER DISPLAY OF LAO ACQUIRED GATED BLOOD POOL DATA IN ANY PROJECTION DESIRED

Robert A. Vogel, MD; David M. Stern, BA; Dennis L. Kirch, MSEE; Michael T. LeFree, BS; Peter P. Steele, MD Veterans Administration Medical Center, Denver, CO.

A new method is presented for the computerized display of gated blood pool cineangiograms obtained in the LAO projection into any view specified by the observer. The method is based upon tomographic acquisition of 8 frame per cardiac cycle gated blood pool data using the 7 pinhole collimator - scintillation camera technique. Initially, tomographic cineangiograms are reconstructed for each of 8 planes spaced 1.0-1.5 cm apart. Using maximum radial gradient criteria, the edge of the left ventricle (LV) is then determined by the computer for each frame, which results in a complete spatial map of the LV surface in 3 dimensions. Once accomplished, the ventricular surface can be reprojected as it would be viewed from any point in space, including from inside the ventricle. Surface contours are made distinguishable by use of shading determined using light reflectivity criteria. Included in this process is the determination of the LV volume for each tomographic section and for the whole LV. Volumes calculated by this method correlated well (r=.98) with those of 8 ventricular phantoms of from 65 to 210 cc capacity. Of the innumerable views into which gated blood pool studies can be reprojected, the RAO, LPO, and inferior surface views appear to be the most clinically relevant. The latter, which cannot be obtained directly by any conventional methods, is particularly helpful for determination of the septal extent of apical aneurysms. Finally, multiple viewer specified projections can be displayed simultaneously, all obtained from a single LAO projection initial acquisition.

MINIATURIZED CARDIAC MODULE FOR CONTINUOUS MONITORING OF LEFT VENTRICULAR PERFORMANCE USING A SEMICONDUCTOR GAMMA DETECTOR: DEVELOPMENT OF A PROTOTYPE AND INITIAL CLINICAL EVALUATION. Harvey Berger, MD, Paul Hoffer, MD, John Steidley, PhD, Alexander Gottschalk, MD, Barry Zaret, MD, FACC, Yale University, New Haven, Ct.

A prototypic miniaturized cardiac module, which allows rapid assessment of left ventricular ejection fraction (LVEF) from the ECG-gated cardiac blood pool, has been developed. The module consists of a detector and a collimator, weighs 175 grams, measures 3 cm in length and 3.5 cm in diameter, and is placed directly on the patient's (pt) chest in the left anterior oblique position. The detector is a 1.5 cm^2 cadmium telluride semiconductor crystal that has a good (approximately 50%) efficiency for Tc-99m. The detector, which is affixed directly to a circular straight bore lead collimator, is connected to a preamplifier and low energy supply. After Tc-99m blood pool labeling (20 mCi), data are recorded for 60 sec on a multichannel analyzer modified to recycle with each ECG R-wave and sort data into 30 msec frames. Using standardized algorithms, the module is first positioned over the LV and then over a background (bkg) region lateral to the LV. Following bkg correction, a high temporal resolution summed relative LV volume curve is obtained. LVEF measured by the module was compared to LVEF obtained by scintillation camera in 13 pts. By camera, LVEF averaged (±SEM) 54±4% (range, 29-70%) and was abnormal (<55%) in 5/13 pts. With the module, LVEF averaged 55±3% (pNS) and correlated well with camera data (r=0.79). End-diastolic counts prior to bkg correction were 32,095±3402.

Thus, LVEF can be determined rapidly with a miniaturized cardiac module affixed directly to the chest. This new system should allow continuous monitoring of LV function in critically ill and ambulatory pts, thereby broadening the scope of radionuclide LV function studies.

MULTIPLE GATED BLOODPOOL CARDIAC SCAN (MUGA) DURING RIGHT ATRIAL PACING (RAP): A SENSITIVE METHOD TO DETECT MYOCARDIAL ISCHEMIA. Dan Tzivoni, MD; Avraham T. Weiss, MD; Avinoam Bakst, MD; Joe L. Rod, MD; Jean Salomon, MD; Dov Warshaw, MD; Mervyn S. Gotsman, MD; Henri Atlan, MD, Hadassah University Hospital, Jerusalem, Israel.

MUGA was performed on 11 patients with angiographically documented coronary disease (CAD) and in 7 normals, during increasing rates of RAP up to 160/min. Images were taken at 45° LAO and 30° RAO views at each rate. Ejection fraction (EF) was computed from LAO view and wall motion (WM) was evaluated visually at each pacing rate. Significant ST depression was observed in 2 normals and 7 CAD patients (Table). A non significant increase was observed in EF in normals. A significant reduction was observed in EF in 9 of the 11 CAD patients. WM analysis revealed reduction in amplitude in the 9 patients in whom EF decreased during pacing.
Conclusion: Changes in EF and WM are more sensitive in detecting myocardial ischemia during RAP than ECG changes. Pacing MUGA is technically easier and probably more precise than exercise MUGA.

PACING ECG			EF% ± SD				
	N	P	REST	100/m	120/m	140/m	160/m
7 normals	5	2	64± 8	63±11	62± 6	69±13	68± 7
11 CAD	4	7	58±16	57±16	57±16	45±18	41±19

LEFT VENTRICULAR DIASTOLIC PERFORMANCE DURING EXERCISE IN CORONARY ARTERY DISEASE: ASSESSMENT OF PEAK FILLING RATE WITH FIRST PASS RADIONUCLIDE ANGIOGRAPHY. Lawrence A. Reduto, M.D., FACC; James B. Young, M.D.; Leslie Del Ventura, B.S.; Donald Glaeser, D.Sc.; Mario Verani, M.D., FACC; Miguel Quinones, M.D., FACC; Richard R. Miller, M.D., FACC. Baylor College of Medicine, Houston, Texas.

Data are lacking concerning the effects of exercise (EX) on left ventricular (LV) diastolic compliance in patients (pts) with coronary artery disease (CAD). Accordingly, LV peak filling rate (PFR), an index of LV diastolic performance and ejection fraction (EF) were determined at rest (R) and during maximal upright bicycle EX in 14 normal (N) and 40 pts with CAD with high frame rate (20 msec) first pass radionuclide angiography utilizing a multicrystal scintillation camera. All N pts increased (>5%) EF from R to EX; mean(±SEM): 65±1% to 82±2% (p<.001). In 17 CAD pts exercised to fatigue (F), EF increased with EX: 54±4% to 66±4% (p<.01). In 23 CAD pts, ischemia (I) during EX resulted in no change (±5%) or decrease in EF 62±2% to 58±2% (p=ns). All PFR were normalized to end-diastolic counts.

	(R) PFR	(EX) PFR	p
N	2700±160 counts/sec	6200±440 counts/sec	<.001
CAD(F)	2280±200 counts/sec	4260±280 counts/sec	<.001
CAD(I)	2740±180 counts/sec	4200±300 counts/sec	<. 05

Mean increase in PFR during EX was lower in both CAD(F) [1980±230 counts/sec] and CAD(I) [1460±270 counts/sec] than N [3500±440 counts/sec] (p <.001). In 19 pts with prior myocardial infarction, mean (R) EF was 55±3%; PFR at R and during EX did not differ from N pts or remaining CAD pts. These data suggest 1) PFR, as an index of LV diastolic performance, may be obtained at R and EX with first pass radionuclide techniques. 2) EX PFR response was less than N in both CAD(F) and CAD(I); 3) despite a normal systolic response during EX, CAD (F) pts manifested abnormal LV EX diastolic performance as assessed by PFR.

SENSITIVITY AND SPECIFICITY OF EXERCISE RADIONUCLIDE ANGIOGRAPHY IN DETECTING CORONARY DISEASE

Patricia McEwan M.D., F.A.C.C., Glenn E. Newman M.D., Steven Port M.D., Mark T. Upton M.D., Frederick R. Cobb M.D., Robert H. Jones M.D., F.A.C.C., Duke Medical Centre, Durham, N.C.

The sensitivity and specificity of exercise (Ex) first pass radionuclide angiocardiograms (RNA) for detecting coronary disease was determined in 144 patients catheterized because of chest pain. All patients underwent upright rest and maximal bicycle Ex RNA. All patients had normal rest left ventricular function. Twenty-eight control patients had normal coronaries. An abnormal rest-Ex response was defined as a failure of the ejection fraction (EF) to rise by 0.05 and/or development of a wall motion (WM) abnormality. The Ex test was considered adequate in 107/144 patients who developed chest pain, ischemic ECG changes or 85% of age predicted maximum heart rate.

		All pts	Pts with adequate Ex
Sensitivity	EF	76%	85%
	WM	52%	58%
Specificity	EF	50%	76%
	WM	100%	100%

EF sensitivity increased from 69% in 1-vessel disease to 85% in 3 vessel disease. Patients with normal coronaries had a 32% incidence (9/28) of abnormal EF response to Ex, but none developed WM abnormalities. Failure of the EF to increase with Ex is a sensitive but not specific indicator of coronary disease, while WM abnormalities are specific but not sensitive. Adequate Ex stress improves the predictive value of the test.

INABILITY TO DETECT CORONARY ARTERY DISEASE AT REST BY PATTERNS OF VENTRICULAR EMPTYING USING CONTRAST ANGIOGRAPHY AND RADIONUCLIDE ANGIOGRAPHY

Barry Denenberg, MD, Todd Makler, MD, Alfred Bove, MD, PhD, FACC, Leon Malmud, MD, David Charkes, MD, James Spann, MD, FACC, Temple University Hospital, Philadelphia, PA.

Fractional left ventricular emptying (FVE) measured by the first third ejection fraction (1/3 EF) has been proposed as an indicator of abnormal ventricular function in patients with coronary artery disease (CAD). To determine the value of this index in early CAD with normal overall EF, we calculated the percent change of ventricular volume by computer assisted analysis of 60 frames/sec biplane contrast angiograms (CON) throughout the cardiac cycle in 33 normals (N) and 23 patients with CAD, and the gated equilibrium radionuclide time-activity curve (RN-TAC) in 8 normals and 6 patients with CAD who had both contrast angiography and RN-TAC. Ejection fraction by CON was normal in both groups (N: 64 ± 4, CAD: 64 ± 5). In all patients there was an excellent correlation of the CON calculated FVE curve and the RN-TAC ($R = .971$). However, there was no difference in FVE at any point in the cardiac cycle between normals and CAD by either CON or RN-TAC. CON 1/3 EF for N was 15 ± 1 and for CAD was 17 ± 3 ($p > .4$). RN-TAC 1/3 EF for N was 23 ± 2.7 and for CAD was 25 ± 4.0 ($p > .7$). Neither the first third ejection fraction nor the entire point by point ventricular emptying curve measured by either contrast angiography or RN-TAC can distinguish between normal and CAD patients at rest.

EVALUATION OF RIGHT HEART FUNCTION IN ADULTS WITH ATRIAL SEPTAL DEFECT USING GATED CARDIAC BLOOD POOL SCANNING

Richard R. Liberthson, M.D., Charles A. Boucher, M.D., FACC, Gerald M. Pohost, Robert E. Dinsmore, M.D. Kenneth A. McKusick, M.D., H. William Strauss, M.D. Massachusetts General Hospital, Boston, MA

Right atrial (RA) and right ventricular (RV) function was assessed in 21 adult patients (pts) with atrial septal defect (ASD) using gated cardiac blood pool imaging. Eighteen pts had pre and postoperative (after 6 months) scans. Clinical findings, pre and postoperative course, and catheterization data were correlated with scan findings. In all pts, the RA and RV were dilated preoperatively. In 9 pts (ages 18 to 42 years, mean 23), RV wall motion was normal. All 9 were asymptomatic and had normal rhythm; pulmonary-to-systemic flow ratios (Qp/Qs) were between 2/1 and 5/1; pulmonary artery systolic pressures (PAP) below 30 mmHg; and RV end-diastolic pressures (RVEDP) below 8 mmHg. All 9 had uncomplicated ASD repair, remained asymptomatic after surgery, and in all, postoperative RA and RV size and wall motion were normal. In the remaining 12 pts (ages 36 to 75 years, mean 58), there was moderate to severe RV hypokinesis. These pts all had preoperative symptoms; 5 were in atrial fibrillation; 7 had clinical heart failure; one had Eisenmengers' physiology; Qp/Qs was between 1.7/1 and 3.0/1 (excepting the pt with Eisenmengers'); PAP exceeded 30 mmHg in 9; and RVEDP exceeded 8 mmHg in 6. Although symptoms and RV function improved in the 9 who had ASD repair, unlike those with normal preoperative RV wall motion, only one had normal postoperative function and became asymptomatic.

In conclusion, cardiac imaging illustrates the close relationship between RV function and pre and postoperative clinical course in pts with ASD. Although postoperative RV function improves in all pts, it does not become normal in those with decreased preoperative RV wall motion.

DETECTION AND QUANTITATION OF ATRIAL SHUNTS IN ADULTS BY GATED RADIONUCLIDE ANGIOGRAPHY

Edward W. Bough, MD, FACC; Elan J. Gandsman, PhD; Ian D. Benham, MD; William E. Boden, MD; David L. North, MS; Richard S. Shulman, MD, FACC, Department of Medicine, Brown University, Providence, R.I.

A gated radionuclide angiographic (GRA) method for the measurement of the pulmonic/systemic flow ratio (Qp/Qs) in patients with atrial septal defects (ASD) has been developed which is simpler to perform and analyze than the first-pass method which requires analysis of tracer recirculation in the lung field. Six adults with ASD and left-to-right shunts and thirty-three patients without shunts or valvular regurgitation underwent GRA in the LAO projection with a 30^0 caudal slant-hole collimator after Tc-99m red cell labeling. End-diastolic and end-systolic frames were identified from the time-activity curve (TAC) of an initial left ventricular (LV) region and were computer subtracted to generate a stroke volume image (SVI). Use of the SVI allowed accurate re-definition of the ventricular regions, especially the right ventricular conus. These regions were used to generate ventricular TACs and to calculate the stroke volume ratio (RVSV/LVSV) which, in the absence of valvular regurgitation, is equal to Qp/Qs. In thirty-three normal subjects, RVSV/LVSV by GRA was $0.94 \pm .05$ ($\bar{m} \pm SD$). The six ASD patients exhibited RVSV/LVSV of 1.4 to 3.7 by GRA, all exceeding the normal range of 0.84 to 1.04 ($\bar{m} \pm 2SD$). Correlation of RVSV/LVSV by GRA and Qp/Qs by oximetry during cardiac catheterization of these six patients was excellent ($r = 0.88$). We conclude that GRA is an excellent non-invasive method for the detection and quantitation of left-to-right shunts in adults with ASD.

FIRST PASS RADIONUCLIDE WALL MOTION ABNORMALITIES ASSOCIATED WITH MITRAL VALVE PROLAPSE SYNDROME.

Jack W. Fleming, MD; E. James Andrews, MD; Nathan Arenson, MD; Antonio J. Ballagas, MD; Aubrey T. Hornsby, MD; D. Bruce McCraw, MD; J. Curtis Williams, MD; Michael Mello, RT; Medical Center Clinic, Pensacola, Florida.

This report concerns our experience with first pass (FP) rest-exercise radionuclide angiocardiogram(RNAC) studies in 75 patients(pts) with mitral valve prolapse (MVP) confirmed by echocardiograms(E). 27 pts had coronary angiography. 5 pts had thallium stress scintigraphy. Some pts with MVP also had significant obstructive coronary disease(CAD). "Cardiomyopathy"(CM) was common in our pts with MVP. Our studies indicate that MVP pts with normal coronary angiograms frequently have abnormal patterns of wall motion abnormality(WMA), regional ejection fraction images(REFI), and global left ventricular (LV) ejection fraction(EF) response to exercise. In addition, MVP pts often have characteristic patterns seen in the FP-RNAC: a) a small bulge(B) is seen in the region of the left atrium during systole; b) the LV infero-basilar border becomes straightened and horizontal during systole. WMA and/or B were less common(30%) in MVP pts with E hammock deformities of the anterior mitral valve leaflet than in other MVP pts(81%).

CONCLUSIONS: 1) MVP frequently is associated with significant segmental and diffuse WMA. 2) Some of these WMA may be due to cardiomyopathy of diverse etiology; some may be related to genetically induced or other pathophysiologic structural and biochemical myocardial abnormalities, independent of ischemic etiology. 3) MVP-WMA may interfere with or be confused with WMA associated with CAD. 4) Regional and global WMA associated with MVP may be present, coincidentally, in pts with CAD; CAD may not be related to WMA in segments uninvolved by CAD; global LVEF response to exercise in these pts may not reflect the degree of relevance of CAD.

NON-INVASIVE MONITORING OF CARDIAC TRANSPLANTS

Steven R. Bergmann, PhD; Rene A. Lerch, MD; Jeffrey E. Saffitz, MD; Sun Lee, MD; Burton E. Sobel, MD, FACC, Washington University, St. Louis, Missouri.

To determine whether rejection of allogeneic cardiac transplants can be monitored non-invasively with an approach adaptable for positron emission tomography, we injected ^{111}indium (^{111}In)-labeled cells prepared from autologous lymphocytes in rats with heterotopic cardiac transplants. Donor hearts from 37 Wistar-Furth (WF) or Lewis (L) rats were anastomosed to the abdominal aorta and vena cavae of L recipients. In 22 technically successful allogeneic transplants (i.e. beating for 72 hr after surgery), rejection (loss of contraction and electrical activity) occurred 7.4 ± 1.3 (SD) days after transplantation associated with extensive myocardial infiltration by plasma cells and lymphocytes. In 15 corresponding isogeneic transplants, contraction and electrical activity remained intact without any microscopic criteria of rejection. Twenty-four hours after injection of recipient animals with ^{111}In-lymphocytes at selected intervals after transplantation, radioactivity was assayed in both autologous and transplanted hearts in each animal before (externally) and after (in tissue samples) sacrifice. Externally detectable labeled cells accumulated progressively with time after transplantation in allogeneic but not isogeneic transplanted hearts with peak accumulation concomitant with functional and microscopic criteria of peak rejection. The ratio of activity/g of transplanted compared to autologous hearts from animals with 7 day old transplants determined by gamma spectrometry was 8.9 ± 1.4 ($p < .001$). In contrast, this ratio did not differ significantly from unity in animals with isogeneic transplants. Thus, rejection of allogeneic cardiac transplants can be detected and monitored externally with autologous ^{111}In-lymphocytes permitting potential evaluation of the efficacy of anti-rejection therapy in vivo.

ADRIAMYCIN CARDIOTOXICITY - ASSESSMENT OF LATE LEFT VENTRICULAR DYSFUNCTION BY RADIONUCLIDE CINEANGIOGRAPHY

John S. Gottdiener, MD; Douglas J. Mathisen, MD; Jeffrey S. Borer, MD, FACC; Robert O. Bonow, MD; Charles E. Myers, MD; Stephen L. Bacharach, PhD; Michael V. Green, MD; Steven A. Rosenberg, MD, NHLBI, and NCI, NIH, Bethesda, Md.

Adriamycin is an effective antineoplastic agent associated with dose dependent impairment of left ventricular function. While left ventricular dysfunction usually appears during or shortly after treatment with adriamycin, most patients (pts) do not survive long enough to determine how long the cardiac effects of adriamycin persist after the drug has been completed. In order to determine the presence of left ventricular dysfunction in pts who did not evidence overt cardiomyopathy during adriamycin therapy, we studied 21 pts in two groups, matched for age and therapeutic regimen, who sustained long term remission of soft tissue sarcoma following 6 months of adjuvant therapy with adriamycin 500-550 mg/m^2. Ejection fraction at rest and during exercise was determined in 11 pts (Group A) 1-12 months (median 4.8 months) and in 10 pts (Group B) 2-3 yrs (median 2.5 yrs) after completing adriamycin. Left ventricular ejection fraction at rest was abnormal (<45%) in 4 of 10 Group A pts (av=47±3%, normal av 51±1%, p<.005) and was abnormal during exercise (<55%) in 5 of 10 pts (av=53±4%, normal av=71±1%, p<.005). Left ventricular dysfunction persisted in Group B pts as evidenced by decreased ejection fraction at rest in 2 of 9 pts (av 51±3%, p<.01) and during exercise in 6 of 9 pts (av 55±3%, p<.005). There was no significant difference in ejection fraction at rest or with exercise between Group A and Group B pts. Hence, left ventricular dysfunction: 1) is evident following adriamycin in half of asymptomatic pts, even at "acceptable" cumulative doses of 550 mg/m^2, and 2) may persist for several years without improvement.

CLINICAL PHARMACOLOGY: SYSTEMIC VASODILATORS AND CARDIOTONICS
2:00-5:30

CAN HYDRALAZINE THERAPY FOR SEVERE, CHRONIC, HEART FAILURE BE SAFELY AND EFFECTIVELY INITIATED OUTSIDE THE HOSPITAL?

Stanley Rubin, MD, FACC; Harold Marcus, MD, FACC; HJC Swan, MD, PhD, FACC, Cedars-Sinai Medical Center, Los Angeles, California

Initiation of vasodilator therapy in chronic heart failure patients requires knowledge of side-effects as well as knowledge of a dose-response relationship. We studied 24 severe, chronic, heart failure patients (NYHA Class III or IV) who were in stable condition and who were electively admitted to the hospital for hydralazine therapy. History, physical, ECG and rhythm strips, routine laboratory tests and invasive hemodynamic monitoring were used to evaluate response to increasing doses of hydralazine. Hydralazine caused severe complications in 21% (5/24): onset or worsening of angina pectoris in 9% (2/24); subendocardial infarction in 4% (1/24); severe renal insufficiency in 4% (1/24); tachycardia-hypotension in 4% (1/24). Hydralazine caused arrhythmias in 8% (2/24): junctional tachycardia in 4% (1/24); isorhythmic A-V dissociation in 4% (1/24). Dose response relationships were examined. A single 20 mg intravenous dose of hydralazine did not increase cardiac output in 17% (4/24). Incremental oral doses of hydralazine increased cardiac output >0.5 l/min/m^2 in the other patients but the required dose ranged from 50-150 mg q6h among the responders. This effective dose could not be predicted from initial clinical or hemodynamic data. We conclude that hydralazine cannot be safely or effectively initiated in an outpatient population of severe, chronic heart failure patients because of the unpredictable occurrence of side effects and because of the inability to predict an effective dose.

MECHANISM OF IMPROVED CARDIAC PERFORMANCE WITH AFTERLOAD REDUCTION IN AORTIC INSUFFICIENCY.

Barry Greenberg, MD, FACC, Edward Murphy, MD, FACC, Henry DeMots, MD, FACC, Shahbudin Rahimtoola, MB, FACC, University of Oregon Health Sciences Center, Portland, Oregon.

The effects of isolated afterload reduction in patients (pts) with aortic insufficiency (AI) are uncertain. Previous studies using parenteral vasodilators have shown improved hemodynamics, however the results are compounded by dual effects of the drugs on venous capacitance as well as afterload. In order to determine the effects of isolated afterload reduction we studied the effects of hydralazine (H), a drug whose predominant effect is to reduce systemic vascular resistance (SVR), in 8 pts with chronic severe AI.

All pts were catheterized and had isolated severe AI. End diastolic volume index (EDVI) was 192±12 cc/m^2. Ejection fraction (EF) was .54±4 and was reduced in 3 pts. Regurgitant fraction (RF) was .64±3.

Hemodynamic measurements and left ventricular (LV) angiography were performed pre and post intravenous H (0.3mg/kg). H increased heart rate from 78±4 to 92±10 ($p<.01$); cardiac index from 3.0±.2 to 5.2±.5 L/min/m^2 ($p<.001$); stroke volume index from 40±3 to 57±5 cc/m^2 ($p<.01$); H reduced arterial pressure from 90±10 to 84±12 mmHg ($p<.01$), LV end diastolic pressure from 21±5 to 13±3 mmHg ($p<.10$) and SVR from 1221±96 to 699±93 dynes-sec-cm^{-5} ($p<.001$). Neither EF, EDVI nor total stroke volume changed significantly. However, regurgitant stroke volume was reduced from 70±10 to 53±9 cc/m^2 ($p<0.05$) and regurgitant fraction from .64±.03 to .47±.05($p<.001$)

These data suggest that isolated afterload reduction improves cardiac performance by favorably redistributing LV stroke volume so that forward flow increases while RF is reduced. Changes in EF do not appear of major importance. H therapy is of potential value in pts with AI.

LONG TERM IMPROVEMENT IN LEFT VENTRICULAR FUNCTION AFTER PRAZOSIN THERAPY.

Stephen A. Goldman, MD; Lynne L. Johnson,M.D. Edith Escala,BS; Paul J. Cannon, M.D. FACC; Melvin B. Weiss, M.D. FACC. College of Physicians and Surgeons, Columbia University, N.Y., N.Y.

To study the effect of Prazosin (PZ) therapy in left ventricular function in patients with chronic stable heart failure, first pass radionuclide angiography at rest (re) and exercise (ex) was performed in 15 patients before PZ and after 7-12 weeks of PZ therapy. There was no significant change in resting ejection fraction (EF) before and on PZ (36±14% vs 37±14%, however ex EF increased from 34±14% to 42±17% ($p<.01$). The difference in EF from re to ex (EF response) changed significantly from -2±6% before PZ to +5±7% during PZ ($p<.01$). Exercise duration increased from 368±82 sec. to 476±82 sec. ($p<.01$). Total work capacity measured in kilojoules increased from 12.6±8.3 to 18.6±10.4 ($p<.01$). The improved EF response on PZ correlated with the improved work capacity ($r=0.69$, $p<.01$) and exercise duration ($p=0.59$, $p<.05$). This improvement occured despite a significant weight gain on PZ from 72.2 ±20.8 kg to 73.5±20.8 kg ($p<.01$).

These data suggest that the change in work capacity achieved on PZ during ex can predict the EF response. The beneficial long-term effects of PZ on LV function may only become evident during exercise and thus may explain the negative results seen by other investigators.

IS THE VASOCONSTRICTION OF CHRONIC HEART FAILURE RELATED TO THE RENIN ANGIOTENSIN SYSTEM?

Leon Stein, MD, FACC; Myron Weinberger, MD; Peter R. Foster, MD, FACC; Indiana University Medical Center, Krannert Institute of Cardiology, Indianapolis, Indiana.

The importance of the renin angiotension system in the homeostasis of heart failure (HF) has been recently emphasized. Plasma renin activity (PRA) rises during acute HF, is usually suppressed during chronic HF and would be expected to rise significantly when systemic vascular resistance (SVR) and mean arterial pressure (AP)fall during vasodilator therapy (VDT). We studied the relationship between PRA and the fall in SVR and AP induced in 8 patients with chronic HF by direct muscle relaxation with Na Nitroprusside (NP) and alpha adrenergic blockade with Prazosin (PZ). After infusion of NP, patients had clinical titration with PZ (average 6 days). PZ was withheld for 24 hrs and measurement repeated before and during PZ. This sequence was repeated after 10 weeks of PZ therapy. Baseline pulmonary artery wedge pressure averaged 28+6 torr, cardiac output 3.2+1.2 l/m, SVR 2513+1210 dcs^{-5}, AP 103+12 torr and PRA 5.3+5.4 ng/ml/3 hr(normal 2 to 10). NP produced a significant drop in SVR, ($p<.02$) and AP ($p<.001$) and PRA increased to 8.9+10.7 (NS). There was no correlation between the drop in AP or SVR and PRA before or during NP. After titration PZ induced a significant drop in SVR ($p<.001$) and AP ($p<.02$), and PRA decreased from 7.1+3.9 to 6.+5.7 (NS). The drop in AP and SVR correlated with PRA before ($p<.01$) but not during PZ. After 10 weeks PZ produced a significant drop in SVR, ($p<.02$) and AP ($p<.005$) and PRA decreased from 6.5+5.2 to 5.2+5. (NS). There was no correlation between the drop in AP or SVR, and PRA before or during PZ. CONCLUSIONS - The PRA is often inappropiately normal in chronic HF and usually does not increase nor correlate with the fall in SVR and AP during acute VDT with NP and chronic VDT with PZ.

LONG TERM TRIMAZOSIN THERAPY IN CARDIAC FAILURE.

Karl T. Weber,MD,FACC, James S. West,MD, Gary T. Kinasewitz,MD, Joseph S. Janicki,PhD, Nathaniel Reichek,MD, and Alfred P. Fishman,MD,FACC, U. Pennsylvania, Philadelphia, Pa.

The influence of long term vasodilator therapy on the exercise capacity of pts with failure remains uncertain. Toward this end, a double blind study was undertaken to assess the response in graded treadmill exercise (E;symptomatic maximum) to vasodilator therapy with trimazosin (T,.3-.9g daily).Twenty-five pts with stable,chronic(.5-6yrs)failure of varying severity(5,class II;11,III;and 9, IV)and etiology(aortic or mitral incompetence, cardiomyopathy, and ischemic heart disease)have been followed for periods up to 37 wks.Echocardiographic LV size and shortening were determined at rest while exercise performance was assessed by monitoring respiratory gas exchange and air flow before(B)and after randomization of placebo(P, 12pts)and T(13pts).Eleven of 12 pts on P for 6 wks were then given T.The mean values for E time(sec),peak O_2 uptake(VO_2,cc/min/kg),anaerobic threshold(AT,sec),and the change from resting to end E in O_2 pulse(ΔO_2P,cc/kg/beat), measured at B and 4-6 wks(t_1)and 12-18 wks(t_2)of T therapy are given below:

	E			$\dot{V}O2$			AT			$\Delta O2P$		
Class	B	t1	t2	B	t1	t2	B	t1	t2	B	t1	t2
II	766	869	944	16	18	20	600	625	667	53	76	90
III	537	666	747	12	14	14	391	475	515	42	60	64
IV	299	443	438	9	10	10	217	317	325	30	42	39

We found: a) a significant($p<.05$)increase in E,$\dot{V}O_2$,AT and ΔO_2P in each class II and III pt and 6 of 9 class IV pts receiving T and which was not apparent with P;b)no significant alteration in resting LV diastolic dimension or shortening with T or P; and c)no evidence of drug tolerance.Thus,T is a promising new vasodilator which provides sustained augmentation in effort tolerance, aerobic capacity and O_2 delivery in pts which chronic failure.

ORAL CAPTOPRIL IN AMBULATORY MANAGEMENT OF SEVERE CONGESTIVE HEART FAILURE: SUSTAINED BENEFICIAL EFFECTS ON VENTRICULAR FUNCTION WITH 6 MONTHS THERAPY SHOWN BY CARDIAC CATHETERIZATION, NUCLEAR SCINTIGRAPHY, ECHOGRAPHY, TREADMILL EXERCISE AND SYMPTOMATOLOGY

Dean T. Mason, MD, FACC; John Hermanovich, MD; Mark Evensen, BS; Najam A. Awan, MD, FACC, Univ. Calif., Davis, CA.

To provide effective ambulatory vasodilator therapy in severe chronic congestive heart failure (CHF), the long-term effects of prolonged administration of the oral angiotensin converting enzyme inhibitor, captopril (CPT) were evaluated by cardiac catheterization, nuclear scintigraphy (MUGA), echocardiography (ECHO), treadmill exercise (TEX) and symptomatology (FC) after 6 months of continuous therapy in 8 patients with severe CHF. Measurements included: LVFP = left ventricular filling pressure, mmHg; CI = cardiac index, L/min/M^2; SI = stroke index, ml/beat/M^2; TSVR = total systemic vascular resistance, dsc^{-5}; EF = MUGA ejection fraction, %; EDD = ECHO LV end-diastolic dimension; TEXD = TEX duration, seconds; NYHA FC.

CPT vs Control: * = $p<0.05$, ** = $p<0.02$, + = $p<0.001$.

	LVFP	CI	SI	TSVR	EF	EDD	TEXD	FC
Control	23	2.0	26	1800	21	65	339	3.7
CPT-Initial	15**	2.4**	32**	1309**				
CPT-6 month	15**	2.3*	32**	1423**	30**	60**	499*	2.3+

Thus initial beneficial hemodynamic effects of CPT on predrug abnormal CI, SI, LVFP and TSVR were maintained during 6 months chronic ambulatory therapy. Moreover, 6 months evaluation demonstrated considerable elevations of lowered LV ejection fraction and exercise tolerance while enlarged intra-LV dimensions and size were decreased. This CPT augmentation of hemodynamics and physical activity resulted in considerably improved NYHA FC. Thus, chronic oral captopril provides markedly salutary sustained effects on cardiac performance in otherwise refractory CHF.

CHARACTERIZATION OF THE INOTROPIC AND BIOCHEMICAL PROPERTIES OF AMRINONE -- A NOVEL CARDIOTONIC AGENT. Marion S. Gaide, PhD; Stephen P. Baker, PhD; Alan M. Ezrin, MS; Lincoln T. Potter, MD; Henry Gelband, MD, FACC; Arthur L. Bassett, PhD, University of Miami School of Medicine, Miami, Florida 33101.

The inotropic activity of amrinone, a bipyridine derivative, (MW = 187.2) was assessed in isolated cat ventricular muscles during 1) phasic isometric contractions (0.5 Hz) in warm Tyrode's solution (4 mM K^+, 150.8 mM Na^+), and 2) maintained depolarization and contracture induced by high K^+ Tyrode's (133 mM K^+, 21.8 mM Na^+). Amrinone (5×10^{-6}–5×10^{-4}M) increased peak contractile force in a concentration-dependent manner while reducing K^+-induced contracture force. An increase in active contractile force and a reduction in K^+-contracture is a "catecholaminergic-like" action in cardiac muscle; however, these inotropic effects persisted even during a high level of β-adrenergic blockade induced by 10^{-3}M nadolol. To determine whether amrinone's action is due to direct activation of β-receptors, competitive binding assays with 10 nM (-)-(^{3}H) dihydroalprenolol (DHA) in 0.1% ascorbic acid were carried out on β-receptors in cat ventricular membranes. No significant displacement of DHA occurred with amrinone concentrations of 1 μM to 0.5 mM. At 1 mM, amrinone inhibited DHA binding to β-receptors by only 10%. We suggest that amrinone's positive inotropic effect is not due to direct β-receptor activation. Reduction in K^+-contracture may result from amrinone's enhancement of subcellular sequestration of Ca^{2+}; this, in turn, may increase the Ca^{2+} pool associated with initiation of phasic contraction.

COMPARATIVE EFFECTS OF ORAL PIRBUTEROL VERSUS INTRAVENOUS DOBUTAMINE ON LEFT VENTRICULAR FUNCTION AND ENERGETICS IN CHRONIC CONGESTIVE HEART FAILURE: UNIQUE ADVANTAGE OF PIRBUTEROL DUE TO VASODILATOR AND INOTROPIC PROPERTIES Najam A. Awan, MD, FACC; John Hermanovich, MD; Dean T. Mason, MD, FACC, University of California, Davis, Ca.

Intravenous dobutamine (DB) markedly augments left ventricular (LV) function by increasing contractility. To evaluate if oral pirbuterol (PBT) similarly improves LV performance, the hemodynamic effects of PBT (20 mg) were compared with DB (20 μg/kg/min) in 7 patients with severe chronic congestive heart failure (CHF). Measurements included: heart rate (HR), bpm; mean blood pressure (MBP), mmHg; LV filling pressure (LVFP), mmHg; cardiac index (CI), L/min/M^2; stroke index (SI), ml/beat/M^2; stroke work index (SWI), gm·m/M^2; total systemic vascular resistance (TSVR), dsc^{-5}; HR x systolic BP product ($M\dot{V}O_2$ index). Drug p vs C (control): * =<0.05, and + =<0.01.

	HR	MBP	LVFP	CI	SI	SWI	TSVR	$M\dot{V}O_2$
C	77	73	26	1.8	23	16	2137	9096
DB	77	77*	22	2.3*	30*	23*	1757†	10185†
C	80	77	27	1.7	22	16	2299	9812
PBT	82	72	19*	2.6†	30*	22*	1370†	9757

Thus oral PBT produces DB-like improvement in cardiac function, decreasing excessive LVFP and raising lowered CI. Importantly, while HR and BP were unchanged with both agents, and CI rise (PBT 49%, DB 33%) similar; PBT effected greater concomitant decline in TSVR and in LVFP (-25%) than DB (-14%) ($p<0.05$). Moreover, DB raised $M\dot{V}O_2$ but was unchanged by PBT. Thus PBT has greater vasorelaxant effects than DB besides its considerable stimulation of contractility. This combination of substantial vasodilator plus marked inotropic actions provides oral pirbuterol with unique salutary properties for chronic CHF therapy; initial PBT ambulatory use has substantiated such benefit.

THE EFFECT OF TERBUTALINE ON LEFT VENTRICULAR FUNCTION AND SIZE
Robert Slutsky, MD; Wayne Hooper, MD; Kenneth Gerber, MD; Guy Curtis, MD; Joel Karliner, MD, FACC; William Ashburn, MD, University of California, San Diego.

To assess the response of the left ventricle (LV) to subcutaneous terbutaline (T), a proposed B2 selective agonist, we evaluated 12 patients (pts) with previous myocardial infarctions using equilibrium radionuclide angiography. Six pts had normal global LV function (LVEF ≥.49) (Group I) and 6 pts had depressed global LV function (LVEF≤ .49) (Group II).

Group I	Rest	10-15	25-30	55-60	125-130*
EDV	144± 16	122± 17	116± 16#	126± 16	139± 15
SV	88± 8	86± 8	86 ±10	86 ±10	87± 8
EF	.64± .04	.71± .04	.74± .04#	.69 ± .04	.64± .04
Group II					
EDV	140± 7	124± 11	115± 10#	125 ± 10	132± 7
SV	51 ±3	62 ±4#	60 ±6#	57 ±3	55 ± 3
EF	.35± .03	.46± .04#	.48 ± .04#	.45 ± .04	.40± .03

*Minutes after terbutaline; EDV = end-diastolic volume; SV = stroke volume #p < .01 vs rest

Cardiac output (CO) increased 30% in Group II pts because of an increase in SV, with little increase in heart rate (+ 3.1 bpm, p = NS). CO increased 7% in Group I due to an increase in HR of 7 beats per minute (+9%) with little change in stroke volume. In both groups EDV and ESV declined with an increase in EF. We conclude that T exerts its most beneficial effect on LV function in patients with depressed global resting LV function, and may prove to be a useful inotropic agent in patients with congestive heart failure.

DIGOXIN: THE ACUTE EFFECTS OF VASODILATOR THERAPY ON RENAL METABOLISM
John J. Cogan, MD; Michael H. Humphreys, MD; C. Jeffrey Carlson, MD; Elliot Rapaport, MD, University of California at San Francisco, San Francisco, California.

In eight patients with functional Class III-IV congestive heart failure of various etiologies, renal digoxin excretion (UVd) and clearance (Cd) was calculated by measuring plasma and urine concentrations of digoxin by radioimmunoassay. Cardiac output by thermodilution (CO), glomerular filtration rate (GFR) by the clearance of Iothalamate, and renal plasma flow (RPF) by the clearance of P-aminohippurate were measured. Fractional excretion of digoxin (FEd) was calculated as Cd/GFR. After a baseline control, nitroprusside (NP) was administered (mean dose 130 ug/min). A second control period followed which was not significantly different from the first, and hydralazine (HZ) was given intravenously (mean dose of 34 mg). Results: ($p \leq .05$ level to be considered significant.) During both the control periods CO, GFR, and RPF were reduced. Both NP and HZ produced the expected improvement in cardiac output although the magnitude of increase was greater with HZ (NP 3.5 to 4.7 liters per min.; HZ 3.6 to 5.8). GFR did not increase significantly with either drug. The Cd was significantly increased with NP (103 ± 55 to 152 ± 70 cc/min) and with HZ (104 ± 66 to 155 ± 117). The FEd also rose significantly (NP 1.7 ± .4 to 2.4 ± .8; HZ 1.9 ± .8 to 2.1 ± .8). The excretion of digoxin (UVd) was significantly increased only with HZ (58 ± 29 to 84 ± 71 ng/ ml.) Cd was higher than GFR as expected during control and remained significantly higher with drug treatment. Conclusions: 1) The Cd and FEd rose significantly with both NP and HZ even though GFR did not change. 2) The UVd increased with HZ but not NP.

COMPARISON OF THE RESPONSE OF DEPRESSED AND NORMAL MYOCARDIUM TO ACETYL STROPHANTHIDIN

John F. Williams, Jr., MD, FACC; Babu Mathew, University of Texas Medical Branch, Galveston, Texas.

It is known that the magnitude of the inotropic response to digitalis glycosides is greater in failing than in non-failing myocardium. However, it is unclear whether the dose-inotropic relationships differ in other ways. Thus, we studied the effect of increasing concentrations of acetyl strophanthidin (AS) on peak isometric force development (PF) and maximal rate of peak isometric force development (max. dF/dt) in normal (n-8) and depressed (n-6) right ventricular papillary muscles from normal and pulmonary artery banded cats respectively. Muscles were stimulated at 12 beats/min. at 30°C. Before AS, PF and max. dF/dt in depressed muscles were 57 and 49 percent respectively of comparable values in normal muscles: the latter averaged 2.8 ± 0.4 g/mm^2 and 14.8 ± 1.7 g/mm^2 sec^{-1}. Threshold and toxic doses of AS were essentially identical in the two groups averaging 1 X 10^{-8}, and 2.6 X 10^{-7} M respectively. Maximal inotropic effects occurred at 1.7 X 10^{-7} and 2.1 X 10^{-7} M in depressed and normal muscles respectively: differences not statistically significant. Although both the absolute and percent increments in PF and max dF/dt were greater at a given AS concentration in depressed muscles, the concentration-inotropic response in both groups was linear between threshold and peak effect. Excluding the magnitude of the inotropic responce, depressed and normal myocardium were remarkably similar in their reaction to AS.

PREFERENTIAL UPTAKE OF 14-C-LIDOCAINE BY ACUTELY ISCHEMIC CANINE MYOCARDIUM: DISTRIBUTION OF DRUG AND BLOOD FLOW IN TRANSMURAL AND LATERAL BORDER ZONES.

William Weintraub, MD; Randolph E.Patterson, MD, FACC; Doris Halgash, BS; John Rogers, BS; Joseph Miao, PhD; Joel Kupersmith, MD, FACC; Mt.Sinai Med.Center, NY, NY.

The distribution of lidocaine (Lido) relative to blood flow (MBF) remains unknown in transmural and lateral border zones (LBZ) of ischemic myocardium (IsM) (from which arrhythmias may arise). Thus, in 14 open-chest dogs after 3 min LAD coronary occlusion we injected 14-C-Lido and microspheres and removed the heart 10 min later. A special microsphere technique labelled normally perfused tissue (NPT) interdigitating with IsM in LBZ. We cut 5mm samples from adjacent zones (Z): central IsM (CIZ), intermediate IsM (IIZ), border IsM (BIZ), border normal (BNZ), and remote normal (RNZ). Microspheres (for MBF) and 14-C-Lido were separated, counted and tabulated as fractions of RNZ value before and after subtracting the contribution of NPT.

	CIZ	IIZ	BIZ	BNZ
MBF (Mixed)	.36+.10	.35±.09	.49±.08*	1.03±.14*
MBF (Corrected)	.31±.09	.29±.08	.29±.08	1.03±.14*
Lido (Mixed)	.72±.05	.72±.06	.88±.05*	1.09±.07
Lido (Corrected)	.67±.07	.68±.07	.78±.08	1.09±.09*

(*)=p<.05 compared to sample to its left. Lido exceeeded MBF in all samples (relative to RNZ) except BNZ, and subtraction of NPT contributions from mixed samples revealed no gradient of MBF or Lido from CIZ to BIZ. Endo/epi ratio in IsM was reduced more severely for MBF (.36±.16) than for Lido (.64±.04). We conclude: (1)Lido is concentrated relative to MBF (2.2 fold) in IsM; (2)Lido concentrates (relative to MBF) more in endo than epi layers of IsM, suggesting diffusion of Lido from cavitary blood to endo, near Purkinje fibers; (3)Mean transmural MBF and Lido are homogenous from center to lateral edge within IsM, and heterogeneity in LBZ is explainable by NPT mixed with IsM.

ONSET AND DOSE DEPENDENCE OF THE DIGOXIN-QUINIDINE INTERACTION

Paul E. Fenster, MD; J. Robert Powell, PharmD; W. David Hager, MD; Penelope E. Graves, ScD; Kenneth Conrad, MD; Steven Goldman, MD, FACC, Arizona Health Sciences Center, Tucson, Arizona

Quinidine (Q) administration has been reported to double steady state digoxin (D) serum concentrations. The time of onset and dose dependence of this interaction were studied in 5 normal adults. Area under the serum D concentration vs time curve (AUC) for 24 hours was determined after daily oral D, at steady state. Daily oral D administration was continued, and AUC for D was determined on the day of starting oral Q, 200 mg q8h; after 7 days (d) of oral Q, 200 mg q8h; and after 7 days of oral Q, 400 mg q8h.

	D alone	D+Q 200mg q8h	D+Q 200mg 7d	D+Q 400mg 7d
MEAN D AUC (ng·hr/ml)	15.2	21.9	32.6	43.1
		p <0.02	p <0.02	p <0.10

Values for AUC were compared using the paired Student's t-test.

The results indicate that there is a significant rise in serum D concentrations immediately upon starting oral Q, and that there is a further significant rise in serum D concentrations with continued Q co-administration.

Conclusion: The onset of the D-Q interaction occurs immediately upon starting Q; however, it may take one week for maximal effect to occur. The results imply that the interaction is dependent on the dose and serum concentration of Q.

TWO AND THREE DIMENSIONAL DISPLAY OF MYOCARDIAL ISCHEMIC "BORDERZONE" IN THE RABBIT, DOG, PIG AND MONKEY.

Alden Harken, M.D., F.A.C.C., Clyde Barlow, Ph.D., Wesley Harden, M.D., and Michael Simson, M.D., University of Pennsylvania, Philadelphia, Pa.

The potential for therapeutic modification of myocardial ischemic zone size has traditionally depended on the existence of a large "borderzone" (BZ) of salvageable tissue between the central infarction and surrounding well perfused areas. A fluorophotographic technique permitting high resolution (30μ) display of myocardial ischemia has been developed. Reduced intracellular NADH (ischemia) fluoresces and may be photographed while oxidized NAD (perfused tissue) does not. The distal LAD was ligated for five minutes in five open-chest rabbits, dogs, pigs and monkeys. A fluorescent dye was injected into the left atrium as a coronary vascular marker and the tissue quick frozen. The ischemic margin was well seen and was jagged in all species. The distance from ischemic to perfused tissue ("borderzone") was less than 30μ in all species. In dogs, however, tissue perfused by collaterals projected even into the center of the ischemic zone. This produced a heterogeneous peri-ischemic transition of apparent BZ. In an attempt to magnify the width of the BZ (non-perfused, non-ischemic zone) the study was repeated in non-working (low MVO_2), hyperoxic (PO_2 > 500) perfused rabbit hearts. The BZ did increase to 329 ± 28μ in width. The central ischemic zone remained > 95% of non-perfused tissue. In a blood perfused, working heart the true BZ is narrow (<30μ) in all species tested. In dogs, peri-ischemic collaterals provide a heterogeneous apparent BZ (up to 8-10 mm) that can be resolved by NADH fluorophotography. True BZ increases to 329 ± 28μ in non-working, hyperoxic rabbit hearts, but the ischemic area remains > 95% of non-perfused tissue. Canine ischemia and coronary anatomy differs from other species tested.

EFFECT OF ISCHEMIA ON MYOCARDIAL PROTEOLYSIS

Roberto Bolli, MD; Nancy Davenport, RN, PhD; Robert E. Goldstein, MD, FACC; Stephen E. Epstein, MD, FACC, NHLBI, Bethesda, Md.

Several studies suggest that during acute myocardial ischemia (AMI) lysosomal hydrolases contribute to the death of cells that otherwise may have remained viable and eventually regained function. However, the effect of AMI, produced in intact animals, on proteolysis (P) has not been evaluated. Thus, we ligated the left anterior descending coronary artery in 29 open-chest dogs; .5mm thick slices were obtained from 1-hr ischemic endocardium (1-EN), 3-hrs ischemic endocardium (3-EN) and epicardium (3-EP) and from control myocardium (C). Slices were incubated for 1, 2 or 3 hrs in "aerobic" medium (Krebs-Ringer-bicarbonate [KRB] buffer, with glucose 10mM and insulin .1 U/ml, saturated with 95% O_2 - 5% CO_2, pH 7.4) or in "ischemic" medium (KRB saturated with 90% N_2 - 10% CO_2, pH 6.8). The protein synthesis inhibitor cycloheximide (CH) was added to both media (.5mM) to block amino acid reutilization. CH did not inhibit P. The overall rate of P was measured by net production of tyrosine by the slices (pmol/mg of tissue, mean ± SE):

	"aerobic" medium				"ischemic" medium			
Incubation	C	3-EP	I-EN	3-EN	C	3-EP	I-EN	3-EN
1 hour	25±2	22±2	20±4	20±2	17±2	12± I	15±3	19±2
2 hours	47±4	-	38±5	-	22±6	-	24±3	27±3
3 hours	72±4	58±4*	54±6*	50±6*	38±4	25± I*	34±4	27±3*

(* = $p<.05$ vs C). A similar pattern was obtained when the production of tyrosine was related to the concentration of protein in the slices. We conclude that P does not increase in AMI either before irreversible damage is believed to occur (3-EP) or shorty after (1-EN, 3-EN). This suggests that cellular proteases do not cause cell death during AMI, making it unlikely that drug-induced inhibition of P would be an important mechanism responsible for preventing ischemic myocardium from becoming necrotic.

DETECTION OF ELEVATED MITOCHONDRIAL CK IN PLASMA AFTER INFARCTION BY A SPECIFIC RADIOIMMUNOASSAY

Ann Grace; Takaya Fukuyama, MD; Robert Roberts, MD, FACC, Washington University, St. Louis, Missouri

Since mitochondrial damage is a hallmark of irreversible injury in ischemic myocardium, detection of a mitochondrial constituent in plasma is likely to provide a definitive in vivo marker of cell death. Accordingly, we developed a specific and sensitive radioimmunoassay (RIA) for mitochondrial CK (CK_m) to analyze plasma samples obtained hourly for 48 hr from dogs with evolving infarction. For use in the assay system, CK_m was isolated from canine myocardium and purified on Sephacryl S200 and CM-Sephadex. Isoenzyme analysis by electrophoresis on cellulose acetate showed a single cathodic migrating band free of other CK isoenzymes. A single protein band was observed on SDS gels. CK_m amino acid composition differed from that of cytosolic isoenzymes. Ouchterlony plates showed no cross-reactivity between CK_m and cytosolic isoenzymes. The RIA was performed in 50 mM Tris, pH 8.5, 0.1% albumin 20 mM EDTA and CH_2OH-CH_2-SH (20 mM) incubated for 1 hr at 23°. ^{125}I-CK_m was 70% bound by the specific antibody but no binding occurred with ^{125}I-MM, -MB or -BB even at 500-fold excess. Unlabeled CK_m (0.2 to 100 ng) but not MM or BB (0.1 to 20,000 IU/L) competitively displaced bound ^{125}I-CK_m. An increase in plasma CK_m was detected consistently 4 hr after infarction (n=60) with an average peak of 150 ± 15 µg/L (7-fold increase) in 20 hr and a return to normal within 48 hr. In contrast, plasma MM CK increased to peak activity approximately 10 hr after occlusion (10-fold increase) and returned to normal within 36 hr. Thus, mitochondrial CK in plasma can be detected by a specific and sensitive RIA, providing an in vivo marker specific for irreversible myocardial injury.

CONDITIONS FOR LIPOSOME UPTAKE BY MYOCARDIAL CELLS

Thomas Mueller, MD, FACC, Kent Hermsmeyer, PhD, Howard Mayer, MS and Melvin Marcus, MD, FACC, Cardiovascular Center and Depts. of Med. and Pharmacology, University of Iowa and V.A. Hosp., Iowa City, Iowa

We have previously shown that liposomes (L), phospholipid vesicles containing an aqueous phase, concentrate in the ischemic region following coronary ligation in dogs. Since L may be useful as drug carriers to an ischemic region, we wished to determine the conditions under which L would be taken up by myocardial cells. Isolated, contracting (120 X/min) cardiac myocytes from neonatal rat ventricle were exposed to L (0.09 ± 0.01 µm diam) having neutral or positive membrane charge and carrying the fluorescent dye, fluoresceinate, in the aqueous phase. Uptake of L was measured quantitatively by fluorescence photometry using 30 msec flashes of UV light at 490 nm to avoid fluorescence fading phenomena. Cells were suffused with oxygenated medium containing 4.7 or 100 mM K^+ /l or with anoxic medium with 4.7 mM K^+ /l. Membrane potentials were measured by direct intracellular recording. Results: Cells suffused with anoxic or oxygenated normokalemic medium for 20 min showed very little fluorescence following L exposure ranging from 5 to 30 sec. The cells exposed to anoxic medium contracted irregularly (30-40 X/min) but were not depolarized. Cells depolarized with 100 mM K^+ medium had 3-4X more fluorescence than other groups. Depolarized cells exposed to positively charged L had 30-50% more fluorescence than those exposed to neutral L. We conclude that L can deliver their contents into cardiac myocytes depolarized by exposure to a high K^+ environment. Anoxia for 20 min did not cause sufficient injury to depolarize cells or cause L uptake. Therefore, L may be useful as drug carriers to injured cells or to cells depolarized by high K^+ concentration from nearby injury in an ischemic area.

INFLUENCE OF LEFT VENTRICULAR DIMENSIONS ON ENDOCARDIAL AND EPICARDIAL QRS AMPLITUDE AND ST SEGMENT ELEVATIONS DURING ACUTE MYOCARDIAL ISCHEMIA

Jon Lekven, MD; Kanu Chatterjee, MB, FRCP, FACC; John V. Tyberg, MD, PhD, FACC; William W. Parmley, MD, FACC, University of California, San Francisco, Ca.

The independent and concurrent influence of acute myocardial ischemia (AI) and changes in ventricular end-diastolic dimensions (LVEDD) on endocardial QRS (Endo-QRS), epicardial QRS (Epi-QRS) in ischemic and nonischemic zones and ST segment elevations (ST) in ischemic zones were evaluated in 17 anesthetized, open-chest dogs before and after left ventricular volume expansion and after coronary artery (LAD) ligation. In 8 dogs regional myocardial blood flow was determined by labeled microsphere technique. Prior to LAD occlusion, and during volume expansion an increase in LVEDD from 42.73±1.59 to 46.43±1.89 mm. ($p < 0.001$) was associated with a decrease in Endo-QRS to 78±2%, and Epi-QRS to 85±3%. Following LAD occlusion and volume expansion, Endo-QRS in the ischemic zone, Endo- and Epi-QRS in the nonischemic zones decreased linearly, but Epi-QRS did not show consistent changes. ST elevation in ischemic zones decreased during volume expansion and was associated with an increase in epicardial blood flow. These findings suggest that volume expansion following acute ischemia may have differential effects on Epi-QRS and ST. As a poor correlation exists between changes in Epi-QRS and epicardial flow, measurement of Epi-QRS may not indicate the magnitude of ischemia in the presence of acute changes in LV volume.

CONCENTRATION-DEPENDENT EFFECTS OF ARRHYTHMOGENIC LYSOPHOSPHATIDES ON MEMBRANES

T. Bruce Ferguson, Jr., MD; Steven R. Bergmann, PhD; Burton E. Sobel, MD, FACC; Washington University, St. Louis, Missouri.

Lysophosphatidyl choline (LPC) and other amphiphilic arrhythmogenic compounds accumulate in ischemic myocardium, augment cyclic-AMP content, alter action potentials, and induce coronary artery constriction and myocardial contracture. Since LPC circulates ubiquitously, is bound to albumin, and spontaneously forms micelles, it is necessary to characterize concentration dependent effects of monomers and micelles in systems providing precisely controlled conditions. Accordingly, washed human RBCs were incubated with selected concentrations of LPC or 1:1 Na-cholate and deoxycholate, chosen because bile salts circulate also, prior to scanning electron microscopy. In Krebs-Henseleit (KH) buffer, the critical micelle concentrations (CMC) assessed by dye spectroscopy of LPC and bile salts were .05 and 2 mM. With albumin added to KH, LPC and bile salts were bound in 1.35 and 0.1:1 molar ratios. Micellar formation required saturation of these binding sites and free concentrations $\geq$ the CMC. Palmitate did not affect binding. At concentrations as low as 6 μM, LPC induced marked anisocytosis and spicule formation as well as cell fusion (n = 20 preparations) whereas monomeric bile salts were without effect (n = 12). At concentrations > the CMC, both species induced prompt lysis (n = 8). The induction of striking membrane alterations by concentrations of LPC below the CMC, in contrast to the case for bile salts, substantiates properties accounting for their arrhythmogenic cardiotoxic effects and indicates that monomers of these lipid amphiphiles exert specific effects independent from nonspecific actions of micelles.

PREDICTION OF BIOCHEMICAL DERANGEMENT IN ISCHEMIC MYOCARDIUM FOLLOWING EXPERIMENTAL CORONARY ARTERY OCCLUSION

Robert E. Rude, MD, Laurence W.V. DeBoer, MD, Joanne S. Ingwall, PhD, Robert A. Kloner, MD, PhD, Sharon L. Hale, BS, Michael Davis D.Sc, Peter R. Maroko, MD,FACC, and Eugene Braunwald, MD,FACC. Peter B Brigham Hospital/ Harvard Med Sch, Boston, MA

It has been suggested that the degree of tissue damage following coronary artery occlusion (CAO) is a function of both the duration and intensity of myocardial ischemia. We sought to determine which indices of ischemia best predicted the extent of ultimate tissue damage after CAO as assessed by depletion of myocardial ATP (mATP). Ten anesthetized dogs underwent 7-30, 30-60, or 60-90 min of CAO with radioactive microsphere determination of regional myocardial blood flow (RMBF) 5 min after CAO. Subendocardial biopsies were obtained from normal and ischemic myocardium in vivo and were analyzed for mATP content (expressed as nmol/mg protein) by liquid chromatography. In non-ischemic sites, mATP was 31.3±1.9. In ischemic sites, mATP was 29.2±6.2 after 7-30 min; 17.3±0.5 after 30-60 min; and 12.5±4.5 after 60-90 min. This fall in mATP after CAO correlated modestly with the duration of ischemia (L, expressed in min), with mATP=38.3-0.38(L), r=0.72, and more poorly with intensity of ischemia, expressed as coronary blood flow deprivation (FD=1.0-[RMBF in an ischemic site/RMBF in normal site]), r=0.35, with mean FD of 0.84±.06. There was a similar poor correlation between mATP and absolute level of RMBF, with r=0.34 when RMBF in ischemic zones was 20.9±9.8 ml/min/100gm. However, mATP depletion correlated extremely well with an index of the overall severity of ischemia (FDxL), with mATP=40.4-0.51 [FDxL], r=0.95. We conclude that this ischemic index (FDxL) is an excellent predictor of mATP fall in the subendocardium following CAO of 7-90 min duration.

TRANSIENT STATE KINETIC STUDIES OF Ca^{2+}-DEPENDENT ATPase AND Ca TRANSLOCATION BY CARDIAC SARCOPLASMIC RETICULUM. ROLE OF THE 22,000-DALTON PROTEIN PHOSPHOLAMBAN

M. Tada, MD; M. Yamada, MD; F. Ohmori, MD; T. Kuzuya, MD; M. Inui, MD; H. Abe, MD, FACC, Osaka University School of Medicine, Osaka, Japan

To elucidate the molecular mechanism by which Ca^{2+}-dependent ATPase of cardiac sarcoplasmic reticulum (CSR) is controlled by its putative regulator phospholamban (PN) and cyclic AMP, we examined effects of cyclic AMP-dependent protein kinase (APK)-catalyzed phosphorylation of PN on the intermediary steps of Ca^{2+}-dependent ATPase coupled with Ca translocation. CSR was incubated with cyclic AMP, APK and ATP in the presence of EDTA (control CSR) and Mg (phosphorylated CSR), and was subsequently assayed for formation of phosphorylated intermediate ($E^{32}P$), rate (v) of ^{32}Pi liberation, and ^{45}Ca accumulation in various concentrations of [γ-^{32}P]ATP or $^{45}CaCl_2$/EGTA buffer. The V_{max} value of ATPase activity and the rate of EP decomposition, as determined by v/[EP] and the rate constant k_d, were about 2-fold higher in phosphorylated CSR than in control. The rates of EP formation and Ca binding, determined by a rapid quenching apparatus, which allowed sequential reactions with 4 msec time resolution, also exhibited marked enhancement in phosphorylated CSR. These effects were more evident when CSR was suspended with EGTA prior to assay (Ca-free CSR) than when pre-incubated with Ca/EGTA buffer (Ca-bound CSR). These results indicate that PN phosphorylation stimulates the turnover rates of Ca^{2+}-dependent ATPase and Ca translocation through the enhancement of formation and decomposition of EP, and thus lend support for our previous proposal that PN phosphorylation by APK can function as a regulatory system for controlling the active Ca transport by CSR.

CHARACTERIZATION OF MYOCARDIAL ATP DEGRADATION FOLLOWING CORONARY ARTERY OCCLUSION.

Laurence W.V. DeBoer, MD, Joanne S. Ingwall, PhD, Robert E. Rude, MD, Peter R. Maroko, MD, FACC, Robert A. Kloner, MD, PhD, and Eugene Braunwald, MD, FACC. Peter B Brigham Hosp/Harvard Med Sch, Boston, MA

Although ATP reduction is a hallmark of ischemia, the fate of its degradative products needs clarification. Definition of metabolic pathways (ATP↔ADP↔AMP↔adenosine ↔inosine↔hypoxanthine) is important for understanding the potential for ATP resynthesis. Accordingly, multiple biopsies were taken of ischemic and normal subendocardium in 16 dogs following coronary artery occlusion. Purines were determined by liquid chromatography. Severity of ischemia was expressed as the product of flow deprivation (by microspheres) and length of ischemia and expressed in relative ischemic units (RIU-in min. %)

	PURINES nm/mg protein		
	Control (c)	Mild Ischemia(m)	Severe Ischemia
RIU (min. %)	0	34±6	151±20
ATP	32.3±1.7	22.0±3*	3.5±1.1***†††
ADP	8.0±0.7	10.4±1.7	4.6±0.6**††
AMP	1.6±0.4	1.9±.5	2.3±0.6
Inosine	0.2±0.1	3.9±.8***	1.4±0.3***††
Hypoxanthine	1.1±.3	2.0±2***	7.8±1.6**††
Σ Purines	43.4±2.5	42.0±4.7	21.0±2.1**††

*p<.05 vs c; **p<.01 vs c; ***p<.001 vs c; †p<.05 vs m; ††p<.01 vs m; †††p<.01 vs m.

Thus, 1) since ADP and AMP do not accumulate, dephosphorylation enzymes are functional in severely ischemic myocardium. 2) In early ischemia coincident with ATP depletion, inosine rises transiently followed by later accumulation of hypoxanthine. Since substantial total purines persist and functioning metabolic pathways are present, the potential for ATP regeneration cannot be excluded during severe ischemia.

THE SIGNIFICANCE OF THE LATE FALL IN MYOCARDIAL pCO_2 FOLLOWING ACUTE CORONARY OCCLUSION.

Shukri F. Khuri, MD, Robert Kloner, MD, and Stephanie Karaffa, BS, West Roxbury V.A. Medical Center, Peter Bent Brigham Hospital, and Harvard Medical School, Boston, MA.

Following coronary occlusion (CO) intramyocardial pCO_2 ($PmCO_2$) rises, peaks and gradually falls. This study was performed to test the hypothesis that this late fall in $PmCO_2$ reflects a decrease in anaerobic metabolism (H^+ produced by cells + bicarbonate buffer $\rightleftharpoons H_2O+CO_2$) due to progressive irreversible cell injury. In 11 anesthetized open chest dogs, the anterior descending coronary artery was occluded for 3hrs (COA), reflow allowed for 45 minutes, and the occlusion reapplied (COB). $PmCO_2$ and intramyocardial $[H^+]$ were measured with a mass spectrometer (MS) and a new pH electrode. When $PmCO_2$ peaked during COB, tissue adjacent to the MS probe was obtained and mean ischemic damage (MIS) scored 0-4+ by morphometrics of 1μ histologic sections. Baseline $PmCO_2$ was 38±1.5 (mean±SEM) and peaked to 104±14 mmHg during COA; after 3hrs it fell to 60±17 mm Hg ($P<0.005$) and post reflow fell to baseline. Likewise, baseline $[H^+]$ was 44±3 n moles and peaked to 173±43 n moles during COA; after 3hrs it fell to 88±17 n moles ($P<0.005$) and post reflow fell to baseline. During COB $PmCO_2$ peaked only to 67±7 mmHg ($P<0.005$ compared to peak $PmCO_2$ during COA) and pH peaked only to 82±8 n moles ($P<0.005$ compared to peak $[H^+]$ during COA). Regional myocardial blood flow was unchanged throughout COA and was not different from that during COB. The magnitude of decline in $PmCO_2$ following COA (i.e. peak $PmCO_2$ - $PmCO_2$ at 3hrs) and the difference between peak $PmCO_2$ during COA and peak $PmCO_2$ during COB both correlated significantly with MIS ($r=0.84$). Hence the late fall in $PmCO_2$ following CO is a manifestation of progressive cell death and a reduced ability to produce anaerobic metabolites during subsequent occlusions.

THE EFFECT OF FIRST-DOSE ADRIAMYCIN ON THE CYCLIC NUCLEOTIDE LEVELS AND FUNCTION OF THE HUMAN MYOCARDIUM

Donald V. Unverferth, MD; Richard H. Fertel, PhD; Raymond D. Magorien, MD; Stanley P. Balcerzak, MD; Robert L. Talley, MD, The Ohio State University College of Medicine, Columbus, Ohio.

Adriamycin, (A) an effective cancer chemotherapeutic agent often induces a cardiomyopathy when the cumulative dose exceeds 550 mg/m^2. Animal studies suggest that large doses of A induce cardiomyopathy by inhibiting cardiac guanylate cyclase and lowering cyclic (c) GMP. This study investigates the cAMP and cGMP levels of human myocardium and relates the findings to measurements of myocardial function. Each of the 10 patients (average age = 48, normal cardiovascular examination) had a previously untreated tumor. Systolic time intervals (PEP/LVET) and echocardiograms (%ΔD) were performed at baseline (B) and 4 and 24 hours after the first dose of intravenous bolus A (average dose = 50 ± 6 mg/m^2). An endomyocardial biopsy procedure was also performed at B, 4 and 24. Two samples from each procedure were analyzed for cAMP and cGMP by radioimmunoassay. The cAMP and cGMP ($\bar{X}$ ± SEM) are in fm/mcg protein. * = $p<0.05$ from B.

	B	4	24
%ΔD	34.2 ± 2.0	37.8 ± 2.4	36.8 ± 2.2
PEP/LVET	.364 ± .021	.326 ± .016*	.325 ± .018
cAMP	2.5 ± 0.4	2.4 ± 0.3	2.5 ± 0.6
cGMP	0.23 ± 0.06	0.16 ± 0.05*	0.15 ± 0.05*

This study demonstrates that pharmacologic doses of A cause a fall of human cardiac cGMP. Despite these early biochemical changes there was no deterioration of cardiac function. The inhibition of guanylate cyclase activity and fall of cGMP may be related to the chronic toxicity of A but this does not impair ventricular function in the first 24 hours.

SURGERY IN CORONARY ARTERY DISEASE
8:30-12:00

RELEASE OF MB CREATINE KINASE FOLLOWING CORONARY ARTERY BYPASS GRAFTING IN THE ABSENCE OF MYOCARDIAL INFARCTION

Dhun Sethna, M.D.; Richard Gray, M.D., FACC; William Shell M.D.; Carolyn Conklin, R.N.; Myles Lee, M.D.; Howard Feldman, M.D.; and Jack Matloff, M.D., FACC. Cedars-Sinai Medical Center, Los Angeles, California.

Elevations of serum MB creatine kinase (MB-CK) activity in the immediate postoperative period in patients undergoing coronary artery bypass is usually associated with myocardial necrosis. However, enzyme elevations (18 ± 2 IU/L, M ± SE) were recently observed in 6 patients in the absence of EKG or scintigraphic (technetium 99 pyrophosphate) evidence of perioperative myocardial infarction. To test the hypothesis that surgical trauma of the atrium and aorta during cannulation for cardiopulmonary bypass may contribute to such elevated MB-CK levels, right atrial appendage and aorta were biopsied at surgery and assayed for total CK (Rosalki technique) and MB-CK (column chromatography). The results are expressed in IU/100 mg tissue protein:

	Total CK (N=9)	MB-CK (N=7)	% MB-CK
Atrium	1068 ± 143	215 ± 42	19.4 ± 1.3
Aorta	18 ± 6	3 ± 1	15.5 ± 2.4

The results indicate that: 1) human atrium is a rich source of CK, the portion representing MB-CK being similar to that present in the ventricle (13%); 2) surgical manipulation of the atria may result in release of MB-CK causing elevated serum enzyme levels in the post coronary artery bypass patient in the absence of myocardial infarction.

RESTORATION OF MYOCARDIAL BLOOD FLOW RESERVE FOLLOWING REVASCULARIZATION.

Donald H. Schmidt, M.D.; Fred M. Blau, M.S.; Linda L. Grzelak, B.S.; W. Dudley Johnson, M.D., FACC, University of Wisconsin-Mount Sinai Medical Center, Milwaukee, Wisconsin.

Despite the controversy surrounding myocardial revascularization (MR), it has never been determined if its success is due directly to improving the supply of blood available to the myocardium during increased oxygen demand. In this study we have measured regional myocardial perfusion (RMP) at rest and following Isoproterenol (ISO) infusion in 15 patients (pts) prior to, and 8-10 days following MR. Results were compared to 10 pts with normal coronary arteries. RMP (ml/min/100 g) was measured with a multicrystal gamma camera from the myocardial washout of Xenon-133 following injection into a coronary artery or graft. RMP was calculated in the region distal to a graft and compared to the same region in the preoperative study. After the control study, 4-8 ug/min ISO was infused to produce a heart rate (HR) increase of approximately 50%. To normalize RMP changes to the change in double product (DP= systolic BP x HR), a response index (RI= ΔRMP/ΔDP x 10^3) was calculated, as well as coronary vascular resistance (CVR= MEAN BP/RMP). Mean results are as follows:

*p<.02	CONTROL			ISO			
+p<.001	HR	RMP	CVR	HR	RMP	CVR	RI
Normal (10)	74	78	1.46	118	137	.73	10.4
Pre-op (15)	73	69	1.48	106	101	1.07	5.9
	↓			↓*	↓+	↓*	↓*
Post-op	85	81	1.25	122	142	.63	13.1

The results show a significant improvement in individual pts in HR, RMP, CVR, and RI with ISO after MR, with values very close to normal. The results demonstrate that the success of MR is a direct result of improved myocardial flow reserve.

SURGICAL RELIEF OF MYOCARDIAL ISCHEMIA DUE TO MYOCARDIAL BRIDGES

Albert E. Raizner, MD, FACC; Tetsuo Ishimori, MD, FACC; Mario S. Verani, MD, FACC; William H. Spencer, MD, FACC; Gene Guinn, MD, FACC; Robert A. Chahine, MD, FACC; Jimmy F. Howell, MD, FACC; Richard R. Miller, MD, FACC, Baylor College of Medicine, Houston, Texas.

Myocardial bridges (MB) have long been suspected of causing ischemia in man. However, firm documentation of ischemia secondary to MB has been lacking. We studied 9 patients (pts), 8 male, 1 female, whose ages ranged from 28 to 66 (mean = 46) years, with MB which produced > 50% systolic narrowing of the coronary artery (CA). Two pts had transmural anterior myocardial infarction which was precipitated by heavy exertion and documented by electrocardiography and enzymes. Both had MB of the anterior descending (LAD) but otherwise normal CA. In the remaining 7 patients, myocardial ischemia was documented by treadmill exercise testing (TET) and exercise scintigrams (ESG) with thallium-201. TET was positive (ST depression > 1 mm) in 6 of 7 pts. ESG showed reversible hypoperfusion during exercise in the myocardial region supplied by the bridged artery in all 7 pts. Four of 7 had anterior perfusion defects with LAD MB. Three pts had anterior and inferior defects: One of these had LAD and right CA MB; 2 had LAD MB and coexistent fixed right CA stenosis. Surgical interruption of the MB was performed in 3 patients because of persistent angina, one of who had bypass to the right CA. Each had complete relief of symptoms and post-operative ESG and TET reverted to normal. Thus, myocardial ischemia and myocardial infarction secondary to MB can be firmly documented in some pts. Surgical interruption of the MB should be considered in pts with refractory symptoms that can be clearly attributed to the MB.

TREATMENT OF ANTERIOR TRANSMURAL MYOCARDIAL INFARCTION IN MAN WITH AND WITHOUT EARLY REPERFUSION

Marcus A. DeWood, MD; Julie Spores; Henry T. Lang, MD; John H. Ganji, MD; Ken I. Sutherland, MD, FACC; William P. O'Grady, MD, FACC, Sacred Heart and Deaconess Medical Centers, Spokane, Washington.

Anterior wall myocardial infarction (MI) is associated with high mortality. The role of early reperfusion for anterior MI with coronary artery bypass grafting (CABG) is uncertain. Ninety-five patients (pts) (mean age ± SD = 52.8 ± 7.2 years) with anterior MI (Group I) were admitted within 24 hours of symptoms and managed conventionally for anterior MI. During the same time period (6/72-12/76) 97 pts (Group II) (age - 53.6 ± 8.1 years) were admitted for anterior MI but were evaluated with early coronary arteriography and treated with CABG. All patients in both groups had chest pain, persistent ST elevation ≥3 mm progressive to Q waves, and evolved creatine kinase elevation. Pts with identifiable coronary spasm, diffuse distal disease of coronary artery and pts considered too ill to withstand CABG were exluded from this study. In-hospital mortality (IHM) and long-term mortality (LTM) (30-68 months) were evaluated.

	IHM	LTM (30-68 months)
Group I	15.7% (15/95)	28.4% (27/95)
Group II	4.1% (4/97)p<.03	11.3% (11/97)p<.01

When patients with shock (i.e., BP less than 85 mm Hg, left ventricular filling pressure greater than 18 mm Hg and hypoperfusion) were excluded, the in-hospital mortality for Group II was 1.1% (1/88). These observations in concurrent groups suggest early reperfusion for evolving anterior myocardial infarction may be helpful in reduction of in-hospital mortality and long-term mortality in selected patients.

HEMODYNAMIC EFFECTS OF INTACT HUMAN PERICARDIUM AFTER CORONARY BYPASS SURGERY.

Richard Gray, M.D., FACC, Jamshid Maddahi, M.D., Marjorie Raymond, R.N., Daniel Berman, M.D., FACC, Hector Sustaita, M.D. and Jack Matloff, M.D., FACC. Cedars-Sinai Medical Center, Los Angeles, California.

Because little is known about the cardiac effects of normal human pericardium, 36 patients (pts) had hemodynamic measurements with multiple gated equilibrium cardiac blood pool scintigraphy in a subgroup of 29 pts before, early (1-6 hours) and 2 days after coronary bypass surgery. Surgery included moderate hypothermia (mean temperature 23°C) and techniques designed to avoid pericardial drying and shrinkage. The pericardium was left open in 25 pts (Group A), and closed in 11 (Group B). No differences in age, preoperative left ventricular function, number of vessels diseased or grafted, total pump or ischemic times or degree of hypothermia were detected between groups. No pt had cardiac tamponade. Compared to Group A, Group B pts had higher right atrial (12 ± 3 vs 9 ± 3, mean ± S.D.), pulmonary capillary wedge (14 ± 4 vs 11 ± 4) and mean pulmonary arterial pressures (21 ± 3 vs 18 ± 4 mmHg), total pulmonary resistance (464 ± 140 vs 339 ± 95 dyne·sec·cm^{-5}) and lower cardiac index (1.9 ± .5 vs 2.3 ± .3 L/m/m^2) (all p<.05) immediately and on postoperative day 2. No differences were noted in postoperative heart rate, arterial pressure, systemic vascular resistance, and right or left ventricular ejection fraction by scintigraphy. Thus with intact pericardium after coronary bypass surgery: 1) an adverse effect on cardiac performance is seen through postoperative day 2; and 2) diminished cardiac output in spite of higher atrial pressures suggests either diminished overall cardiac compliance or an altered Starling function relationship.

RESECTION OF VENTRICULAR ANEURYSM MODIFIED BY ELECTROPHYSIOLOGIC ASSESSMENT IN PATIENTS WITH INTRACTABLE VENTRICULAR TACHYCARDIA AND LEFT VENTRICULAR ANEURYSM

William B. Allen, MD; James D. Maloney, MD, FACC; Geoffrey O. Hartzler, MD; David R. Holmes, Jr., MD, FACC; Francisco J. Puga, MD, Mayo Clinic and Mayo Foundation, Rochester, Minnesota

Patients (pts) with left ventricular aneurysm (LVA) complicated by recurrent ventricular tachycardia (RVT) have a poor prognosis with current medical therapy, standard LVA resection and/or revascularization. Recent reports suggest that extensive LVA resection, subendocardial excision, or encircling endocardial ventriculotomy may be more effective in interruption of the RVT mechanism. The importance of preoperative and intraoperative RVT induction, epicardial and endocardial mapping, and assessment of residual myocardial function remain uncertain. Observations related to 15 pts with LVA-RVT undergoing surgical resection or isolation of LVA utilizing preoperative and intraoperative electrophysiologic data are reported. Epicardial (12 pts) plus endocardial mapping (3 pts) were performed. Extensive LVA resection modified by mapping data were performed in 13 pts. Five of 13 pts had resection of a portion of the septum and right ventricle. One of 13 pts had LVA resection plus encircling ventriculotomy; 2 pts had LVA plication. Eight of 15 pts had revascularization.
Two pts died in the early postoperative period, one with RVT. All survivors were improved hemodynamically with a mean follow-up of 19 months (range 2 to 40). Spontaneous RVT has been observed or suspected in only one patient. Excision or isolation of LVA ischemic margins appear important. Preoperative and intraoperative electrophysiologic assessment appears advantageous in patient selection and designing surgical intervention.

COMPARISONS OF THE EFFECTS ON SURVIVAL OF CORONARY ARTERY SURGERY IN SUBGROUPS OF PATIENTS FROM SEATTLE HEART WATCH

T.A. DeRouen, PhD, K.E. Hammermeister, MD, FACC, H.T. Dodge, MD, FACC, University of Washington, Seattle, WA

Previous comparisons of survival between medical and surgical cohorts in Seattle Heart Watch demonstrated significantly higher survival among surgical patients overall, and in the only attempt to look at subgroups, in those with 2 vessel disease. The purpose of this study was to further evaluate the effect of surgery in subgroups of patients, utilizing additional follow-up (average time in study now 5.5 years), to identify subgroups in which the effect of surgery was greatest, as well as others in which the effect was less beneficial or ineffective. Cox's regression model for survival data was used to evaluate the effect of surgery in subgroups while adjusting for differences between the cohorts in 7 variables earlier identified as having prognostic importance: ejection fraction, presence of ventricular arrhythmias on the resting ECG, age, heart murmur, stenosis of left main coronary artery, number of stenotic ($\geq$70%) vessels, and use of diuretics. The analysis was based on 1533 patients (1158 surgical, 375 medical) on whom complete data for these 7 covariates was available. Subgroups in which surgical patients demonstrated significantly higher ($P<0.01$) survival than medical patients included those with 2 or 3 vessel disease; those of age $\geq$ 48; those with no heart murmur; no ventricular arrhythmias on the resting ECG; with < 50% stenosis of the left main artery; not taking diuretics; without a history of congestive heart failure; absence of cardiomegaly. Differences between medical and surgical survival in complementary subgroups were not significant, although most showed a slight edge for surgery. However, certain subgroups demonstrated no beneficial, or even an adverse effect of surgery - those of age < 48, especially those with 1 vessel disease.

MEDICAL VS. SURGICAL THERAPY: QUALITY OF LIFE AFTER 5 YEARS

RO Russell Jr, MD, FACC; JB Wayne, PhD; ED Charles, PhD; JJ Kronenfeld, PhD; N Kouchoukos, MD, FACC; A Oberman, MD, FACC; WJ Rogers, MD, FACC; JA Mantle, MD, FACC; CE Rackley, MD, FACC; The Univ of Ala in Birmingham, Birmingham, Alabama

This study examines perceived health status (st), use of health services, employment st., occupational st., and family income for comparable groups of patients (pts.) treated medically or surgically for unstable angina pectoris. Data for the pts. randomized into the Ala. portion of the Natl. Coop. Unstable Angina Study were obtained at baseline, in 1977 ($\bar{x}$=38 mo.), and in 1979 ($\bar{x}$=58 mo.). The medical (M), surgical (S), and late surgical (LS) pts. all felt their health had improved during the study with LS pts. reporting the greatest improvement. M pts. perceived themselves to be least healthy, but had the fewest restricted activity days due to heart disease (M=30, S=48, LS=72). Groups did not differ in use of health services. The employment results indicate a change between 1977 and 1979. In 1979, 62% of M and LS pts. who were working at baseline continued to work vs. 42% for the S pts. Regression analysis with non-work income, perceived health st., work st. prior to entry into the study, and treatment modality as significant independent variables explained 87% of the variance in return to full-time empl. Discriminant function analysis with these same variables predicted empl st. correctly in 97% of the cases. Age was not a factor in empl. or retirement. 68% of the pts. employed in "white-collar" jobs at baseline were working in 1979 vs. 49% of the pts. employed in "blue-collar" jobs. 88% of those empl. remained in the same industry; only 61% remained in the same job. While the S pts. were less likely to return to full-time empl., by 1979 their family incomes were comparable to the other groups. Although M pts. perceived themselves to be less healthy, other measures of quality of life were similar for M and S pts.

IMPROVED LONGEVITY FOLLOWING CORONARY ARTERY BYPASS (CAB) SURGERY: IS IT REAL OR IS IT AN ILLUSION?

Virendra S. Mathur, MD, FACC; Robert J. Hall, MD, FACC; Efrain Garcia, MD, FACC; Carlos M. de Castro, MD, FACC, Clayton Foundation Research-St. Luke's Episcopal Hospital and Texas Heart Institute, Houston, Texas.

Several recent publications from large surgical centers point to near normal life survival following CAB employing currently practiced improved techniques. A valid criticism has been the absence of a proper control group without surgery from these non-randomized studies. To examine the issue very critically, we analyzed 5 year actuarial survival (SUR) in two categories of subsets from a series of 846 consecutive personally observed patients, 98% of whom have been followed. We examined the SUR in several subsets of patients whose prognosis without surgery is unequivocally considered poor and we analyzed the SUR in several subsets of patients with different prognostic gradations related to the severity of disease. The 5 yr SUR for pts operated between 3/73 and 6/76 are as follows: 3-vessel (304), 93.4%; 3-vessel with abnormal LV (238), 93.3%; 3-vessel with ejection fraction <0.45 (70), 91.5%; 3-vessel with functional class III & IV (249), 92.2%. Three-vessel with ejection fraction <0.45 and FC III & IV (65), 90.9%; 3-vessel with 90-100% obstruction in all major vessels (170), 90.9%. The 5 yr SUR according to prognostic gradations was as follows: one, 2 and 3-vessel, 93.5%, 93.1%, 93.4%; functional class I through IV, 100%, 97.1%, 91.2%, 92.3%; ejection fraction <0.45 and >0.45, 89.1%, 93.6%; normal vs abnormal LV 93.6% vs 92.5%; with prior infarction vs without infarction 92.7% vs 93.0%.

Conclusion: Restoration of survival to near normal levels in patients with uniformly poor prognosis and elimination of anticipated life survival differences between patients with varying severity are strong indications that prolongation of life with CAB is real.

RESIDUAL LESIONS AFTER CORONARY BYPASS: AN IMPORTANT VARIABLE AFFECTING LATE SURVIVAL

Gerald M. Lawrie, MD, FACC; George C. Morris, Jr., MD, FACC; Abraham Silvers, Ph.D; Don W. Chapman, MD, FACC, Baylor College of Medicine, Houston, Texas.

A residual lesion (RL) is a coronary stenosis of >70% without a functioning graft attached distal to it. To determine the influence of RL on early and late survival (S), the S was determined of 844 patients with 1,2, or 3 vessel coronary disease operated on between 1968 and 1972. Mean age was 53 years (range 26-75). There were 750 males (88.8%). A single diseased vessel (DV) was present in 162 patients (19.2%), 2DV in 387 (45.9%) and 3DV in 295 (35.0%). The proportional hazards model for S was used to give a multivariate analysis to assess the influence of the following objective variables on long-term S: age at operation (op.); sex; number (no.) of DV; preop. left ventricular function (LV); period of surgery, early (1969-70) or late (1971-72); no. of RL. S was determined at least 5 years after op. in all cases. Analysis indicated that the following variables independently were associated with overall S: age at op. ($P<0.01$); no. of DV ($P<0.04$); quality of preop. LV ($P<0.001$); number of RL ($P<0.01$). Sex did not influence S ($P>0.2$). Periop. mortality (30 day) appeared to be associated with age, no. of DV, preop. LV, time period of surgery, and RL. However, late S (>30 day) was associated only with preop. LV ($P<0.01$) and the presence of RL ($P<0.002$). Late S did not correlate with age, preop. DV, nor with the period of surgery. Thus although the no. of DV influenced periop. mortality, late S was uninfluenced by the preop. DV ($P>0.1$). This study suggests that functioning bypass grafts may influence late S in multivessel coronary disease by eliminating the influence on S of the successfully bypassed DV and that the extent of RL is an important variable in long-term S.

LONG-TERM RESULTS OF CORONARY ARTERY BYPASS FOR UNSTABLE ANGINA: MORTALITY, MYOCARDIAL INFARCTION AND ANGINA

Dennis M. Davidson, MD, Irene Lamb, RN, John S. Schroeder MD,FACC, Stanford University Medical Center, Stanford, CA

The first 81 patients (pts) to undergo coronary artery bypass surgery (CABS) for unstable angina pectoris had treadmill exercise evaluation at mean times of 18, 40 and 72 months (mos) after CABS. Angina was assessed at those times and at a mean time of 90 mos. The prevalence of angina rose from 19% during the first year to 53% during the 4th and 5th years after CABS. Clinical and treadmill variables did not predict cardiac deaths or events occurring during the first 3 post-CABS years. Few events were recorded from 9-36 mos. Thereafter, the incidence of cardiac events increased sharply. Life table analysis showed that events were more frequent in pts with either pre-CABS evidence of a myocardial infarction or in those who reported angina at the 18 mo followup visit ($p<.001$). Maximal heart rates on the 18 and 40 mo treadmill tests were correlated with later events, but they added no independent prognostic information.

Conclusion: The prevalence of angina increased steadily during the first 5 postoperative years. Cardiac death and myocardial infarction rates began to rise 3 years after surgery. These events were more frequent in persons with evidence of myocardial infarction before surgery and in those who reported angina during the first two years after surgery. Treadmill testing added no independent prognostic information.

FIVE YEAR FOLLOW-UP OF MAXIMAL TREADMILL STRESS TEST IN ASYMPTOMATIC WOMEN AND MEN

William H. Allen, MD, FACC; Wilbert S. Aronow, MD, FACC; Phil Goodman, BS; Perri Stinson, PhD, University of California, Irvine

Of 1,077 asymptomatic adults who had a maximal treadmill stress test (MTST), 888 (82.5%) had a 5 year follow-up (FU) including 105 of 113 persons (92.9%) with a positive MTST. Of 888 persons (311 women and 577 men), 48 (5.4%) had coronary heart disease (CHD) at FU. Upsloping S-T depression $\geq$ 1.5 mm did not correlate with CHD at FU. Downsloping or flat S-T depression $\geq$ 1.0 mm did not correlate with CHD at FU in women or in men $\leq$ 40 years but correlated with CHD at FU in men > 40 years, $P < 0.01$. No change or an increase in R wave did not correlate with CHD at FU in women but correlated with CHD at FU in men > 40 years, $P < 0.001$. An exercise time (ET) $\leq$ 3 min correlated with CHD at FU in women, $P < 0.001$. An ET $\leq$ 5 min correlated with CHD at FU in men > 40 years, $P < 0.001$.

	Sens	Spec	PV	RR
S-T (women)	9.1%	96.6%	6.3	1.9
S-T (men > 40)	41.2%	79.1%	17.3	2.4
R wave (women)	20.0%	97.0%	5.6	1.9
R wave (men > 40)	47.1%	77.8%	18.6	2.7
R wave or S-T (men)	64.7%	62.9%	16.2	2.9
ET $\leq$ 3 min (women)	40.0%	96.6%	28.6	13.6
ET $\leq$ 5 min (men > 40)	26.5%	96.2%	42.9	5.6
S-T or ET $\leq$ 5 min (men)	52.9%	76.0%	18.9	3.0

Sens = sensitivity; spec = specificity; PV = predictive value of abnormal test; RR = risk ratio

We conclude: in asymptomatic adults at FU after a MTST, 1) downsloping or flat S-T depression $\geq$ 1.0 mm correlated with CHD in men > 40 years, 2) no change or an increase in R wave correlated with CHD in men > 40 years, and 3) an ET $\leq$ 3 min in women and $\leq$ 5 min in men > 40 years correlated with CHD.

EFFECTS OF CORONARY ARTERY BYPASS SURGERY VERSUS MEDICAL THERAPY ON WALL MOTION ABNORMALITIES

John McAnulty, MD,FACC; Ronald Naito, MD; Cynthia Morris, BS; Frank Kloster, MD,FACC; University of Oregon Health Sciences Center, Portland, Oregon.

The effect of coronary artery bypass surgery (CABS) on left ventricular(LV)wall motion abnormalities(WMA)was evaluated in a prospective manner after random assignment to surgical(S,n=36)and medical(M,n=40)therapy. Follow-up LV angiograms were performed at 8.4 months in S vs 8.1 months in M. The two groups did not differ(p>.10)in age,sex,previous myocardial infarction(MI),severity or coronary artery disease, ejection fraction(EF), or in location type, or number of WMA(46/108 in S and 45/114 in M). Graft patency was 77%. Interval infarctions occurred in 3 S and 1 M.

Wall motion improvement in S patients(pts)with patent grafts(17/69 segments, 25%)or disregarding graft patency (24/108,22%)was greater than in M pts(14/114,12%) (p<.05). Seven WMA improved in S despite graft occlusion to that segment. Exclusion of segments with a previous MI did not change the results.

WMA worsened in 12/69(17%) S segments with patent grafts and 19/108(18%)overall vs 22/114(19%) in M(p=n.s.). New WMA in initially normal segments developed in 17/62(27%) segments in S and 14/69(20%)segments in M(p=n.s.);5 new WMA segments in S and 1 in M developed in regions of intercurrent MI.

Mean EF for S and M was similar and did not change(p=n.s.)for either group at the time of follow-up(S-0.62 to 0.61; M-0.61 to 0.60). EF improved by more than 15% in 5 S and 4 M.

WMA improved more frequently with S than with M treatment but this is not always attributable to a patent graft. WMA may develop or worsen despite S and without intercurrent MI. Alterations in local segmental WMA is not reflected in global LV function as characterized by EF.

LONG TERM FOLLOWUP OF PATIENTS MANIFESTING SEVERE ST DEPRESSION DURING MAXIMAL BRUCE EXERCISE TESTING AND HAVING ANGIOGRAPHICALLY NORMAL CORONARY ARTERIES.

Craig M. Pratt, MD; Gary Nussey; Donna Kanon, BMa; D.Gregg Hopkins, MD; and Richard R. Miller, MD, FACC; Baylor College of Medicine, The Methodist Hospital, Houston, Texas.

All patients (pts) who underwent Bruce exercise testing (ETT) for evaluation of chest pain in the past seven years at The Methodist Hospital were screened for those manifesting severe ST segment depression($\geq$2mm downsloping, flat or upsloping .08 seconds after the J point).Of these, 34 pts (9 female, 25 male) had angiographically normal coronary arteries (No CAD) and adequate followup information. These pts (mean age 55 years) had a mean followup of 3.3 years (range, 1-7 years). In addition to severe ST depression, this group had the following ETT characteristics: 1) average time to ST normalization=7 minutes; 2) failure of blood pressure rise >10mm Hg=3/34 pts (9%); 3) Ventricular premature beats (VPBs) with exercise=9/34 (26.7%); 4) Couplets or VTACH with exercise 3/34(9%); 5) VPBs post exercise 7/34(20%); 6) VPBs before exercise 5/34(15%); 7) 20/34 pts had 2mm maximal ST depression, 9/34 3mm ST depression, 5/34 4mm ST depression. Catheterization revealed mean left ventricular end-diastolic pressure 10mm Hg, and normal left ventricular contractility.

Present status of these pts (3.3 year mean followup) shows a trend to symptomatic improvement. Angina disappeared in 63%, is improved or unchanged in 27% and worse in only 10%; 26/34 pts(76%) have maintained their previous employment and only 4/34 pts(12%) necessitated job change because of continued chest pain. Importantly, in the 3.3 year followup interval there were no deaths. Thus, the prognosis of $\geq$ 2mm ST depression during ETT in pts with no CAD is excellent, both for survival and continued productive employment status.

ABBREVIATED RAPID ONSET EXERCISE STRESS TESTING FOR THE EXPOSURE OF VENTRICULAR ARRHYTHMIA

Thomas B. Graboys, MD, FACC; Arno Schoeneberger, MD; Regis A. DeSilva, MD; Virginia Towne; Bernard Lown, MD, FACC, Cardiovascular Laboratory, Harvard School of Public Health, Boston, Massachusetts

Exercise stress testing is an important method for exposing advanced grades of ventricular premature beats (VPBs). Deletion of the "warm-up" phase produces a physical stress akin to sudden "start-stop" activity and more closely approximates demands of daily life. The provocation of VPBs was compared in a standard Bruce protocol (ETT) and a "mini-stress" during which patients (PTs) advanced through each of the eight Bruce protocol stages every 15 seconds. The study involved 52 PTS, 43 males and 9 females average age 49 years. Hemodynamic and ST segment changes were similar during both exercise forms of testing. Thirty-eight PTS (73%) undergoing the Bruce ETT exhibited VPBs while 33 (64%) did so during "mini-stress." In 10 PTS ETT yielded more advanced grades of VPBs than mini-stress while 7 PTS, including 3 with VT, had a greater yield with the mini-stress. Hence, an abbreviated exercise test may be a valuable adjunct in management of PTS with known or suspect ventricular arrhythmia.

HEMODYNAMIC RESPONSES TO STATIC EXERCISE ARE DEPENDENT ON THE MASS OF MUSCLE ACTIVATED.

F. Andrew Gaffney, M.D., Bente Danneskiold-Samsøe, M.D., Ula Halskov, M.D., and Gunnar Grimby, M.D., Ph.D. August Krogh Institute, University of Copenhagen, Denmark.

The generally accepted concept that hemodynamic responses to static exercise (Static Ex) are determined by the percent of Maximum Voluntary Contraction (%MVC) but not the mass of muscle activated was reexamined in 10 healthy subjects (S), (7 male, 3 female, 21-24 yrs) on 2 days, 6 weeks apart. Static Handgrip (parallel bar) and knee extension, (Tornvall chair) MVC's were determined (best of 3). S's maintained the contraction (Day 1 20% MVC. Day 2 18% MVC) for 5 minutes with measures of HR (ECG) and mean blood pressure (Cuff, 1/3 pulse pressure + diastolic) every 30 sec. Order of contraction was varied with 20 min. rest between contractions. Differences between handgrip and knee extension HR and $\overline{BP}$ responses for the 2 studies were virtually identical.

		Rest	0:30	2:30	5:00
	HR	82±3	97±4	108±3	109±4
	beat/min	85±2	90±3	91±3	97±4
Knee					
Hand	$\overline{BP}$	89±2	101±2	128±4	140±4
	MM Hg	88±2	97±3	109±2	121±3

(Mean±S.E.)

HR and $\overline{BP}$ were higher with the larger contracting muscle mass throughout both studies (ANOVA p=.005). This would suggest that hemodynamic responses to isometric exercise are dependent on the mass of muscle activated. The higher knee extension heart rates suggest a greater cardiac output. This, in the presence of a larger muscle bed with mechanically compromised blood flow could account for the higher $\overline{BP}$ with knee extension.

MECHANISMS OF INCREASED R WAVE MAGNITUDE WITH EXERCISE IN PATIENTS WITH CORONARY ARTERY DISEASE.

Harisios Boudoulas, MD, FACC; Stephanos Dervenagas, MD; Richard P. Lewis, MD, FACC; The Ohio State University College of Medicine, Columbus, Ohio.

An increase of the R wave magnitude with exercise has been used to establish the presence of myocardial ischemia in patients (pts) with coronary artery disease (CAD). The present studies were undertaken in three different groups to define the mechanisms for this phenomenon. I. The effect of Isoproterenol (Iso) infusion (2 μg/min/10 min) on the R wave magnitude was studied in 10 normals before and after propranolol (Pr) administration 160 mg daily for 2 days. The R wave magnitude decreased with Iso (-10.8 $\pm$ 1.6%, $p<0.001$) but remained unchanged when Iso was given after Pr (-0.9 + 2%). II. A maximal Treadmill exercise test was performed in 25 pts with CAD, not on therapy with stable angina and no resting myocardial perfusion defects or segmental contraction abnormalities. The R wave magnitude increased with exercise in 10 pts (+8.2 $\pm$ 3%, $p<0.01$) and decreased in 16 (-11.2 $\pm$ 3%, $p<0.01$). The number of coronary arteries with obstruction $\geq$70% was greater in pts in whom the R wave magnitude increased with exercise compared to pts in whom the R wave magnitude decreased (2.1 $\pm$ .12 vs 1.2 $\pm$ .1, $p<0.01$). This suggests that more extensive ischemia was present in pts in whom the R wave magnitude increased with exercise. III. In 10 pts with CAD and stable angina in whom the R wave magnitude decreased with exercise before therapy (-10.8 $\pm$ 1.6%, $p<0.01$), Pr resulted in an increase of the post-exercise R wave magnitude (+7.9 $\pm$ 3.2%, $p<0.05$). It is concluded that the increase of the R wave magnitude with exercise is related to inability of the ischemic myocardium to respond to adrenergic stimulation. Furthermore, changes of the R wave magnitude to diagnose ischemia must be interpreted with caution in pts who are on β-blocking agents.

EXERCISE EJECTION FRACTION DIMINISHES AFTER RECOVERY IN POSTOPERATIVE AORTOCORONARY BYPASS PATIENTS.

James L. Cockrell, Jr., BS; Peter N. Zeitler, MS; Lucy S. Goodenday, MD; Richard K. Foster, MD; Rodney V. Pozderac, MD; V.A.M.C and University of Michigan, Ann Arbor, MI, and Medical College of Ohio, Toledo, OH.

Exercise (E) ejection fraction (EF) improves in postoperative coronary artery bypass patients, but serial changes in EEF in the postoperative period have not been reported. We therefore measured EEF in 8 men using radionuclide ventriculography approximately 3 weeks following surgery, when they had reached a 3 MET level of exercise tolerance in an inhospital rehabilitation program prior to discharge. After 9 weeks of a home recovery program the patients were reevaluated, using the identical protocol, and these results compared to the initial studies:

	At Highest Work Rate:	($\pm$ S.D.)	
Post-Op.	Pulse	EEF	EEF - Rest EF
3 weeks	129 $\pm$ 12	.71 $\pm$ .10	.16 $\pm$ .10
12 weeks	136 $\pm$ 13	.61 $\pm$ .10	.08 $\pm$ .08
P <	.02	.005	.005

All 8 patients showed diminished EEF at 12 weeks. Measurements made at matched workloads and heart rates exhibited reduced EEF as well. Exercise tolerance improved in most cases.

We conclude that peak EEF and EEF minus resting EF diminished significantly between the 3rd and 12th weeks after aortocoronary bypass. This may reflect diminished left ventricular performance at 12 weeks following surgery. Other possibilities include training-induced left ventricular enlargement or the existence of an hyperadrenergic state immediately following surgery which subsides at 12 weeks.

#1 in Holter Technology.

Only ICR offers the software technology of microprocessors in Holter systems. No other Holter system can scan, organize and select more information than ICR, or allow you to view and check that information in so many ways. More information . . . more meaningful information . . . gives you the ability to make a better informed diagnosis.

Microprocessor technology means that the ICR Holter system can be updated as your diagnostic needs change, and as technological advances are made. ICR is changing Holter medicine everyday, making it more practical and more useful. That's why we make our equipment easy to update.

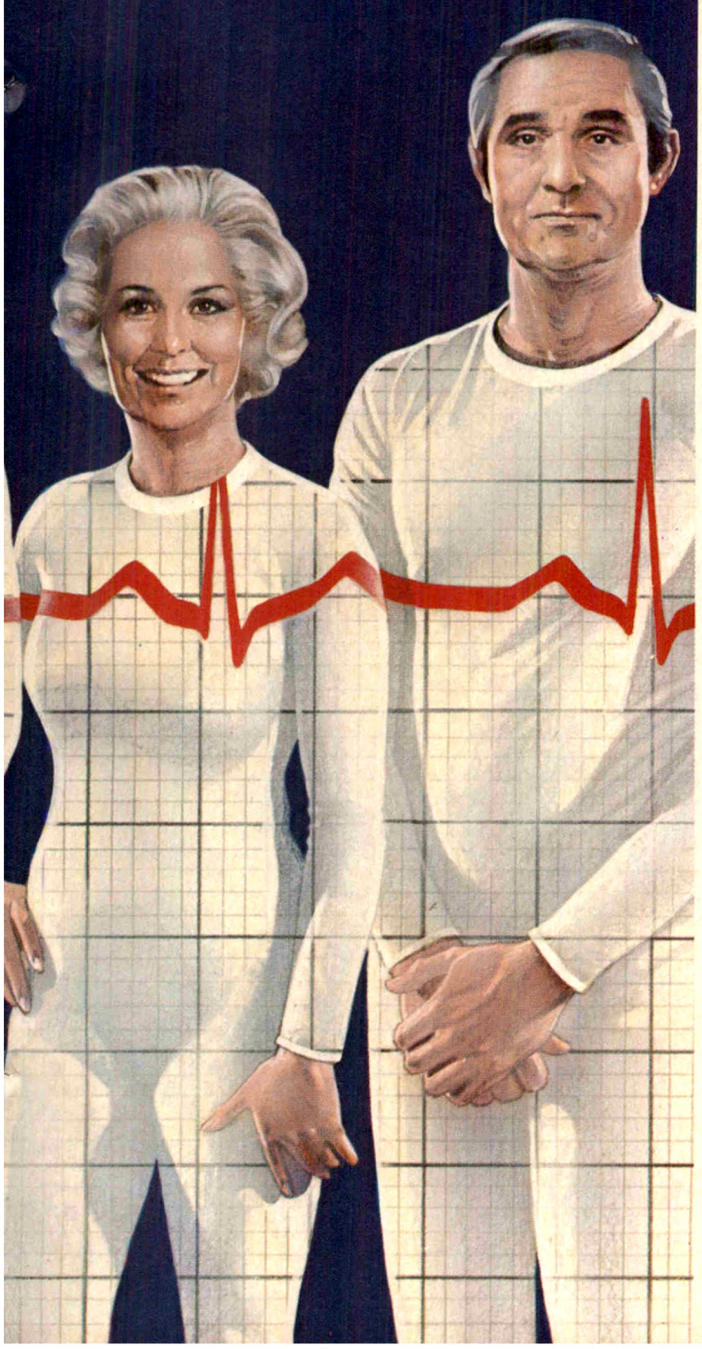
Scores well in long-acting effectivenes

in susceptible
cardiac arrhythmias

Duraquin®

(QUINIDINE GLUCONATE TABLETS)

SUSTAINED-RELEASE TABLETS, 330 mg



□ **scored for convenient titration**

□ **long-acting, steady-state plasma levels**
Achieved shortly after 24 hours... maintained for 12 hours.*

□ **priced for greater economy**
Cost is approximately 20% less than other long-acting quinidine gluconate therapy.†

*Quantity of drug and frequency of administration needed to achieve desired clinical results must be determined for each patient.
†*Red Book*, 1979.

Duraquin®
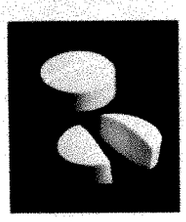
(QUINIDINE GLUCONATE TABLETS) SUSTAINED-RELEASE TABLETS, 330 mg



BRIEF SUMMARY OF PRESCRIBING INFORMATION
DURAQUIN® (quinidine gluconate tablets) Sustained Release
AHFS Category 24:04

CLINICAL PHARMACOLOGY. In clinical studies, single doses of Duraquin produced a mean maximum plasma level at 2 hours which was maintained for 12 hours. This broad plateau indicates slow, continuous absorption from the gastrointestinal tract.

In multiple dose studies, administration of Duraquin tablets, 660 mg every 12 hours, produced steady state (equilibrium) plasma levels shortly after 24 hours. The average quinidine plasma levels (Cramer and Isaksson assay[1]) were 0.81 mcg/ml and the mean peak levels were 1.16 mcg/ml in a group of normal male subjects weighing 75 Kg. Following the last dose at steady state, quinidine plasma levels decreased at an approximate rate of 50% in 10 hours. This compares to the expected plasma half-life of 6.3 hours for quinidine sulfate tablets, USP.

Therapeutic and toxic effects coordinate better with plasma levels than with dosage. While therapeutic levels of 3 to 6 mcg/ml with a range of 1.5 to 9 mcg/ml have been reported, these values are based on peak plasma levels determined by the less specific Edgar and Sokolow assay.[2] This procedure yields quinidine levels averaging 22% higher than the Cramer and Isaksson assay. Plasma levels vary considerably in patients receiving identical doses. Therefore, it is advisable to adjust the dosage by monitoring plasma quinidine levels.

INDICATION. Duraquin tablets are indicated for the prevention of premature atrial, nodal, or ventricular contractions. They are also indicated for the maintenance of normal sinus rhythm following spontaneous reversion or electrical conversion of atrial, nodal, or ventricular tachycardia, atrial flutter and fibrillation (either paroxysmal or chronic).

CONTRAINDICATIONS. 1. History of hypersensitivity to quinidine manifested by thrombocytopenia, skin eruption, febrile reactions, etc.

2. Complete A-V block

3. Complete bundle branch block or other severe intraventricular conduction defects exhibiting marked QRS widening or bizarre complexes

4. Myasthenia gravis

5. Arrhythmias associated with digitalis toxicity

WARNINGS. 1. (a) In the treatment of atrial fibrillation with rapid ventricular response, ventricular rate should be controlled with digitalis glycosides *prior* to administration of quinidine.

(b) In the treatment of atrial flutter with quinidine, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine.

Recent reports have described increased, potentially toxic, digoxin plasma levels when quinidine is administered concurrently. When concurrent use is necessary, digoxin dosage should be reduced and plasma concentration should be monitored and patients observed closely for digitalis intoxication.

2. Quinidine cardiotoxicity may be manifested by increased PR and QT intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia. Appearance of these toxic signs during quinidine administration mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. Note: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia.

3. "Quinidine Syncope" may occur as a complication of long-term therapy. It is manifested by sudden loss of consciousness and ventricular arrhythmias with bizarre QRS complexes. This syndrome does not appear to be related to dose or plasma levels but occurs more often with prolonged QT intervals.

4. Because quinidine antagonizes the effect of vagal excitation upon the atrium and the A-V node, the administration of parasympathomimetic drugs (choline esters) or the use of any other procedure to enhance vagal activity may fail to terminate paroxysmal supraventricular tachycardia in patients receiving quinidine.

5. Quinidine should be used with extreme caution in:

a) the presence of incomplete A-V block, since a complete block and asystole may result. Quinidine may cause unpredictable abnormalities of rhythm in digitalized hearts. Therefore, it should be used with caution in the presence of digitalis intoxication (see 1.(b) above).

b) Partial bundle branch block.

c) Severe congestive heart failure and hypotensive states due to the depressant effects of quinidine on myocardial contractility and arterial pressure.

d) Poor renal function, especially renal tubular acidosis, because of the potential accumulation of quinidine in plasma leading to toxic concentrations.

PRECAUTIONS. 1. Test Dose—A preliminary test dose of a single tablet of quinidine *sulfate* should be administered prior to the initiation of the sustained release gluconate to determine whether the patient has an idiosyncrasy to the Quinidine molecule.

2. Hypersensitivity—During the first weeks of therapy, hypersensitivity to quinidine, although rare, should be considered (eg, angioedema, purpura, acute asthmatic episode, vascular collapse).

3. Long-Term Therapy—Periodic blood counts and liver and kidney function tests should be performed during long-term therapy and the drug should be discontinued if blood dyscrasias or signs of hepatic or renal disorders occur.

4. Large Doses—ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered.

5. Usage in Pregnancy—The use of quinidine, in pregnancy, should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus.

6. Nursing Mothers—The drug should be used with extreme caution in nursing mothers because the drug is excreted in breast milk.

7. General—In patients exhibiting asthma, muscle weakness, and infection with fever *prior* to quinidine administration, hypersensitivity reactions to the drug may be masked.

DRUG INTERACTIONS. 1. Caution should be used when quinidine and its analogs are administered concurrently with coumarin anticoagulants. This combination may reduce prothrombin levels and cause bleeding.

2. Quinidine, a weak base, may have its half-life prolonged in patients who are concurrently taking drugs that can alkalize the urine, such as thiazide diuretics, sodium bicarbonate, and carbonic anhydrase inhibitors. Quinidine and drugs which alkalize the urine should be used together cautiously.

3. Quinidine exhibits a distinct anticholinergic activity in the myocardial tissues. An additive vagolytic effect may be seen when quinidine and drugs having anticholinergic blocking activity are used together. Drugs having cholinergic activity may be antagonized by quinidine.

4. Quinidine and other antiarrhythmic agents may produce additive cardiac depressant effects when administered together.

5. Quinidine interaction with cardiac glycosides (digoxin); See WARNINGS.

6. Antacids may delay absorption of quinidine but appear unlikely to cause incomplete absorption.

7. Phenobarbital and phenytoin may reduce plasma $T_{1/2}$ of quinidine by 50%.

8. Quinidine may potentiate the neuromuscular blocking effect in ventilatory depression of patients receiving decamethonium, tubocurare, or succinylcholine.

ADVERSE REACTIONS. Symptoms of cinchonism (ringing in the ears, headache, disturbed vision) may appear in sensitive patients after a single dose of the drug.

Gastrointestinal: The most common side effects encountered with quinidine are referable to this system. Diarrhea frequently occurs, but it rarely necessitates withdrawal of the drug. Nausea, vomiting, and abdominal pain also occur. Some of these effects may be minimized by administering the drug with meals.

Cardiovascular: widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardias and fibrillation; paradoxical tachycardia, arterial embolism and hypotension.

Hematologic: acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis.

CNS: headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, photophobia, diplopia, night blindness, scotomata); optic neuritis.

Dermatologic: cutaneous flushing with intense pruritus.

Hypersensitivity reactions: angioedema, acute asthmatic episode, vascular collapse, respiratory arrest.

DOSAGE AND ADMINISTRATION. Dosage should be titrated to give the desired clinical effect, eg, elimination of paroxysmal rhythm or reduction in premature contractions (See CLINICAL PHARMACOLOGY). This will often require prolonged ambulatory ECG monitoring, as hour-to-hour variability renders brief ECG recordings unreliable. When doses larger than 2.5 g/day are used, quinidine blood levels should be monitored, if possible, and serial ECGs should be followed (See WARNINGS and PRECAUTIONS).

For prevention of premature contractions and maintenance of normal sinus rhythm following electrical conversion, the usual dosage is from 330 mg to 660 mg every eight hours, most patients requiring the higher dose.

In elderly patients, and in patients in the lower end of the normal weight range, plasma quinidine determinations should be considered. Dosage adjustments may be required.

OVERDOSAGE. Cardiotoxic effects of quinidine may be reversed in part by molar sodium lactate; the hypotension may be reversed by vasoconstrictors and by catecholamines (since the vasodilation is partly due to alpha-adrenergic blockade).

HOW SUPPLIED. N 0071-0850 (P-D 850) Duraquin (quinidine gluconate tablets) 330-mg tablets are supplied in bottles of 100 tablets and in unit-dose packages of 100 (10 strips of 10 tablets each).

CARDIOLOGY: FRESNO, CALIFORNIA

The University of California, San Francisco is searching for a chief of cardiology in the Fresno-Central San Joaquin Valley Medical Education Program. The position is situated at the Veterans Administration Medical Center in Fresno. Candidate should be qualified for academic appointment at the level of associate professor or professor. Interested individuals may submit their C.V. to Howard F. Morrelli, M.D., Professor of Medicine and Pharmacology, Chief, Medical Service, Veterans Administration Medical Center, 2615 E. Clinton, Fresno, CA 93703. The University of California is an equal opportunity employer.

1976 – 1977 – 1978 – 1979 – 1980

marquette's case* ...

still the only exercise system with an intelligent microcomputer

...and still obsolescence protected

In 1976 Marquette introduced CASE (Computer Assisted System For Exercise) with its new unique features of noise rejection, compressed record, arrythmia detection and final report.

In 1977 we introduced some notable improvements such as extended final report and incremental averaging. More important, every CASE owner was able to update his system through simple software revision.

In 1980 we're introducing new features. • S-T integral measurement • Worst case S-T slope interval • Further improved final report . . . All with a simple software update.

This is what Marquette is doing about obsolescence and the protection of your investment!

Visit our booth at the ACC meeting in March.

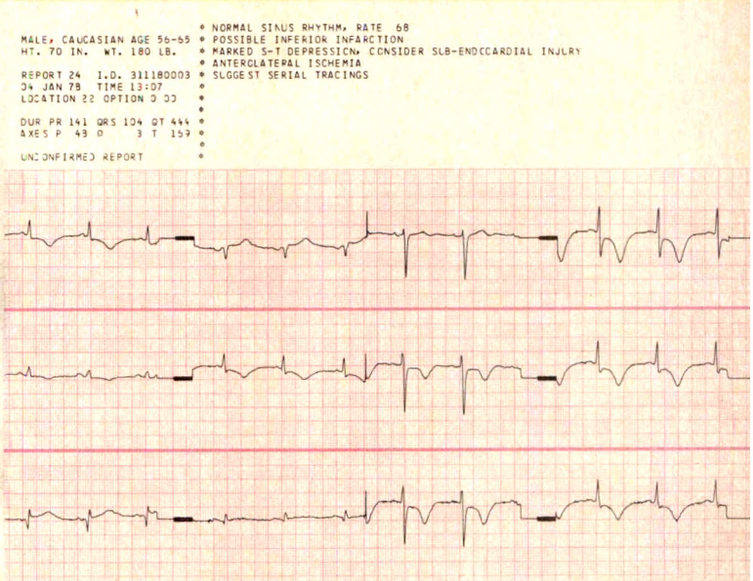
ECG Cost Containment



Now At Work In More Than 100 Hospitals

MUSE (Marquette's Universal System for Electrocardiography) offers substantial cost containment benefits for ECG analysis, storage and management. The MUSE system's high productivity and elimination of bulky storage files insures substantial reduction in operating costs. Its unique capability of being shared by several hospitals offers substantial reduction of investment, and facilitates obtaining HSA (Hospital Services Administration) "certificate of need."

The system consists of a central processor and storage system with remote μMUSE systems connected by telephone lines. Each user has total capability, equal convenience and data base privacy. ECG tracings are taken locally and transmitted to the central processor. It, in turn, automatically dials the appropriate μMUSE remote terminal, and transmits an analyzed ECG report for physicians over-reading and editing.

This approach not only proves cost effective, but the clinical benefits are substantial due to highly accurate ECG parameter measurements and decreased turn-around time.

The ever-growing list of MUSE users is testimony to its cost containment and clinical effectiveness. To learn more about Health Care Cost Containment write for the free booklet entitled: *Health Care Cost Containment With ECG Computer Systems*.

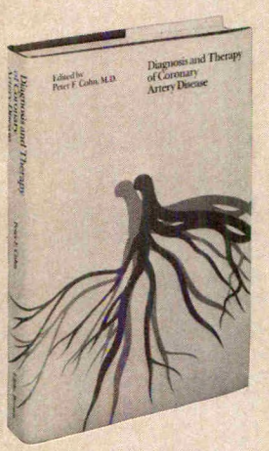
YESTERDAY'S REFERENCES WEREN'T WRITTEN FOR TODAY'S CARDIOLOGIS

Keep pace with books from Little, Brown



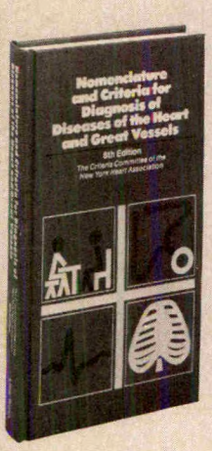
DIAGNOSIS AND THERAPY OF CORONARY ARTERY DISEASE

Edited by Peter F. Cohn, M.D., Harvard Medical School; Peter Bent Brigham Hospital, Boston

"This book should be read by all doctors who wish to understand more about the most serious epidemic in the industrialised world." — *The Lancet*

From Peter Bent Brigham Hospital and Harvard Medical School comes the best clinically oriented reference available today on coronary artery disease. It contains up-to-the-minute diagnostic and therapeutic information, and explores the controversial issues surrounding this timely topic. The outstanding list of contributors includes such renowned experts in cardiology as Braunwald, Kannel, Zaret, Bruce, Hellerstein, Feigenbaum, Bigger, and Rackley. DIAGNOSIS AND THERAPY OF CORONARY ARTERY DISEASE provides comprehensive coverage of the diagnosis, evaluation, prevention, and therapy of coronary artery disease.

509 pages, illustrated. #150320, $32.50

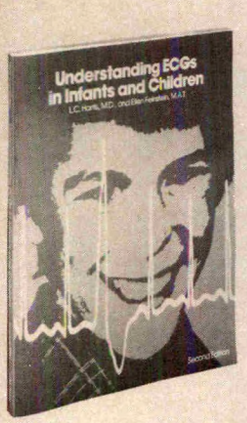


NOMENCLATURE AND CRITERIA FOR DIAGNOSIS OF DISEASES OF THE HEART AND GREAT VESSELS, Eighth Edition

By The Criteria Committee of the New York Heart Association, M. Irene Ferrer, M.D., Chairman

For its eighth edition, this classic reference has been revised with the newest knowledge in cardiology, including the latest diagnostic techniques.

349 pages, illustrated. Clothbound, #605360, $13.95; paperback, #605379, $9.95



UNDERSTANDING ECGs IN INFANTS AND CHILDREN, Second Edition

By L.C. Harris, M.D., M.R.C.P. (London) and Ellen Feinstein, M.A.T., both of The University of Texas Medical Branch, Galveston

This compact, precise self-instruction text is the complete guide to pediatric ECGs.

109 pages, illustrated. #348260, $12.50

You are cordially invited to attend a Pfizer Educational Symposium on

Calcium Inhibition In Angina: Basic and Clinical Studies

Chairman and Moderator:
Eugene Braunwald, M.D.
Hersey Professor of the Theory & Practice of Medicine Harvard Medical School

The symposium will immediately follow the 29th Annual Scientific Sessions of the American College of Cardiology and will be held at:

The Statesman's Ballroom of
The Sheraton Houston Hotel
777 Polk Avenue, Houston, Texas

March 13, 1980
1:30 to 5:30 P.M.

If you would like to attend the symposium and have not yet registered, please do so at the Pfizer Laboratories booths 156, 158 and 160 at the Albert Thomas Exhibit Center.

Be sure not to miss the exciting film, THE CLINICAL SIGNIFICANCE OF CORONARY ARTERY SPASM. This film will be shown continuously at the Pfizer Laboratories "Frontiers in Cardiology" exhibit (island #164) at the Albert Thomas Exhibit Center from 8 a.m. to 5 p.m. on Monday, March 10 to Wednesday, March 12 and from 8 a.m. to 12 p.m. on Thursday, March 13.

You may also obtain a copy of the brochure, "New Concepts in Ischemic Heart Disease: The Role of Coronary Artery Spasm" at booths 156, 158 and 160.

RESPONSE TO EXERCISE EARLY AFTER UNCOMPLICATED ACUTE MYOCARDIAL INFARCTION IN UNMEDICATED PATIENTS

William B. Kruyer, MD; Gerald M. Koppes, MD, FACC; Charles H. Beckmann, MD, FACC; and Frederic G. Jones, MD, FACC, Wilford Hall USAF Medical Center, San Antonio TX.

Cardiovascular function and follow-up have not been adequately defined early after an uncomplicated acute myocardial infarction (AMI) in unmedicated patients (pts). Ninety such pts were studied with treatmill testing (TT) submaximally at 3 weeks and maximally at 8 weeks. The exercise heart rate (HR), rate-pressure product (RPP), and oxygen uptake ($\dot{V}O2$) at 3 weeks were 120±17 beats/min, 179±43 and 17.4±1.0 ml/kg/min and at 8 weeks were 157±20, 271±55, and 24.3±3.7 respectively. Maximum HR, RPP and $\dot{V}O2$ with the 3 week TT were 78%±15, 87%±13 and 74%±10 respectively of the 8 week maximum values. Exercise variables at submaximal equivalent exercise work did not change from the 3 to 8 weeks. At maximal exercise 15.6% had ST changes alone, 8.9% had angina alone and 12.2% had both. Pts were followed for a mean of 23.7 months for complications — death, reinfarction, bypass grafting, and progression to AHA Class III-IV. Complications occurred in 27% with angina and ST changes, 29% with ST changes, 25% with angina, 8% with ventricular ectopy only, 12% with normal 8 week TT and 17% in the group as a whole. Another 18 pts who were unmedicated and uncomplicated could not perform a maximal 8 week TT and 39% suffered long term complications. In conclusion, these reference values serve as safe limits in performing TT early after AMI. ST changes and/or angina and inability to complete a maximal 8 week TT identify pts at risk for later complications even though these pts may have been considered to be in a low risk category clinically.

IMMEDIATE PSYCHOLOGICAL IMPACT OF EXERCISE TESTING SOON AFTER MYOCARDIAL INFARCTION

Craig K. Ewart, PhD, C. Barr Taylor, MD, Albert Bandura, PhD and Robert F. DeBusk, MD, FACC, Stanford University Medical Center, Stanford, CA.

Patients' confidence in their ability to resume normal activities after myocardial infarction (MI) was measured in 10 men mean age 50, before and after completion of a symptom-limited treadmill exercise test (TM) 3 weeks after the acute event. Confidence was assessed immediately before and after TM, using a self-efficacy scale in which patients rated their ability to 1) walk, 2) jog variable distances 1 block - 2 miles and 3) engage in sexual intercourse for various periods 1 - 20 minutes. The pretest evaluation also measured depression (by questionnaire and structured interview) and sexual satisfaction and adjustment to MI. Results: confidence in all 3 areas of functioning increased significantly ($p < 0.05$), especially with respect to sexual ability ($p < 0.02$). The increase in sexual confidence was most pronounced in patients who had the least confidence in their ability and lowest satisfaction scores prior to TM. Increments in sexual satisfaction were correlated with pre-TM depression as measured by the Beck questionnaire and Hamilton interview ($r=0.78$, 0.81, respectively, $p < 0.05$). Conclusions: 1) exercise testing soon after MI enhances patients' confidence in their ability to resume normal activities including sexual intercourse. 2)Because sexual capacity and sexual satisfaction are good measures of overall adjustment to MI, the enhanced confidence observed in these patients suggests that TM testing soon after MI may have a generalized psychological benefit. 3) This benefit is greatest for patients who are most depressed and/or report the poorest sexual adjustment.

EARLY POST-MYOCARDIAL INFARCTION TREADMILL STRESS TESTING: AN ACCURATE DISCRIMINATOR OF MULTI AND SINGLE VESSEL CORONARY DISEASE.

Colin M. Fuller, MD; Albert E. Raizner, MD,FACC; Mario S.Verani, MD,FACC; Patricia A. Nahormek,MD; Alfredo Montero,MD, Richard R.Miller,MD,FACC, Robert A. Chahine,MD,FACC. Baylor College of Medicine, Veterans Administration Hospital, Houston, TX.

Because the first months after myocardial infarction (MI) are a relatively high risk period, early detection of post-MI patients (pts)with multivessel coronary disease (CAD) may be important. Accordingly,22 consecutive pts (mean age 53 years,range 40-65) without heart failure or angina underwent limited treadmill testing (LTT) (peak heart rate 120 or symptoms) an average of 13 days post MI. Twelve pts had inferior MI and 10 anterior MI. The 7 pts with LTT-induced angina (AP) and/or ischemic ST segment depression (+LTT) underwent cardiac cath (CC) 4 weeks post-MI; 15 pts with -LTT had maximum (MAX) TT and CC 8-12 weeks post-MI. The 3 major coronary arteries were scored for stenoses (score): normal=0; <50%=1; 50-90%=2; multiple 50-90%=3; 91-99%=4; 100%=5.

LTT	N	Score		SVD%	MVD%	Events
+LTT	7	10.7±2.6	$>p<.001$	15	85	5
-LTT	15	6.6±2.6		80	20	1
+LTT†	4	11.0±2.8	$>p<.001$	0	100	3
-LTT†	12	5.5±1.4		100	0	1

N=number pts; SVD=single vessel stenosis; MVD=multivessel stenoses; Events=post-discharge unstable angina; †=first MI. None of the 10 pts with -LTT who underwent MAX TT at 10 weeks post-MI, had a positive MAX TT. Thus, pre-discharge LTT in MI pts is predictive of extent of CAD and subsequent unstable angina. Importantly, these data suggest that -LTT excludes multivessel stenoses in pts with first MI and thereby may select subsets of pts in whom post MI coronary arteriography may be either beneficial or unnecessary.

ADVANTAGES OF EXERCISE IMAGING IN PATIENTS WITH EQUIVOCAL TREADMILL EXERCISE TESTS

Louis Wasserman, MD, Abdulmassih S. Iskandrian, MD, FACC, Gary Anderson, MD, FACC, Hamid Hakki, MD, Bernard L. Segal, MD, FACC, Cardiovascular Institute of Hahnemann Medical College and Hospital, Philadelphia, Pennsylvania

Equivocal Treadmill Exercise Tests (TET) are seldom reported and thus their true prevalence is unknown. At our institution, 33% of all TET are equivocal. 65 patients (pts) with equivocal TET underwent exercise thallium-201 perfusion imaging (Ex-P), as well as coronary arteriography. All pts were evaluated for chest pain suspected to be angina pectoris. The TET were inconclusive because of the presence of ST depression in the resting ECG, or inadequate heart rate response during exercise (in the absence of diagnostic ischemic ST changes). Based on the results of Ex-P, the pts were divided into: Group I (20 pts) with perfusion defects (PD) in the exercise images (that filled partially or completely in the redistribution images), and Group II (45 pts) with normal exercise images. 19 pts in Group I (95%) had severe coronary artery disease (CAD >70% narrowing of one or more vessels). 37 pts in Group II (82%) had no CAD. Thus, the correct diagnosis was predicted in 56 pts (86%). The sensitivity and specificity of Ex-P were 70% and 97% respectively. In conclusion, Ex-P is extremely useful in pts with equivocal TET. Its high specificity suggests that pts with exercise induced PD have, in general, severe CAD. The absence of PD, however, does not entirely exclude CAD. Such normal images may be related to inadequate stress.

LOCALISATION OF SINGLE VESSEL CORONARY ARTERY DISEASE BY EXERCISE ELECTROCARDIOGRAPHY AND THALLIUM SCANNING.
Richard F. Dunn, FRACP; Ben Freedman, MB; Ian K. Bailey, FRACP; Roger F. Uren, FRACP; David T. Kelly, FRACP, FACC, Hallstrom Institute of Cardiology, Sydney, Australia.

In 39 patients (pts) with single vessel disease (SVD) and no previous infarction exercise thallium scanning and exercise ECG (E.ECG) were compared to try and identify the site of coronary obstruction. Significant (>70% diameter reduction) stenosis was present in the left anterior descending (LAD) in 21 pts, in the right coronary (RCA) in 14 pts and in the circumflex (LCX) in 4 pts. Anterior wall thallium defects (TD) were present in 17 of the 21 pts (81%) with LAD and 1 of the 18 pts (6%) with RCA or LCX ($p<.0005$). Inferior wall TD were present in 2 of the 21 pts (10%) with LAD and all 18 pts (100%) with RCA or LCX ($p<.0005$). Ischaemic ST depression (ST↓) (≥1mm) on E.ECG in the inferior leads (L2,3,AVF) was present in 14 of the 21 pts (67%) with LAD and 7 of the 18 pts (39%) with RCA or LCX (p=NS). Lateral (V4-6) ST↓ was present in 14 of the 21 pts (67%) with LAD and 10 of the 18 pts (56%) with RCA or LCX (p=NS). ST↓ in V2-3 was present in 8 of 21 pts (38%) with LAD and 2 of 18 pts (11%) with RCA or LCX (p=NS). ST elevation (ST↑) in V1 and/or AVL (≥1mm) was present in 11 of 21 pts (52%) with LAD and none of the pts with RCA or LCX ($p<.005$). Exercise TD can localise the site of coronary obstruction in pts with SVD but exercise ST↓ does not. ST↑ in V1 and/or AVL may identify LAD disease.

TUESDAY, MARCH 11, 1980
AM
CORONARY ARTERY DISEASE: NATURAL HISTORY AND PATHOLOGY
8:30-10:00

A NATURAL HISTORY STUDY OF ASYMPTOMATIC CORONARY DISEASE
James R. Hickman, Jr., MD, Gregory S. Uhl, MD, Rosa L. Cook, RN, MS, Peter J. Engel, MD and Andrew Hopkirk, MD, RAF, USAF School of Aerospace Medicine, Brooks Air Force Base, TX

Ninety males, age 45 ± 4.7 years, with asymptomatic coronary disease (ACD) without previous infarction (MI) were followed for 57 ±2.5 months (range 3-102 mos) to detect initial events (E), defined as angina (A), MI, or sudden death (SD). Seventy-eight patients had lesions ≥50%; 12 had lesions ≥30% <50%. Group I, 64 patients, remained asymptomatic (asx), while Group II (22 patients) had E. Four patients had bypass surgery (BP) while asx, 3 remaining asx after BP. In Group II, E's occurred as A in 16 patients (31 ±5 mos), MI in 4, and SD in 2. There were no other cardiac deaths. Four A patients had subsequent MI's. Three A patients had BP for symptoms, 2 remain asx. The distribution of events was not significantly different between single, double, and triple vessel disease (TVD). "High risk" (HR) lesions, defined as ≥30% left main (LM), 90% proximal left anterior descending (PLAD), or TVD with 3 vessels ≥75%, were found in 22 patients. Seventeen HR patients (77%) were asx at 45± 9 mos. Of 11 HR TVD, 2 had BP while asx, 2 others developed A, and 7 others remain asx at 50 ± 8.5 mos. Of 3 PLAD's, 2 are asx (34, 38 mos) and one has A at 22 mos. Of 8 LM's, 4 are asx at 46± 10 mos, 2 have A, one had BP while asx, and one had SD. Group I and II did not differ when risk factors (RF) of cholesterol, smoking, hypertension, and family history were compared singly, but 10 of 22 in Group II had≥ 3 RF vs 7 of 64 in Group I ($p<0.001$). We conclude in ACAD that (1) the 5 year prognosis is good, even for HR patients, (2) angiographic severity is not a strong predictor of events while ≥ 3 RF may be a strong predictor, and (3) angina, as opposed to SD or MI is the most common initial event.

COMPARISON OF RADIONUCLIDE AND CONTRAST TECHNIQUES IN ASSESSING EJECTION FRACTION AT REST AND DURING EXERCISE
Bim Sharma, MD; Gary Francis, MD, FACC; S. H. Tsai, MD. Hennepin County Medical Center and the University of Minnesota, Minneapolis, Minnesota.

To validate the technique of radionuclide angiography at rest and during exercise, left ventricular ejection fraction (EF) was determined in 26 patients using contrast ventriculography (CV) and multigated aquisition blood pool imaging (MUGA). Both Exercise-CV and Exercise-MUGA were performed in 15 patients with coronary artery disease. Contrast ventriculography was done in the RAO view using the single plane area-length method. MUGA was performed using a semi-automatic edge detection time-activity technique in the LAO view. Submaximal supine exercise was performed at the same workload and for similar time periods with both techniques. MUGA and contrast ventriculography were done within 24 hours of each other. Rest-CV demonstrated a mean ejection fraction of 58±4% (mean±SE), while the Rest-MUGA mean ejection fraction was 53±4%. The correlation between Rest-CV and Rest-MUGA was $r=.83$, $p<.0001$. The mean ejection fraction during Exercise-CV was 61±4% and during Exercise-MUGA was 58±4%. The correlation between Exercise-CV and Exercise-MUGA was $r=.69$, $p<.006$. The change in ejection fraction from rest to exercise with contrast ventriculography was not significantly correlated with the change in ejection fraction from rest to exercise by MUGA ($r=-.19$, $p>.6$). Thus, although the ejection fraction with CV and MUGA correlated well for both rest and exercise, *changes in ejection fraction* from rest to exercise did not correlate. These data suggest that further studies are required to resolve the difference between these two techniques for assessing left ventricular function.

CORONARY HEART DISEASE IN 48 AUTOPSY PATIENTS 30 YEARS OF AGE AND YOUNGER
Renu Virmani, MD, Max Robinowitz, MD, and Hugh A. McAllister, Jr., MD, FACC, Armed Forces Institute of Pathology, Washington DC

Few reports have appeared describing the morphologic appearance of coronary arteries (CA) in fatal coronary heart disease in patients (pts) less than 30 years of age. 48 cases ages 16-30 years (avg 24) were studied; 46 were men, 2 women; 38 were Caucasian, 10 Black. In 21 pts death occurred suddenly without chest pain, while in 27 there was a history of chest pain or discomfort before death. Of the 34 pts in whom a history of risk factors could be elicited, only 14 (41%) had a known predisposition to coronary heart disease (angina pectoris, 1; diabetes mellitus 2; systemic hypertension, 3; hyperlipoproteinemia, 2; obesity, 4; mediastinal irradiation, 2). In all 8 in whom ECGs were done, a pattern of infarction was present. The heart weights ranged from 240-550 g (avg 381). Gross acute myocardial infarction was seen in 17 (35%); histologically necrosis was present in 23 (48%). Transmural scars were present in 3 pts, and subendocardial scars in 7 pts. Of the 4 major CA examined, only one CA was >75% narrowed in cross sectional area by atherosclerotic plaque in 24 pts; 2 in 17; 3 in 4; and all 4 CA in only 3 pts. The most common CA involved was the left anterior descending (LAD) in 41 (85%); in 18 pts it was the only CA involved. Isolated left main CA disease was present in 3 pts. Thrombi were present in 25 (52%) pts, and again LAD CA was the most often involved. The atherosclerotic plaques mostly consisted of foam cells, fibrous tissue, and pultaceous debris with minimal calcific deposits, yet in the majority of these young pts the aorta was minimally atherosclerotic.

SUDDEN DEATH WHILE RUNNING IN CONDITIONED RUNNERS: Coronary Disease is the Culprit

Bruce F. Waller, MD, William C. Roberts, MD, FACC, National Heart, Lung, and Blood Institute, Bethesda, Maryland

The amount and extent of coronary arterial (CA) narrowing by atherosclerotic plaques (A) in conditioned runners is unknown. We studied at necropsy 6 runners who ran 2-20 miles/day (m=8) or 14-110 miles/week (m=52) for 1-10 years (m=4). All died while running, and at necropsy all had coronary disease (severe A in 5 [aged 40-53 years, all men] and a congenital coronary anomaly without atherosclerosis in 1 [17-year-old girl]. Of the 5 men, during life only one ever had angina and none had an evidence of a myocardial infarct. The single symptomatic runner also had an abnormal electrocardiogram (ECG) and a positive exercise stress test (EST). The ECG and EST in the other 4 men were negative. At autopsy, all 5 men had > 75% cross-sectional area (XSA) narrowing of the right (R), left anterior descending (LAD) and left circumflex (LC). Of the 3 men in whom the entire lengths of the R, LAD, LC and left main were examined histologically (total 5-mm segments = 155), 68 (43%) were narrowed > 75% in XSA by A and 25 (17%), 51-75%. Four of the 5 men had healed (clinically silent) myocardial infarcts. Thus, coronary disease is the major killer of conditioned runners.

INCIDENCE OF THROMBUS IN LEFT VENTRICULAR ANEURYSM; SENSITIVITY OF THE ANGIOGRAM AND RELATION BETWEEN ANTICOAGULATION AND EMBOLIZATION

Guy S. Reeder, MD; Maria Lengyel, MD; Abdul J. Tajik, MD, FACC; Hugh C. Smith, MD, FACC; Gordon K. Danielson, MD, FACC; James B. Seward, MD, FACC, Mayo Clinic, Rochester, MN.

In order to determine the sensitivity of biplane left ventricular cineangiography in detecting thrombus in left ventricular aneurysm, we reviewed the charts of 100 consecutive patients who underwent left ventricular aneurysmectomy. Forty-six percent of aneurysms contained thrombus, and almost all (96%) of the aneurysms were anteroapical in location; these findings are in keeping with those reported in the literature. The cineangiogram was truly positive for thrombus in 15 of 48 patients and truly negative in 39 of 52, which yields a sensitivity of 31% and a specificity of 75%. The incidence of thrombus was not significantly different between 26 chronically anticoagulated patients and 74 nonanticoagulated patients (50% vs. 47%); however, a longer duration of anticoagulation was associated with a decreased incidence of thrombus ($P = 0.02$). The incidence of clinically detectable embolism was 5%, again in keeping with results in the literature; no anticoagulated patient experienced embolism. Thus, we found that half of left ventricular aneurysms contain thrombus, embolism is uncommon, and our results to date indicate that chronic anticoagulation decreases the incidence of both thrombus formation and embolism. The left ventricular cineangiogram proved to be insensitive for detection of left ventricular thrombus, and therefore the need for a more sensitive technique is evident.

WALL THICKNESS IN SINGLE VESSEL CORONARY DISEASE: EVIDENCE AGAINST A CAUSAL ASSOCIATION OF ISCHEMIA AND HYPERTROPHY.

Kenneth J. Silverman, MD and Bernadine H. Bulkley, MD, FACC, The Johns Hopkins Medical Institutions, Baltimore, Maryland.

That myocardial ischemia per se may lead to hypertrophy remains controversial; if true, localized ischemia should lead to cardiac asymmetry. To examine this, we studied wall thicknesses of autopsied hearts of 20 patients with single vessel coronary disease (> 75% narrowing of one major coronary artery) without myocardial infarction. Patients with congenital or valvular heart disease were excluded. Wall thickness was measured for each vascular distribution from cross-sectional radiographs and gross specimens at the level of maximal left ventricular chamber diameter below the critical coronary artery narrowing. Five of the hearts had disease of the right, 7 the left anterior descending, and 8 the circumflex coronary artery. Each area with patent coronaries served as controls. Heart weight ranged from 280 to 927 gms (avg 569 gms); 14 (70%) of the patients had had hypertension. Wall thickness ranged from 0.9 to 2.1 cm (mean 1.6 cm) for each of the 3 vascular distributions. Analysis of variance showed no significant difference in wall thickness in any vascular distribution with or without coronary stenosis.

Thus, localized ischemia as would be created by a critical coronary stenosis in a single vessel, even in the presence of hypertension, does not produce left ventricular asymmetry, suggesting that coronary disease per se is not a stimulus for myocardial hypertrophy.

HEALING OF CORONARY ARTERY INTIMAL DISSECTION AFTER PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY

Gerald Dorros, MD, FACC; Donald A. Spring, MD, FACC; Lutheran Hospital of Milwaukee, Milwaukee, WI.

Percutaneous transluminal coronary angioplasty (PTCA) was performed 19 times on 18 patients (pts), with 19 distinct coronary arterial stenoses using the Gruntzig dilatation technique with entry from the brachial (12 pts), or femoral (7 pts) artery. The stenosis was crossed and dilated in 14 pts (15 cases). 13 pts had a successful dilatation; 1 of the 13 had a restenosis, and a 2nd dilatation. 1 patient (pt) had 2 different stenoses dilated. 1 pt had myocardial revascularization (MR) after PTCA. 6 of the 14 pts had angiographic evidence of coronary artery intimal dissection (CAID) following PTCA. 5 of the 6 pts were asymptomatic and had no MR. 1 of the 5 pts had angina within 1 week, was restudied at 3 months (mos.), had a marked stenosis with collaterals, and had a repeat PTCA. The other 4 pts remained asymptomatic. The 5th pt with CAID had chest pain and ST segment elevation immediately after PTCA, which spontaneously resolved prior to MR. No pts had evidence of myocardial necrosis by CPK enzymes, EKG, or pyrophosphate scan. All pts had angiograms at 3 and 12 mos., thallium stress tests every 3 mos., and antiplatelet or anticoagulation drugs for 6 mos. 5 pts with successful PTCA and CAID had functional improvement and no angina. The post MR pt was asymptomatic. The followup angiograms show the healing process. These results suggest arterial healing and repair occurs in CAID due to PTCA, as reported in peripheral angioplasty. Therefore, CAID need not be cause for alarm when encountered during PTCA. In fact, CAID may be an expected finding in the healing-regression response to PTCA.

MODIFICATION OF PLATELET FUNCTION IN THE TREATMENT OF VASCULAR DISEASE

THE EFFECTS OF AN ANTIPLATELET DRUG ON MYOCARDIAL ISCHEMIA IN PATIENTS WITH CORONARY ARTERY DISEASE.
Andrew Selwyn, MB,MRCP; Anne Jonathan; Kim Fox, MB, MRCP, Postgraduate Medical School, London, U.K.

Recent research has suggested that platelets may be involved in the genesis of myocardial ischemia.Seven ambulatory patients with angiographically proven coronary artery disease were studied with 24 hour recording of the ECG and analysis of ST segment changes after three, 2 week periods. These were nitroglycerine (GTN) plus placebo, GTN plus Ticlopidine (ICI 105062, an oral pyridine compound) and GTN plus placebo,(randomly allocated). Number of episodes of ST depression when the heart rate (HR) was <70/min. was 7 ± 1.2 on placebo and 1 ± 0.3 on Ticlopidine ($P<.001$). Number of episodes of ST depression when the HR was >90/min was 13 ± 2.7 on placebo and 9 ± 1.8 on Ticlopidine. Nocternal ST segment depression represented 17 ± 4 % of the total on placebo and 6 ± 1.7% on Ticlopidine ($P=.001$). The drug caused no side effects and produced marked inhibition of platelet aggregation in vitro. This pilot study showed that the administration of Ticlopidine was associated with a significant reduction in the number of episodes of ECG evidence of ischemia occuring without increase in heart rate and at night. This would support the hypothesis that platelets play a role in the genesis of myocardial ischemia.

QUANTITATION OF PLATELET DEPOSITION IN GORE-TEX FEMORAL ARTERY IMPLANTS IN THE CANINE MODEL AND ITS REDUCTION WITH DIPYRIDAMOLE AND PROSTACYCLIN
Kevin M. Strathy, BA; Mrinal K. Dewanjee, PhD; Michael P. Kaye, MD; Shyam Rao, PhD; Valentin Fuster, MD; Mayo Clinic and Mayo Foundation, Rochester, Minn.

The effect of dipyridamole (DP) and prostacyclin (PGI_2) on platelet deposition on Gore-Tex (GT) and autologous vein grafts (VG) has been studied in the femoral artery in 12 dogs with autologous ^{111}In-labeled platelets (In-Pl). DP (2.5 mg/kg/day) was given beginning 2 days prior to surgery, and PGI_2 was infused at 25 ng/kg/min from the onset of surgery until the removal of the grafts. Ten minutes after administration of 300 µCi of In-Pl, 4 mm GT (5 cm) and autologous VG (5 cm) were implanted. The time course of In-Pl deposition was monitored with an NaI(Tl) probe with a slit collimator, a gamma camera, and a gamma counter. Platelet deposition on GT grafts reached a plateau level in 3 hours. Dogs were imaged and sacrificed 3 hours post surgery, and the radioactivity per unit weight of grafts, blood, undamaged brachial vein, and other tissues was determined with a gamma counter. Graft/blood and GT graft/vein graft ratios are tabulated below:

	Control (n=6)		DP (n=3)		PGI_2 (n=3)	
	GT	VG	GT	VG	GT	VG
Graft / Blood	15.7 ± 9.7	2.1 ± 1.4	11.7 ± 10.0	1.4 ± 1.1	4.7 ± 4.1	2.0 ± 1.9
GT Graft / VG	7.5 ± 6.8		8.4 ± 9.7		2.4 ± 3.0	

DP resulted in 25% decrease in platelet deposition on GT, while PGI_2 reduced deposition by 70%. The thrombogenicity of GT in the first 3 hours is 8 times higher than that of autologous VG. This quantitative study demonstrates the effectiveness of DP and PGI_2 in the reduction of platelet deposition leading to the occlusion of vascular grafts.

MODIFICATION OF PLATELET FUNCTION BY ASPIRIN AND DIPYRIDAMOLE ACROSS THE MYOCARDIAL VASCULAR BED IN CORONARY DISEASE PATIENTS
Jawahar Mehta, MD, FACC; Paulette Mehta, MD; Carl J. Pepine, MD, FACC; Robert L. Feldman, MD; C. Richard Conti, MD, FACC, University of Florida and VA Medical Center, Gainesville, Florida

Platelet aggregation has been shown to be lower in coronary venous blood compared to aortic blood in coronary disease patients (pts) possibly related to adhesion of platelets to atherosclerotic vasculture. We studied the effects of aspirin (ASA) 650 mg and dipyridamole (DP) 100 mg on platelet aggregation responses to epinephrine and ADP and counts in coronary venous and aortic blood in 17 pts with documented coronary artery disease. In all 17 pts, platelet aggregation was lower ($P<0.01$) in coronary venous blood (epinephrine 55 ± 10%, ADP 49 ± 9%) than in aortic blood (epinephrine 89 ± 3%, ADP 75 ± 3%) blood. A 30% reduction in platelet counts was also present in coronary venous blood compared to aortic blood ($193,000\pm16,000$ and $275,000\pm19,000/mm^3$, respectively, $P<0.02$). ASA administration in 10 pts eliminated the differences in platelet aggregation between coronary venous blood (epinephrine 48 ± 7%, ADP 53 ± 5%) and aortic blood (epinephrine 54 ± 8%, ADP 54 ± 4%). DP given to other 7 pts also significantly reduced the difference in platelet aggregation between coronary venous (epinephrine 71 ± 12%, ADP 56 ± 8%) and aortic blood (epinephrine 74 ± 9%, ADP 58 ± 9%). The gradients in platelet counts were also eliminated both by ASA and DP. (coronary venous blood: $265,000\pm23,000/mm^3$, aortic blood: $271,000\pm20,000/mm^3$, P-NS). Thus, both ASA and DP affect platelet sequestration in the atherosclerotic vasculature similarly. These observations support the hypothesis of platelet adhesion in atherosclerotic coronary beds.

PROTECTIVE EFFECT OF ASPIRIN FOLLOWING ACUTE CORONARY ARTERY OCCLUSION
Joseph Reiser, Ph.D., William B. Gough, Ph.D. Gary J. Anderson, MD., FACC.William Likoff Cardiovascular Institute. Hahnemann Medical College & Hospital, Phila, Penna.

Aspirin (ASA) pretreatment in dogs subjected to acute coronary occlusion (CO) significantly decreases the incidence of sudden death due to ventricular fibrillation. The purpose of this study was to determine a possible mechanism of action of aspirin in preventing ventricular fibrillation. The left anterior coronary artery was acutely ligated (2.5 cm from its origin) in dogs orally pretreated for seven days with ASA (600 mg/day, n=6) or placebo (n=6). Ventricular fibrillation threshold (VFT) was measured using 100 Hz, 100 msec trains in nonischemic left ventricle; ventricular functional refractory periods (FRP) were measured in normal, transitional and ischemic regions. Serum free fatty acid (FFA) levels were also determined. Control VFT's were $12.9\pm.4$ and 16.1 ± 1.7 mA in placebo and ASA treated groups, respectively. At 15, 30, 60 min post CO, placebo VFT's decreased to 12.1 ± 1.2, 10.3 ± 1.3, 12.3 ± 1.3 mA, respectively. In contrast, VFT's of ASA pretreated animals increased during the first hour post CO to 16.2 ± 2.4, 20.1 ± 2.5 ($p<.01$) and 17.2 ± 2.6 respectively. FRP's of the ischemic and transitional areas shortened in both groups following CO. However,the degree of shortening during CO was consistently less in the ASA group indicating a decrease in the dispersion of refractoriness after ASA treatment. Unlike previous studies, FFA significantly increased during CO in both placebo and ASA groups ($p<.05$). These studies indicate 1) pretreatment with ASA decreases the vulnerability of the ventricle to fibrillation during early acute CO, 2) ventricular protection may be due to more homogenous refractoriness and 3) ASA does not appear to alter the FFA response to CO.

SULFINPYRAZONE DECREASES VEIN GRAFT OCCLUSION IN PATIENTS FOLLOWING CORONARY ARTERY BYPASS SURGERY

Peter P. Steele, MD; Joseph O. Rainwater, MD; Robert A. Vogel, MD, Veterans Administration Medical Center, Denver, CO.

Platelets probably contribute to occlusion of saphenous vein grafts following coronary artery bypass surgery (CAB). Platelet survival time (SURV) is shortened in patients with vein graft occlusion and sulfinpyrazone (SFP) increases SURV in patients with CAB. Men treated with SFP (800 mg po qd) after CAB who have undergone post-operative angiography for either recurrence of angina (A) (N=50; studied 8-50 mos after CAB; ave 33 mos) or new myocardial infarction (MI) (N=18; studied 6-43 mos after CAB; ave 26 mos) were matched retrospectively to men with CAB who had not received SFP (A; N=50; studied 8-50 mos; ave 33 mos; MI; N=18; studied 6-43 mos; ave 26 mos). Men were matched for factors responsible for graft occlusion: location and severity of occlusive lesions, location of grafts and time of angiography after CAB. In men re-studied for A, SFP decreased graft occlusion (10% in SFP; 11/110 grafts vs 26%; 29/110 grafts; $P<0.01$; chi square); and similar results were observed in MI (8% in SFP; 3/38 grafts vs 29%; 11/38 grafts; $P<0.05$). New total occlusion of proximal lesions in grafted arteries was not altered by SFP in either A (43% in SFP; 38/88 arteries vs 38%; 35/92 arteries; NS) or MI (63%; 20/32 arteries vs 48%; 15/31 arteries; NS). SFP appeared to slow progression of atherosclerosis in ungrafted arteries or distally in grafted arteries (12% in SFP had > 25% further decrease in luminal diameter; 25/204 arteries vs 21%; 42/204 arteries; $P<0.05$). Results suggest that SFP decreases graft occlusion following CAB and may favorably alter progression of coronary atherosclerosis. Platelets may be involved in both processes.

PHYSICAL CONDITIONING REDUCES EPINEPHRINE-INDUCED PLATELET AGGREGATION FOLLOWING MYOCARDIAL INFARCTION.

R. Sanders Williams, MD, R. Scott Eden, BS, Judith Andersen, MD, Duke University Medical Center, Durham, North Carolina.

Because platelet mediated coronary vasospasm or thrombosis may be important in the pathogenesis of myocardial infarction, we studied the effects of physical conditioning (PC) upon in vitro platelet aggregation (P-AG) in response to epinephrine (EPI) (10^{-3} to 10^{-6}M), ADP (10^{-3} to 10^{-6}M), and collagen, in 7 male survivors of myocardial infarction aged 50 to 61. Subjects were conditioned (walk/jog/ergometry) for 1 hour, three times weekly, for six months and functional capacity assessed by treadmill performance increased from 5.2 ± 0.4 to 9.2 ± 1.2 METS ($p = .009$). The resting P-AG response to EPI was significantly reduced following PC: peak primary wave P-AG fell from 40 ± 11% to 18 ± 7% ($p = .006$); peak total P-AG fell from 50 ± 11% to 18 ± 7% ($p = .002$). The maximum rate of EPI-induced primary wave P-AG was also reduced from 45 ± 15%/min to 12 ± 4%/min, though this change fell short of statistical significance ($p = .091$). In platelet samples drawn immediately following maximal treadmill exercise, measurements of EPI stimulated P-AG were similarly reduced following PC: peak primary wave P-AG fell from 31 ± 6% to 11 ± 4% ($p = .049$); peak total P-AG fell from 39 ± 8% to 16 ± 7% ($p = .039$); and peak rate of primary wave P-AG fell from 33 ± 10 to 12 ± 2%/min ($p = .069$). On the other hand, P-AG in response to ADP (10^{-3} to 10^{-6}M) or collagen was unchanged following PC, either at rest or following maximal exercise.

We conclude that physical conditioning reduces EPI induced P-AG in survivors of myocardial infarction, perhaps reflecting a platelet alpha receptor subsensitivity following PC, and that this effect is observed both at rest and following maximal exercise. This effect may be associated with a reduced risk for subsequent coronary artery events in these patients.

8:30-12:00

INTRACELLULAR POTASSIUM ACTIVITY IN GUINEA-PIG ATRIAL MUSCLE

Donald H. Singer, MD, FACC; Clive Marc Baumgarten, PhD; Eric D. Miller, BA, Northwestern University and The University of Chicago, Chicago, Illinois.

Intracellular K activity (a_K^i) of guinea-pig atrial strips was measured with single barrel K ion-selective microelectrodes (ISE) made with Corning 477317 liquid ion-exchanger. The average potentials observed with both the ISE and a conventional 3 M KCl-filled microelectrode were used to calculate a_K^i.

a_K^i was altered by changing a_K^o within the physiological range and was significantly lower at 1.81 mM a_K^o than at 3.62 or 7.24 mM.

$[K^+]_o$ (mM)	a_K^o (mM)	a_K^i (mM±SE)	E_m (mV±SE)	E_K (mV±SE)	n (exp)
2.5	1.81	92.9±2.6	-86.5±0.8	-105.1±0.8	18
5.0	3.62	102.1±3.8	-79.5±0.5	- 89.1±1.1	9
10.0	7.24	98.6±1.6	-63.5±0.2	- 69.8±0.5	5

In contrast to the results obtained by others in ventricle and Purkinje fiber, E_m remained significantly positive to E_K when a_K^o was 7.24 mM. At this a_K^o, a very high concentration of acetylcholine (ACh) ($1x10^{-4}$M) caused a 1-3 mV hyperpolarization verifying that E_m was positive to E_K.

At an a_K^o of 1.81 mM, ACh ($2x10^{-6}$M; 5-23 min) hyperpolarized E_m by 7.0±0.9 mV (SE,n=15). Despite ACh, E_m remained far (> 10 mV) from E_K. Simultaneously, the ISE at a remote site recorded a 7.3±0.7 mV hyperpolarization. Thus, a_K^i did not appear to change. In 7 of 20 runs, a small (< 1 mV) decay of the ACh hyperpolarization and/or a 1-3 mV overshoot on washout was noted. The steady state to peak voltage change of both the ISE and E_m on washout was significantly greater than that during ACh onset. This behavior is consistent with accumulation of K in extracellular clefts during ACh exposure.

EFFECTS OF HYPERKALEMIA ON SINUS NODE FUNCTION: SINO-VENTRICULAR CONDUCTION AND SINO-ATRIAL REENTRY

Robert J. Hariman, MD; Chia-Maou Chen, MD; Department of Cardiology, U. S. Public Health Service Hospital, Staten Island, New York

The effects of hyperkalemia on sinus node (SN) function were studied in anesthetized dogs. A SN electrode with 48 terminals was sewn on the epicardial surface of the SN. SN electrograms showing diastolic and upstroke slopes were recorded at 100 uV/cm and a time constant of 0.1 sec through unipolar leads consisting of terminals of the SN electrode and an indifferent electrode on the superior vena cava. Electrograms from the His bundle (HB), crista terminalis (CT) and various sites of the right and left atria were recorded through multiple plunge and plaque electrodes. Vagal stimulation was delivered through a Palmer electrode placed on decentralized right vagus nerve. Hyperkalemia up to 10-12 mEq/l induced by intravenous infusion of KCl (1 mEq/min) resulted in: 1) gradual decrease in diastolic slope and increase in sino-atrial conduction time; the increase in sino-atrial conduction time might promote sino-atrial reentry, which was abolished by vagal stimulation; 2) gradual decrease in amplitude and disappearance of atrial electrograms and P waves, but persistence of SN, CT and HB electrograms; the constant sequential activation of the SN, CT and HB preceding QRS complexes during spontaneous rhythm and bradycardia induced by vagal stimulation proved sino-ventricular conduction via the CT and HB in the absence of atrial electrical activity; and 3) various degrees of sino-ventricular block during more advanced hyperkalemia, due to failure of conduction from the SN to CT. This study may provide a better insight into the effects of hyperkalemia to the heart.

ATRIAL ENLARGEMENT CAN CAUSE ARRHYTHMIAS WITHOUT ALTERING TRANSMEMBRANE POTENTIALS

Penelope A. Boyden, PhD, Lawrence P. Tilley, DVM, John J. Fenoglio, Jr., MD, FACC, and Andrew L. Wit, PhD, College of Physicians and Surgeons, New York, N.Y.

Preparations isolated from enlarged arrhythmic human atria have abnormal transmembrane potentials (TP), suggesting that the abnormal TP may result from the atrial enlargement and cause the arrhythmia. The disadvantages of studies on human atria are the small size of the specimens available and the fact that TP from the enlarged atrium cannot be compared with TP of normal atrium. Dogs with naturally occurring mitral insufficiency have enlarged left atria and persistent atrial arrhythmias. We recorded TP from the isolated right and left anterior atrial wall of 19 dogs with mitral insufficiency (MI) and compared them to TP from normal dogs (N). The left atrial volume of MI dogs (45cc) was greater ($p < .001$) than left atrial volume of normal dogs (6cc). Right atrial volumes were normal. Ten MI dogs had intermittent arrhythmias (Group I), and 9 MI dogs had persistent atrial fibrillation (Group II). Resting potential (RP) of left atrial fibers in I (74 $\pm$ 6 mV) and in II (74 $\pm$ 8 mV) were not different from each other ($p > .05$) or from RP of normal left atrial fibers (74 $\pm$ 4 mV). RP of left atrial fibers were not different from RP of right atrial fibers in all groups (I = 71 $\pm$ 9 mV), II = 72 $\pm$ 5 mV, N = 75 $\pm$ 2 mV). Mean action potential (AP) amplitude, V_{max} of phase 0 and AP duration of left atrial fibers in I and II were not different from normal or right atrial values. There was no abnormal impulse initiation even in the presence of norepinephrine in either group. These studies suggest that sustained arrhythmias can occur in enlarged atria without chronic changes in transmembrane potentials.

CELLULAR ELECTROPHYSIOLOGY OF A MOTTLED INFARCT IN DOGS 4 AND 15 DAYS AFTER CORONARY OCCLUSION AND REPERFUSION

Joseph F. Spear, PhD, FACC; Eric L. Michelson, MD; E. Neil Moore, DVM, PhD, FACC, University of Pennsylvania, Philadelphia, Pa.

Normal (N) and infarcted tissues (I) were removed from 8 dogs 4 and 15 days after 2-stage left anterior coronary occlusion modified by a reperfusion stage. All dogs had pacing induced sustained ventricular tachyarrhythmias. In 58 cells transmembrane potentials were recorded using standard microelectrodes; strength-interval curves were generated using 4 msec duration current injected through the recording microelectrode. Resting potentials (RP) and action potential amplitudes (A) were significantly less in I as compared to N ($p=.005$, $p=.001$) but were not different in I after 15 days versus 4 days. While action potential duration at full repolarization was not reduced, cells in I at 4 and 15 days had depressed plateaus with durations at 30% repolarization (D_{30}) significantly reduced ($p=.001$, $p=.003$). Excitability and refractoriness of cells within I were not abnormal. Interestingly, threshold current (T) was significantly less for cells in I at 4 and 15 days ($p=.001$, $p=.002$) while the relative and absolute refractory periods (RRP, ARP) were not different from N.

	RP (mV)	A (mV)	D_{30} (msec)	T (μA)	RRP (msec)	ARP (msec)
N	83.3±5.8	99.5±6.8	105±41	1.22±.67	219±50	166±45
4I	76.8±9.8	91.1±14.7	64±23	.60±.38	208±42	148±38
15I	77.0±3.9	88.3±9.0	56±36	.51±.37	223±40	168±39

In conclusion, susceptibility to arrhythmias and action potential changes persist for 15 days following infarction in this model. Cellular excitability and refractoriness are not abnormal.

ELECTROPHYSIOLOGY OF RIGHT ATRIAL HYPERTROPHY IN CHILDREN

William J. Untereker MD, Robert Hariman MD, Allan Hordof MD, Robert Boxer MD, Richard Edie MD, Michael Rosen MD, FACC, Columbia Univ., College of P&S, New York, NY

Previous studies have shown that maximum diastolic potential (MDP) of diseased human atria is lower than that of normal human atria. We have shown, as well, a relationship between ECG P wave duration and MDP of isolated human atrial fibers. The purpose of this study was to attempt to relate P wave duration with atrial conduction in the intact heart and the cellular electrophysiology of human atrial fibers. We studied children (ages 2.5-11 yrs) with congenital heart disease and ECG evidence of right atrial hypertrophy who at surgery had large right atria. Preoperative ECG's were recorded and at the time of surgery, bipolar electrograms were recorded from high and low right atrium during sinus rhythm. Atrial tissue was taken from the atriotomy site and studied by standard microelectrode techniques. We used linear regression to determine the relationships between maximal measured P wave duration on ECG and (1) high to low right atrial conduction time (RACT), (2) high to low right atrial conduction velocity (RACV) and (3) MDP of the tissue specimen. We also studied the relationship between RACV and MDP. The ranges of MDP were -37 to -70.1 mV; the RACV, .67-1.33 M/sec; the P wave durations, 75-102.5 msec. There were significant correlations between changes in P wave duration and RACT ($r=.88$, $p<.01$); P duration and RACV ($r=.72$, $p<.05$); and P duration and MDP ($r=.82$, $p<.01$); and MDP and RACV ($r=.65$, $p<.05$). Hence, in right atrial disease there is a significant relationship between the extent of right atrial conduction delay on ECG, RACT and RACV, and MDP of isolated atrial fibers. This emphasizes the relationship between diseased-induced changes in cellular electrophysiologic properties and their effects on conduction in the intact human heart.

ANALYSIS OF ISCHEMIC MYOCARDIAL INJURY IN VITRO - A MICROELECTRODE STUDY

Nenad Belic, MD; John R. Thompson, BA; Donald H. Singer, MD, FACC, Northwestern U Medical School, Chicago, IL.

The separate contributions of hypoxia (HY) & poor perfusion (PP) to ischemic myocardial injury are not well-defined. An in vitro method has been developed to differentiate these effects. Ten dog papillary muscle slices were first equilibrated in oxygenated Tyrode's solution (TS) at 37°C. Six slices were then exposed to hypoxic TS (pO_2=36 mmHg) & four to PP by superfusion with paraffin oil which permitted O_2 diffusion (pO_2=156 mmHg) but no washout of metabolites & other solutes. After 1 hr of HY or PP, tissues recovered in oxygenated TS for 1 hr. Using standard microelectrode technics, action potentials (AP) were recorded from multiple intramural cells before & during HY & PP, & after one hr recovery.

		Control	3-4 min	7-10 min	45-60 min	Recovery
RP	HY	83±0	78±2	66±3	64±1	82±1
(mV)	PP	83±1	69±2	66±2	N/A	83±1
AMP	HY	107±1	103±2	82±7	79±2	108±1
(mV)	PP	107±1	88±4	76±5	N/A	109±2
APD	HY	132±2	99±8	60±8	62±3	146±2
(ms)	PP	128±4	65±7	56±7	N/A	143±3

Resting potential (RP), AP amplitude (AMP), & AP duration @ 75% repolarization (APD) all decreased ($p<.05$) in both HY & PP. After 1 hr recovery in both groups, RP & AMP returned to control values; APD was lengthened ($p<.05$). All cells exposed to PP were inexcitable from 19.0±4.2 min until reflow with oxygenated TS. Cells exposed to HY remained excitable throughout. Conclusions: 1) Neither HY nor PP alone, when limited to 1 hr in duration, causes cell death. 2) Accumulation of metabolites & other solutes, rather than HY, is responsible for cell inexcitability. 3) Membrane effects (increased APD after recovery) of HY & PP are similar.

TRANSMEMBRANE ACTION POTENTIAL CHARACTERISTICS OF VENTRICULAR CELLS DURING VENTRICULAR FIBRILLATION. Toshio Akiyama, M.D., F.A.C.C.; University of Rochester Medical Center, Rochester, New York.

Transmembrane action potentials (AP) from ventricular cells during ventricular fibrillation (VF) have not been systematically studied. We have recently developed a motion-compensated micropipette holder (MCMH) which bears a Ling-Gerard type micropipette and a Tyrode's-filled epicardial well, and which moves in synchrony with heart motion. Stable, continuous impalement of a single subepicardial cell of in-situ beating heart is often possible for several min. Withdrawal of micropipette into Tyrode's solution allows accurate measurement of resting potential (V_R) and overshoot potential (V_{OV}). AP of subepicardial ventricular cells were recorded in-situ in 12 open-chest fluothane-anesthetized dogs prior to occlusion (control) of proximal left anterior descending artery (PLAD) and during VF, produced by reperfusion (5 dogs) and reperfusion plus direct AC-current application (7 dogs) after 30 min occlusion of PLAD. During control, characteristics (mean ± SEM) of AP at serum Na 140 and K 4.5 mEq/L are: excitation rate (R) 115 ± 3 beats/min, V_R -79.4 ± 1 mV, V_{OV} 16.9 ± 4.9 mV, 90% AP duration (PAD) 246 ± 8 msec. During first 10 min of VF, characteristics of AP from the reperfused areas remain relatively constant, except for gradual decline in R, and are: R 193 ± 32 beats/min, V_R -58.6 ± 3.1 mV, V_{OV} 2.8 ± 3.4 mV, APD 130 ± 11 msec. They are all significantly different from control values at $p<0.001$ except for R. During VF in 5 dogs subepicardial cells are made inexcitable without change in V_R by superfusion with verapamil 2×10^{-6} g/ml but not by TTX 5×10^{-6} g/ml. In summary, 1) during VF, accurate, stable AP recording is possible, and 2) most subepicardial cells in reperfused areas seem to have AP of slow channel type.

REGIONAL DIFFERENCES IN TRANSMEMBRANE ACTION POTENTIAL (AP) IN GUINEA PIG HEART DURING GLOBAL ISCHEMIA. Luiz Belardinelli, MD; Stephen Vogel, PhD; Rafael Rubio, PhD; and Robert M. Berne, MD; Dept. of Physiol., Univ. of Virginia, Charlottesville, VA, and Research Unit, Instituto de Cardiologia do R.S., Porto Alegre, Brasil.

We examined the ischemic myocardial APs at a time when arrhythmias occur. Isolated guinea pig hearts were perfused at a constant flow (10ml/min) with Krebs-Henseleit solution gassed with $95\%O_2+5\%CO_2$(37°C, pH7.4) and paced at 3Hz. Transmembrane APs were recorded using floating microelectrodes. During global ischemia, there was a progressive decrease of the resting potential (RMP), and a decrease in the AP rate of rise ($+\dot{V}_{max}$) and 50% duration (table).

		Ischemia		
	Control	3-6 min.	15-19	20-24 min.
RMP (mv)	-82±1.7	-74±1.3	-70±2.8	-66±2.0
$+\dot{V}_{max}$ (V/sec)	237±52	196±51	49±9.0	39±5.0
Duration(msec)	109±16	76±7.0	57±3.0	59±4.0

After 15-30 min. of ischemia, ventricular tachycardia and reentry-type arrhythmias could be frequently induced and/or terminated by extra-stimuli. At this time simultaneous impalements with two microelectrodes revealed that the RMP, $+V_{max}$ and duration of the ischemic APs were consistently more depressed in the left ventricle (LV) than in the right ventricle (RV). Increasing the heart rate exacerbated these differences. The ischemic APs in the LV were more depressed by lidocaine ($5X10^{-5}$M) than those in the RV. The slow channel blocker, verapamil ($5X10^{-6}$M), did not affect the ischemic APs. In conclusion, the regional variation in the AP during ischemia is a possible factor in the observed reentrant-type of arrhythmias. The pharmacological responses of the ischemic APs suggest the fast sodium channel is involved in the ischemic AP.

MECHANISM OF VENTRICULAR FIBRILLATION OF THE NORMAL MYOCARDIUM John Bianchi; William Balke; Leonard S. Dreifus, MD, FACC; Eric L. Michelson, MD, Thomas Jefferson University, Philadelphia, Pa.

Epicardial delay and diastolic bridging in the ischemic myocardium are frequently observed in association with the onset of ventricular tachycardia and fibrillation (VF). Because epicardial or intramyocardial spread from the ischemic to the normal zone is not always evident, electrophysiologic studies were designed to determine how abnormal electrical activity results in VF of normal myocardium. Two portions, one normal and the other ischemic, of dog ventricular muscle joined by a network of Purkinje fibers (P) were studied by the extrastimulus technique. Pacing in the proximal island of ischemic tissue (I) permitted conduction through the P network to a distal island of normal tissue (N). Action potentials were recorded in I, P and normal tissues. After a train of 8 basic drive stimuli, 2 premature stimuli produced reentry in I which was irregularly transmitted to N. Recordings at N demonstrated: 1) multiple irregular responses with cycle lengths ranging from 90 to 150 msec, 2) Wenckebach conduction between 2 or more adjacent N fibers, 3) irregular entrance block into multiple N fibers, and, 4) inhomogeneous rapid excitation of N fibers which resulted in total disorganized electrical activity of the distal N fibers. Conclusion: Microreentry in a small island of ischemic tissue can produce rapid irregular and inhomogeneous excitation of normal myocardium via the Purkinje network which is sufficient to cause ventricular fibrillation.

VENTRICULAR REFRACTORINESS AT TWICE DIASTOLIC EXCITABILITY THRESHOLD: AN UNPREDICTABLE SOURCE OF VARIABILITY Eric L. Michelson, MD; Joseph F. Spear, PhD, FACC; E. Neil Moore, DVM, PhD, FACC; University of Pennsylvania and Lankenau Hospital, Philadelphia, Pennsylvania

A canine model of chronic infarction has been developed in which sustained ventricular tachyarrhythmias can be reproducibly initiated using routine methods of programmed electrical stimulation (PES). This model is well suited to the evaluation of routine electrophysiologic techniques. Using constant current unipolar cathodal stimulation (pulse width 2 msec, drive cycle length 300 msec) ventricular strength interval curves (SIC) were constructed via plunge electrodes located at multiple sites within areas of normal and infarcted myocardium in 10 animals in order to determine the relationship of refractoriness measured at twice minimum diastolic threshold (VRP) to both the effective (ERP) and relative refractory periods at those sites.

	(in msecs)	ERP	RRP	VRP	VRP minus ERP
Normal	range	109-153	122-170	124-174	3-26
N=43	mean±SD	123± 13	149± 13	150± 15	18± 5
Infarct	range	120-230	116-283	114-247	0-62
N=38	mean±SD	158± 27	195± 41	185± 35	27±16

This analysis revealed marked disparities between VRPs and ERPs. In normal myocardium VRPs were approximately equal to RRPs. VRPs usually fell along that part of the SIC where small changes in current caused relatively large changes in measured refractoriness. This region was exaggerated in SICs at sites within areas of infarction. This unpredictable and marked variability of the VRP with respect to the ERP should be considered in interpreting PES studies done at twice diastolic excitability threshold, especially in abnormal ventricles.

COMBINATION QUINIDINE-DIGOXIN: UNIQUE ELECTROPHYSIOLOGIC CHANGES PRODUCED IN CANINE PURKINJE FIBER

William Muir, DVM; Randy Lynn, BS; Richard Sams, Ph.D.; Stephen Schaal, MD, FACC, Ohio State University College Vet. Med. and College of Medicine, Columbus, Ohio.

Microelectrode studies of digoxin (D), quinidine (Q) and combination digoxin-quinidine (D-Q) were performed on dog Purkinje fiber (PF) in tyrodes (T) and blood superfusion (BS) from donor dog to elucidate electrophysiologic mechanisms for the arrhythmogenic D-Q interaction. At a potassium (K) of 2.7 mM in T, (D) (1-4 ng/ml) produced no change in resting membrane potential (RMP), upstroke velocity (dv/dt), action potential duration (APD) $_{40}$ & $_{50}$. APD $_{75}$ & $_{90}$ decreased as did effective refractory period (ERP). Bolus (Q) (levels of 1-5 ug/ml) produced no change in RMP, decreased dv/dt and APD$_{40}$ & $_{50}$ and increased APD $_{75}$ & $_{90}$ and ERP. D & Q produced the same changes in BS studies in which Q was infused in donor digitalized dog whose blood superfused PF from a digitalized dog. Combination D-Q produced changes both in T and BS similar to that of Q alone except for the dramatic production of 2 levels of steady state potential (-90 & -50 to -60 mv). The lower RMP developed in 4 of 8 T studies at peak Q concentration and in 2 of 10 with BS at therapeutic plasma levels of both D & Q. The lower RMP was characterized by spontaneous rhythmic activity, sustained oscillatory afterpotentials or total quiescence. Hyperpolarizing current pulses, pacing, or increasing extracellular K switched RMP from lower to higher values. These studies demonstrate that D-Q combination produces electrophysiologic changes responsible for arrhythmias at therapeutic plasma levels. Furthermore, the D-Q combination probably effects a fall in K conductance which results in 2 levels of RMP.

AXIAL ANGIOGRAPHY IN ATRIOVENTRICULAR CANAL MALFORMATIONS: ANATOMICAL-ANGIOGRAPHIC STUDY

Benigno Soto, MD, FACC; Albert D. Pacifico, MD, FACC; Lionel M. Bargeron, Jr., MD, FACC, University of Alabama Medical Center, Birmingham, Alabama.

The angiographic representation of the three basic anomalies of atrioventricular (A-V) canal malformations were studied in 20 patients. The diagnosis was verified at operation in each, ranging in age from 2-10 years. Fifteen patients had common atrioventricular valves and 5 had two atrioventricular valves.

A) The atrial septal defect (ostium primum) was best demonstrated in the four chamber view after selective opacification of the left atrium. B) The abnormal ventricular septum was best defined by the left ventriculogram in the elongated right anterior oblique and four chamber views. It appears as a concave contour of the upper portion of the ventricular septum varying from shallow to very deep. C) The anatomy of the A-V valves was best demonstrated in four chamber view. When a common A-V valve was present, a unique ring was seen sitting on top of both ventricles. The leaflets were demonstrated by their displacement during the cardiac cycle. When two valves are present, their rings were demonstrated on top of each ventricle. The anatomical relation between the A-V valves and the ventricular septum was successfully demonstrated in the majority of cases.

Associated malformations such as atypical ventricular septal defects, A-V valve insufficiency, or asymmetry in the ventricular size were also best demonstrated in four chamber view.

This analysis shows that the use of specific axial instead of conventional projections improves angiographic definition of A-V canal malformations.

QUINIDINE TOXICITY: AN ELECTROPHYSIOLOGICAL EVALUATION IN CARDIAC PURKINJE FIBERS.

Francis M. Weld, MD, FACC; Jeffrey Rottman, BA; J. Thomas Bigger, Jr., MD, FACC, Columbia University, New York, NY

To evaluate possible mechanisms of quinidine toxicity, we studied the effects of quinidine at 10-50 mg/liter on isolated calf and dog Purkinje fibers superfused with physiological solution containing $[K]_o$=4.0mM. At 10-20 mg/liter, quinidine decreased maximum upstroke velocity ($\dot{V}$max), overshoot, action potential plateau and conduction velocity, and made resting and maximum diastolic voltages more positive. Exposure to 50 mg/liter caused absolute refractoriness in 5-30 minutes in all fibers, with a resting voltage of -40 to -50 mV. Quinidine at 10-50 mg/liter did not induce either early or delayed afterdepolarizations in fibers driven at 1/sec. Early afterdepolarizations sometimes appeared transiently in fibers exhibiting spontaneous slow automatic firing elicited by hypokalemia. We investigated the mechanism by which quinidine suppresses $\dot{V}$max with a double microelectrode voltage clamp technique. Maximum upstroke velocity approached control values when a 10-15 second constant conditioning voltage clamp preceded membrane excitation, suggesting that steady-state voltage-dependent availability of $\dot{V}$max was not significantly depressed. However, quinidine markedly delayed recovery of $\dot{V}$max following membrane repolarization from -20 mV. The time constant for quinidine-induced slowed recovery was about 5 seconds at normal resting voltages. We conclude that afterdepolarizations must be a rare manifestation of quinidine toxicity in driven fibers, that the most significant manifestation of quinidine toxicity in driven fibers is depression of action potential phase 0, and that the mechanism for phase 0 depression is markedly slowed $\dot{V}$max recovery kinetics.

A COMPREHENSIVE ASSESSMENT OF ATRIO-VENTRICULAR VALVE MORPHOLOGY IN SINGLE VENTRICLE.

Fernando M. Picchio,MD, Robert M. Freedom,MD,FACC,Joyce R. Harder,MD,C.A.F. Möes,MD, Walter J. Duncan,MD.The Hospital for Sick Children,Toronto, Ontario, Canada.

Recognition of the form and function of atrio-ventricular (AV)valvesis essential to the surgical management of the patient with single ventricle(SV).Because standard and axial angiocardiography may not provide adequate visualization of the AV valves we have utilized two-dimensional echocardiography(2DE)to assess the AV valve(s) in 33 patients.Angiographically,23 patients(76%)had SV of left ventricular type,3(9%)had SV of right ventricular type and 5(15%)had SV of an indeterminate type.By 2DE,7patients (21%)had absent right AV connection,8(24%)had absent left AV connection,11(33%)had double inlet SV and 6(18%)had common AV valve.The diagnosis of SV by both methodologies was concordant in all cases.Conversely,there was diagnostic discordance of types of AV connection in 8 patients (24%).In 4,absence of left AV connection was noted on 2DE while the angiographic diagnosis was either uncertain or a common AV valve.In another 4,absent left AV connection diagnosed angiographically was proven incorrect when 2AV valves were shown by 2DE.Measurement calipers were used to compare AV valve size in those cases with 2AV valves. Two patients demonstrated significant underdevelopment of the left AV valve-possibly precluding a Fontan type of repair.In conclusion,2DE is a highly reliable technique in the diagnosis of SV and has been shown to provide a detailed and accurate assessment of AV valve morphology-thus playing a major role in the pre-operative selection for "complete repair".

THE PULMONARY VASCULAR BED (PVB) IN PATIENTS WITH TETRALOGY OF FALLOT (TOF) WITH OR WITHOUT PULMONARY ATRESIA.
Marlene Rabinovitch, MD; Victoria H. deLeon MD; Aldo R. Castaneda, MD; and Lynne Reid, MD, The Children's Hospital Medical Center, Boston, Massachusetts.

At postmortem in 12 patients (pts) with TOF AND 5 with TOF + pulmonary atresia (PA), quantitative macro and microscopic study of the lung parenchuma and PVB was carried out, to determine the type and severity of abnormality in growth and development which could influence surgical outcome. Lung volume, alveolar number and size were evaluated. Barium injection and dissection permitted analysis of the size and distribution of the pulmonary and systemic collateral arteries (SCA). Intraacinar pulmonary artery (IAPA) structure and growth were assessed microscopically. There was lung hypoplasia in 6/12 TOF and in 4/5 TOF+PA pts based upon a decrease (↓) in total alveolar number. The intralobar pulmonary arteries were hypoplastic in 7/11 TOF and in 2/4 TOF+PA pts studied who had small or inadequate SCA communications. Three TOF+PA pts had 2 or more direct aortopulmonary SCA; these were partially obstructed muscular arteries at the hilum but normal pulmonary arteries in structure and distribution within the lung. In 1 pt they were the only blood supply to 2 lobes. Reduction inthe size of IAPA occurred in 3/12 TOF and in 4/5 TOF+PA pts. The 7 pts with surgically created systemic to pulmonary shunts of more than one year duration had, in addition, increased arterial muscularity (severe in 6); this was associated with a ↓in artery number in 5, with thromboses in 3, and in 2, with Heath-Edwards Grade IV changes. Early corrective surgery may prevent the development of these abnormalities by eliminating decreased pulmonary blood flow (lung hypoplasia) and systemic pulmonary shunts, (vascular changes); also, ligating direct aortopulmonary SCA may, in some cases, be detrimental.

LONG TERM AFTERLOAD REDUCTION THERAPY IN CHILDREN
Lee N. Benson, MD; Peter M. Olley, MD; David L. Gilday, MD; Richard D. Rowe, MD. The Hospital for Sick Children, Toronto, Canada

Prazocin (P) has been found to be an effective agent for afterload reduction therapy in adults, however, the long term use of P in children has not been well studied. The hemodynamic response of five children (3 with EFE, 1 with neonatal myocarditis and 1 with an anomalous left coronary artery) unresponsive to anticongestive therapy was monitored acutely during P therapy and by echocardiographic and radionuclide angiography (RA) during the 3-11 month follow-up. P was initially given in a dose of 40 ug/kg/6 hourly. Cardiac index (dye) increased and filling pressure fell in the first 24 hours after beginning P. Echographically, left ventricular systolic time intervals fell from a mean of .47 prior to P, to .42 at 1 week and .41 in follow-up with no change in left ventricular end-diastolic dimension during the study. Ejection fraction by RA prior to P averaged .24 and rose to an average of .35 at 1 week and .40 at follow-up. Frequent increases in dosage were required (range 40 to 175 ug/kg/q6 hourly) to maintain effectiveness, no patient suffered any drug complication. Two patients with EFE died 2-4 months after beginning therapy. P is effective acutely in improving heart failure in children, however, long term usefulness requires frequent dosage manipulation and has less certain benefits.

USE OF CAROTID ARTERY FLOW (CAF) PATTERNS AS ASSESSED BY DOPPLER ULTRASONOGRAPHY FOR THE NONINVASIVE EVALUATION OF BLALOCK-TAUSSIG SHUNT (BTS) PATENCY
Gerald A. Serwer, MD, Page A.W. Anderson, MD, FACC, Brenda E. Armstrong, MD, Duke University, Durham, N.C.

As use of BTS for palliation of cyanotic heart disease is wide spread and noninvasive evaluation of BTS patency can sometimes be difficult, work was undertaken to determine if alterations in CAF were produced by BTS and if such alterations can aid in assessing the adequacy of the BTS. 45 patients (pts) underwent evaluation of CAF utilizing an 8 mHz continuous wave Doppler velocitometer. All studies were performed on the carotid artery originating from the innominate artery with pts in the supine position. Analog records were recorded by a strip chart recorder. Pts were divided into 2 groups. Group I(n=29)(N) ages 1 day-17 yrs, heart rate (HR) 45-162/min, was composed of pts with no BTS. All CAF patterns were qualitatively similar despite the presence of a variety of intracardiac defects or patent ductus arteriosus. Following QRS there was a rapid increase followed by a gradual decline in CAF velocity. In early diastole there was a second increase in CAF velocity. There was continuous forward flow at all times. Group II(n=16)(S), ages 1 day-10yrs, HR 100-165/min, was composed of pts who had undergone BTS. 8 were studied pre and post shunt performance. Shunt patency was confirmed in all by a rise in PaO_2>20torr, cardiac cath, and/or the presence of a continuous murmur. Pre-op studies showed CAF patterns identical to N. All 16 post-op pts showed marked differences in the CAF pattern demonstrable in the immediate post-op period. CAF became 0 in late diastole in all. Retrograde CAF occurred when the BTS produced congestive heart failure (CHF). Features of CAF patterns separating N from S were unaffected by age or HR. The presence of a patent BTS induced characteristic changes in CAF patterns with additional distinctive changes present when BTS produced CHF.

DIGOXIN DISPOSITION IN PREMATURE INFANTS.
Ronald L. Simonton, MS; Alois R. Hastreiter, MD, FACC; Ronald L. van der Horst, MD, FACC; Win L. Chiou, MD; Henry Mangurten, MD; Gilbert Lam, MD. University of Illinois Hospital, Chicago, Illinois.

Since information on the disposition of digoxin in premmature infants is lacking, an analysis of pharmacokinetic parameters was performed in 6 premature neonates (ages 4-7 days, gestational ages 29-35 wks, weights 0.92-1.90 kg). The infants received a single I.V. bolus of 0.02 mg/kg of digoxin and had their plasma concentration (Cp) monitored for 48 hours. Mean Cp ± standard error of the mean (SEM) at 6 of 13 time intervals studied were as follows: 10 min-24.9±2.0, 1 hr-10.3±1.1, 6 hr- 2.9±0.5, 24 hr-2.5±0.3 and 48 hr-2.1±0.4 ng/ml. Utilizing NONLIN and BMDP computer programs, the data was described by a three exponential model (EXM) of the type $Cp=Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$. The mean SEM of the calculated pharmacokinetic parameters were: plasma half-life ($T_{\frac{1}{2}}$)= 67±7 hr^{-1}, area under the curve (AUC)=337±38 ng/ml x hr, volume of the central compartment (Vc)=0.58+0.1 L/kg, body clearance (Cl)=19.7±1.7 ml/min/1.73m^2, apparent volume of distribution ($V_{d\beta}$)=6.2±1.0 L/kg, and volume of distribution at stead state (V_{dss})=5.7±0.9 L/kg. This data suggests that in premature infants compared to full term neonates or older infants $T_{\frac{1}{2}}$ is lengthened, while V_C, Cl, $V_{d\beta}$, and V_{dss} are reduced. The data was also analyzed with a 2-EXM; however, as in older age groups, 3-EXM resulted in a significantly better fit than 2-EXM.

PEDIATRIC ELECTROCARDIOGRAPHY AND ELECTROPHYSIOLOGY

SUPRAVENTRICULAR TACHYCARDIA IN CHILDREN: CLINICAL FEATURES, RESPONSE TO TREATMENT AND LONG TERM FOLLOW-UP IN 217 PATIENTS. Arthur Garson, Jr, MD; Paul C. Gillette, MD, FACC, Dan G. McNamara, MD, FACC, The Lillie Frank Abercrombie Section of Pediatric Cardiology, Baylor College of Medicine, Houston, Texas

Despite the fact that supraventricular tachycardia (SVT) is the most common symptomatic dysrhythmia in children, relatively few cases are seen in most hospitals, and thus investigation of large numbers of patients is seldom possible. We reviewed the records of 217 children seen at Texas Children's Hospital whose first episode of SVT occurred before 18 yrs (median age 24 mos). The majority came from within 100 miles of Houston (64%). There were 112 males and 105 females. SVT occurred in 6% of first degree relatives. Of the 49 with congenital heart disease (CHD), SVT began before any operation in 26 and >2 wks postoperatively in 23. WPW was present on surface ECG in 47/217 (22%). CHF accompanied the first episode of SVT in 28/74 pts who were 4 mos old or younger (38%) vs 27/143 pts (19%) >4 mos old ($p<.001$). The first episode terminated without treatment (Rx) in 55/197 (28%). Rx was successful in stopping SVT within 48 hrs in 90/142 (63%). Successful acute Rx were: digoxin 57/84 (68%), cardioversion 12/20 (60%), vagal maneuvers 12/19 (63%), phenylephrine 3/9 and overdrive pacing 4/5. Chronic Rx was instituted in 149/207 (72%). SVT recurred at least once in 86% of all pts. On follow-up (mean 4.6 yrs, range 2 days-25 yrs), episodes of SVT were still present in 56%; 29% had no SVT, but were taking Rx and only 14% were free of SVT without Rx. Three pts died, 2 from incessant SVT and 1 from a CVA after VSD repair. We conclude that long term status was difficult to predict, except SVT was present in: less pts whose age at onset was ≤4 mos vs those whose age at onset was >4 mos (41% vs 64%, $p<.005$) and less pts with unoperated CHD vs those without CHD (31% vs 62%, $p<.001$). Finally, early recurrence was not a poor prognostic sign: 63% of those whose SVT recurred at least once had no SVT on long term follow-up. We recommend chronic Rx for at least 1 year in all aged pts with SVT, whether or not the first episode terminates spontaneously.

DUAL ATRIOVENTRICULAR NODAL PATHWAY CONDUCTION - A COMMON ELECTROPHYSIOLOGICAL PHENOMENON IN CHILDREN WITHOUT ARRHYTHMIAS
Alfonso Casta, MD; Grace S. Wolff, MD, FACC; Ashok V. Mehta, MD; Dolores Tamer, MD, FACC; Otto L. Garcia, MD, FACC; Arthur S. Pickoff, MD; Pedro L. Ferrer, MD; Ruey J. Sung, MD, FACC; Henry Gelband, MD, FACC. Departments of Pediatrics and Medicine, University of Miami, Florida.

Dual atrioventricular (A-V) nodal pathways (DP) as a mechanism for reentrant tachycardia (RT) are well known in adults and children but the incidence of DP in children without arrhythmias is unknown. Electrophysiological studies were performed in 39 consecutive patients (pts): 22 preoperative with heart defects and 17 with surgically repaired defects. Ages ranged between 2-18 yrs; there was no evidence of arrhythmia. Atrial extrastimulations were coupled to sinus and/or paced atrial rhythms at decremental coupling intervals until A-V nodal effective refractory periods (ERP) and functional refractory periods (FRP) were reached. DP were identified by a sudden increase ("jump") in A-V conduction time (A_2H_2), which ranged between 40-185 msec, and resulted in discontinuous A-V nodal conduction curves (A_1A_2, H_1H_2). DP were found in 12/39 pts (31%); 8/22 (36%) in the preoperative pts and 4/17 (24%) in the postoperative pts. The ERP of the fast pathway ranged between 220 and 450 msec; FRP between 225 and 585 msec. The ERP of the slow pathway ranged between 215 and 400 msec; FRP between 430 and 665 msec. and both were atrial limited in 6 pts. Values for ERP and FRP for preoperative and postoperative pts did not differ significantly. Echoes occurred in 1 pt. and RT in none. We conclude that DP are common in children even in the absence of overt arrhythmias. While an underlying mechanism exists for RT, long term follow up will be necessary to determine if these pts are at risk for developing RT.

CARDIAC RHYTHM AFTER THE MUSTARD OPERATION FOR TRANSPOSITION OF THE GREAT ARTERIES
Constance J. Hayes, MD; Robert A. Boxer, MD; Ehud Krongrad, MD, FACC; Welton M. Gersony, MD, FACC, Columbia-Presbyterian Medical Center, New York, N.Y.

Arrhythmias have been reported with varying frequency following the Mustard operation for transposition of the great arteries (TGA). However, followup data has been of limited duration. In addition the time-course relationship of the development of arrhythmias has not been previously elucidated. The cardiac rhythms of 75 patients (pts) who underwent this procedure at CPMC were reviewed. All had normal sinus rhythm (NSR) preoperatively. Six months following surgery, 62 pts (82%) were in NSR while 13 pts (17%) had various junctional or atrial arrhythmias. In followup of 12 to 90 months (m = 32 mo.) only 13 pts (17%) remained in NSR. Forty-seven pts (63%) had atrial or junctional arrhythmias; 15 pts were lost to followup. Of the 47 pts with arrhythmias 2 died suddenly and 2 have had pacemakers implanted.
Postoperative ambulatory monitoring was carried out on 33 pts 1 month to 8 yrs following surgery. Ten pts had NSR; 7 had bradycardia tachycardia syndrome; 7 had atrial arrhythmias; 6 had predominantly junctional arrhythmias and 3 had NSR with junctional escape beats. Four pts had multiple PVC's. Three of 7 pts without arrhythmias on routine electrocardiograms had arrhythmias on ambulatory monitoring. In conclusion, (1) the incidence of arrhythmias after the Mustard operation increases with time; (2) sequential ambulatory electrocardiographic monitoring of this group of patients is important in the detection of arrhythmias.

ELECTROPHYSIOLOGIC CONSEQUENCES OF MUSTARD REPAIR OF TRANSPOSITION OF THE GREAT ARTERIES
Victoria L. Vetter, MD; Leonard N. Horowitz, MD,FACC; University of Pennsylvania, Philadelphia, Pa.

Electrophysiologic studies were performed in 15 patients (pts) with d-transposition of the great arteries (TGA) in whom the Mustard procedure was performed 2 months to 10 years previously. The protocol included programmed atrial (A) and ventricular (V) stimulation with single and double stimuli during spontaneous rhythm (SR) and 2 paced cycle lengths (CL), A and V rapid pacing (CL 600-250 msec) and catheter atrial endocardial mapping (AEM). SR was sinus in 4 pts and junctional in 11 pts. Atrial studies were normal in 2 pts. Sinus node dysfunction was present in 4 pts (sinus rates <60, sinus node recovery times 2.5-30 sec). AEM showed marked intra-atrial conduction disturbance (IACD) which prevented sinus impulses from reaching the AV node in 5 pts. Atrial flutter was inducible by PAS in 5 pts. In these 5 pts, IACD was present and atrial refractory periods increased at shorter paced CLs. Complete AV block localized to the AV node was present in 4 pts, in 2 of these the junctional escape focus was normal, in 2 it was depressed. Ventricular electrophysiology was normal in all pts. We conclude that the electrophysiologic consequences of the Mustard procedure for TGA include abnormalities of automaticity, refractoriness and conduction and explain the arrhythmias observed following this operation.

CARDIAC RHYTHM IN SUDDEN INFANT DEATH SYNDROME
Terrence J. Montague, MD; Philip C. Bagnell, MD; Douglas L. Roy, MD; Eldon R. Smith, MD, Dalhousie University, Halifax, Nova Scotia, Canada.

Although the etiology of sudden infant death syndrome (SIDS) remains uncertain, cardiac dysrhythm (particularly bradycardic arrest and dysrhythm associated with QT interval prolongation) continues to be proposed as a likely mechanism. In an ongoing effort to assess this possibility, we utilized continuous 24-48 hr electrocardiography (ECG) to monitor cardiac rate and rhythm in 9 patients (pts) with "near-miss" SIDS. There were 7 females and 2 males with an age range of 9 days to 20 weeks (wks). All were previously well although 2 had sibs die of SIDS. Each had normal physical and routine laboratory examinations, including electroencephalography and 12-lead ECG (lead II mean QT_c = 0.407 ± 0.029 [S.D.] sec; lead V_1 mean QT_c = 0.393 ± 0.013 sec).

Sinus rhythm, ranging from 73 to 225 beats/min (mean 140 ± 9) was the prevailing rhythm in all pts. Six pts had frequent episodes of mild sinus arrhythmia (SA); one also occasionally had wandering atrial pacemaker. Two pts had infrequent moderate SA and another had one period of marked SA (adjacent cycle length variation > 100%). Atrial ectopics occurred infrequently in 2 pts. QT_c from monitoring leads was normal in all (mean 0.393 ± 0.002) with the maximum variation during the monitoring period averaging 0.099 ± 0.025 sec. Because of marked SA, one pt received a pacemaker at age 4 wks. Despite documented appropriate function of the pacemaker the pt had another "near-miss" at 6 wks and died suddenly of indeterminable cause at 8 wks. These observations suggest: (1) cardiac dysrhythm (including QT prolongation) is not readily detected in a population at high risk of SIDS and (2) bradydysrhythm or bradycardic arrest is not the primary cause of death in all cases of SIDS.

CARDIAC FUNCTION
8:30-12:00

LEFT VENTRICULAR FUNCTION AT REST AND DURING EXERCISE IN MARATHON RUNNERS
Walter J. Paulsen MD, Derek R. Boughner MD., PhD., David A. Cunningham PhD., University Hospital,London,Ontario.

To determine the cardiac adaptations to prolonged endurance training left ventricular echocardiograms were performed in 8 active marathon runners, mean age 27 yrs. These recordings were made at rest and during 12 mins of supine bicycle ergometer exercise with workloads increasing by 25 watts every 3 mins to a maximum of 125 watts. When compared to 10 sedentary controls the significant differences ($p < 0.01$) for runners versus controls were as follows: increased maximum oxygen consumption, 72.8±5 vs 41.4 ±6 ml/kg/min; left ventricular end diastolic diameter 56±2 vs 52±5 mm; left ventricular posterior wall thickness,10.3 ±0.7 vs 8.5±1.0 mm; left ventricular mass 316±28 vs 187±44 gm. There were decreases in resting heart rate 54±4 vs 73±9 beats/min; resting pressure-rate product, 6248±888 vs 8430±1370; and resting peak velocity of circumferential fiber shortening (peak Vcf), 1.4±0.1 vs 1.7±0.2 circum/sec. During exercise at a workload of 125 watts there were decreases in heart rate 112±7 vs 144±15 beats/min; pressure-rate product 20684±2260 vs 28430±1247; and peak Vcf, 2.5±0.1 vs 3.0±0.3 circ/sec.
However, peak Vcf has been shown to vary directly with pressure-rate product. When peak Vcf was corrected for changes in pressure-rate product, there was no significant difference between the runners and controls either at rest or during exercise. These data indicate that prolonged endurance training results in an increased left ventricular chamber size and wall thickness but echocardiographic estimates of myocardial contractility remain unchanged.

THE ELECTROPHYSIOLOGIC PROPERTIES OF NORMAL NEONATAL AND ADULT CANINE CARDIAC PURKINJE FIBERS. Robert Reder, MD, Dennis Miura, MD, Peter Danilo, Jr., PhD, Michael Rosen, MD, FACC, Columbia Univ., College of P&S, New York, NY

To determine the basis for age-related changes in the transmembrane action potentials (AP) of canine cardiac Purkinje fibers (PF), we used standard microelectrode techniques to study PF from neonatal and adult beagles. Neonatal PF have a lower maximum diastolic potential (MDP) (-86.2±3.8 mv -91.5±5.9 mV (M±SD)), AP amplitude (amp) (126.1±4.7 vs 130.8±6.8 mV) and maximum upstroke velocity of phase 0 ($\dot{V}_{max}$) (533±90 vs 634±103 V/sec) than adults ($P<.05$). AP duration measured at 50% (141.0±13.9 vs 185.4±19.9 msec) and 100% repolarization (245.4±22.7 vs 286.9±28.0 msec) was shorter and phases 1 (11.9±10.9 vs -1.9±7.2 mV) and 2 (11.9±10.9 vs 1.3±6.8 mV) occurred at higher levels of membrane potential in neonates ($P<.05$). The lower MDP in neonates appears to result from a lower intracellular K activity (a_K^i) (studied with a K^+ sensitive microelectrode). Neonatal PF showed greater depression of AP amp and $\dot{V}_{max}$ on superfusion with the rapid Na^+ channel blocker, tetrodotoxin (TTX), than adults, attributable to an apparent age-related change in the fast Na^+ channel. An outward K current blocker, 4-aminopyridine, altered phase 1 more in adults than neonates. Adult PF AP repolarization was more sensitive to AHR-2666, a putative inward Ca^{+2} blocker and less sensitive to TTX than neonates, suggesting that the contribution of Ca^{+2} to the AP plateau diminishes and that of Na^+ increases with age. All drug-induced changes were significant ($P<.05$). In summary, as age increases from the neonate to the adult there are significant changes in a_K^i and MDP, in the fast inward Na^+ current, in an early repolarizing K^+ current, and in the slow, inward Ca^{++} and Na^+ currents. These in part explain the age-related changes in AP contour.

CORONARY ARTERY CONSTRICTION AND HEMODYNAMIC RESPONSES DURING ISOMETRIC HANDGRIP IN PATIENTS (pts) WITH CORONARY ARTERY DISEASE (CAD)
B Greg Brown, MD PhD, Robert B Petersen, PhD, Cynthia D Pierce, BS, Maylene Wong, MD, Wadsworth VA Hosp., L.A., CA; Edward Bolson, MS, Harold T Dodge, MD FACC, University of Washington, Seattle, WA.

The effect of handgrip (HGP) on arterial caliber and on resistance to flow in large and in small coronary vessels (CVR) is unknown. Twelve pts with CAD underwent catheterization and coronary arteriography. Coronary sinus flow (CSF) was measured by thermodilution. All hemodynamic measurements and selected coronary arteriograms were made just before (CON), and at 4-5 minutes during sustained HGP at 11 kg±2-SD (25% of max.) A computer-based angiographic analysis estimated dimensional changes during HGP in 30 diseased coronary artery segments in these pts. Lumen cross-sectional area in the "normal" part of the segment (A_n), minimum stenosis area (A_{min}), and stenosis flow resistance (R_s) were estimated.
Results: (increase ↑; decrease ↓)

	CSF (ml/min)	HEART RATE (bt/min)	SYST. A_o PR (mmHg)	MEAN WEDGE (mmHg)	A_n	A_{min}	R_s	CVR
					PERCENT CHANGE FROM CONTROL VALUE			
CON	101	69	134	15	-	-	-	-
HGP	184*	84^X	170^X	25*	11%↓^{X}	9%↓^{X}	29%↑^{X}	27%↓^{X}

CON vs HGP: NS = not significant; *=p<.05; ^{X}=p<.01.

All pts had forearm pain and fatigue; two had chest pain and one, PVC's. Pressure-rate product rose 58%^{X}. Small vessels dilated with increased metabolic demand, but diseased arteries constricted in spite of increased systemic pressure. HGP thus can impair the distribution of coronary flow in CAD, and should enhance ischemic abnormalities detected by non-invasive techniques.

EFFECTS OF DIGOXIN ON LEFT VENTRICULAR PERFORMANCE AND MYOCARDIAL BLOOD FLOW DISTRIBUTION DURING ISOMETRIC EXERCISE IN CORONARY DISEASE

Douglas P. Jensen, MD; Peter P. Steele, MD; Michael T. LeFree, BS; Dennis L. Kirch, MSEE; Joseph O. Rainwater, MD; Robert Vogel, MD, Veterans Administration Medical Center, Denver, CO.

Left ventricular (LV) dysfunction occurs during isometric exercise (ISO) in patients with coronary disease (CAD). Six men with CAD involving the left anterior descending underwent measurement of myocardial blood flow distribution (MBFD) (^{201}Tl; tomographic imaging), LV ejection fraction (EF) (first transit radionuclide; ^{99m}Tc), and interventricular septal thickening fraction (IVSTF) (thickening from end-diastole to end-systole: end-diastolic thickness, echocardiography) at rest and during ISO (handgrip for one min at 50% max). Studies were undertaken before and after a month's treatment with digoxin (D) 0.25 mg qd (level 0.68 ± 0.10 ng/ml; AVE ± SEM) and a third time after an additional week of D 0.5 mg qd (level 1.72 ± 0.25 ng/ml). ISO was associated with a decrease in LVEF (rest 0.51 ± 0.05; ISO 0.40 ± 0.04; P<0.05) and a decrease in IVSTF (rest 0.34 ± 0.04; ISO 0.20 ± 0.04; P<0.05). After four weeks of D, LVEF was preserved during ISO (rest 0.52 ± 0.05; ISO 0.49 ± 0.07; NS vs rest), as was IVSTF (rest 0.42 ± 0.06; ISO 0.41 ± 0.07; NS vs rest). D did not alter MBFD during ISO (integral count rate difference; T=15; Wilcoxon). After one week of D at 0.5 mg qd; LVEF and IVSTF continued to be preserved during ISO (LVEF rest 0.45 ± 0.04; ISO 0.45 ± 0.05; NS; IVSTF rest 0.35 ± 0.05; ISO 0.34 ± 0.06; NS) and MBFD was improved (control vs D; T=6). Results suggest that D at a low dose improves LV performance during ISO in CAD without altering MBFD, and at a higher dose D also improves MBFD.

EFFECTS OF ACUTE VOLUME LOADING ON RIGHT VENTRICULAR FUNCTION IN CHRONIC PULMONARY HYPERTENSION.

J.V. Nixon, MD, James Harper, James Jones and Charles B. Mullins, MD, FACC. Southwestern Med School, Dallas, TX.

Acute volume loading is ineffective in improving right ventricular (RV) function in experimental acute pulmonary hypertension. To determine its value in the presence of RV hypertrophy produced by chronic pulmonary hypertension, the effects of the intravenous infusion of normal saline, 22 ml/kg, on left (LV) and RV function were studied 6 months after pulmonary arterial (art) banding to a mean pressure (P) of 40 mm Hg in 9 dogs. Biplane cineangiographic RV and LV volumes (vols) and P were obtained before and after infusion. Tricuspid regurgitation (TR) was quantified as the difference between total RV stroke volume (SV) from angiographic vols and forward RVSV by dye dilution. Infusion was accompanied by increases in right atrial (1.6±.2 vs 4.4±.5 mm Hg, $p<.005$), pulmonary art systolic (103±6 vs 111±6 mm Hg, $p<.001$) and mean P (40±3 vs 51±3 mm Hg, $p<.05$), RV end-diastolic vol (60±5 vs 68±5 ml, $p<.005$) and P(4.8±.5 vs 8.4±.8 mm Hg, $p<.001$), RVSV (30±2 vs 34±2 ml, $p<.005$) and cardiac output (3.21±.35 vs 4.05±.27 L/min, $p<.005$). While LV end-diastolic vol (51±3 vs 57±2 ml, $p<.01$) and P (5.8±.9 vs 9.7±.9 mm Hg, $p<.005$) and LV end-systolic vol (22±2 vs 25±1 ml, $p<.05$) all increased, LV ejection fraction decreased (60±3 vs 56±2%, $p<.05$). RV and LV dp/dt, heart rate, RV end-systolic vol and LVSV remained unchanged. The degree of TR remained constant. Although cardiac output improved and TR was not increased, systolic and mean pulmonary art P both increased, RV function determined by RV dp/dt and ejection fraction was unchanged, and LV function determined by ejection fraction deteriorated. Thus, acute volume loading of the hypertrophied RV has an overall detrimental effect in chronic pulmonary hypertension.

EFFECTS OF INTRA-AORTIC BALLOON DIASTOLIC AUGMENTATION AND NITROPRUSSIDE ON POSTOPERATIVE REGIONAL LEFT VENTRICULAR FUNCTION

Ronald C. Hill, MD, James D. Sink, MD, W. Randolph Chitwood, Jr., MD, Craig O. Olsen, MD, Robert N. Jones, MD, Jim L. Cox, MD, Andrew S. Wechsler, MD, Duke and VA Medical Centers, Durham, North Carolina

Ultrasonic transducers (3 mmd) were implanted chronically along the minor axis of the left ventricle at mid-wall depth into a region supplied by a bypass graft. Arterial, left atrial and pulmonary pressures, EKG and regional dimensions were monitored. Eight patients, studied continously, were assessed 24-48 hours postoperatively for qualitative and quantitative effects of nitroprusside infusion (NP) and 4 patients were evaluated during intra-aortic balloon assistance (IABA). Following all studies, the transducers were withdrawn with no complications. Data (mean±SEM) are presented for extent (ΔL) and rate (dl/dt) of systolic excursion following normalization to an initial end-diastolic length of 10 mm.

			Arterial (mmHg)	
	ΔL(mm)	dl/dt(mm/sec)	Systolic	Diastolic
Control	1.6±.2	12.1±1.8	147.3±6.4	73.1±2.3
NP	1.9±.2*	15.3±2.4*	101.5±9.6*	53.8±3.5*
Control	1.7±.4	10.5±2.6	134.2±10.1	66.7±2.8
IABA	2.2±.4*	14.4±3.0*	116.7±8.6*	136.7±8.7*

*p<.05 compared to control

Both enhanced ΔL and dl/dt. Although IABA was associated with significantly less systolic unloading (p<.025), increase in the systolic shortening was greater than with NP alone. These studies imply that diastolic pressure augmentation with IABA, not present with NP, resulted in an increased supply/demand accounting for functional enhancement out of proportion to systolic unloading alone.

ACUTE AND LONG-TERM EFFECT OF VASODILATORS ON RESTING AND EXERCISE HEMODYNAMIC MEASUREMENTS AND EXERCISE TOLERANCE.

Barry Massie, MD, FACC; Barry Kramer, MD; Edward Shen, MD; Frances Haughom, RN. VA Hospital, University of California, San Francisco, CA.

Acute hemodynamic improvement has been demonstrated with several vasodilators (VD) and has been shown to be sustained with some. The chronic effect of VD on exercise (EX) hemodynamics and its relation to EX capacity have not been reported. We measured cardiac output (CO) and pulmonary capillary wedge pressure (PCW) at rest and during upright bicycle EX before (Pre) and after 48 hours (VD-acute) on a combination of oral hydralazine and sublingual isosorbide dinitrate in 11 patients (PTS) with chronic heart failure. Seven were electively restudied at 3 months (VD-chronic) and 48 hours after stopping VD (Post). EX capacity, assessed by duration of EX on a Mets treadmill protocol, was measured serially in all 11 PTS. Measurements in the 7 restudied patients are shown below.

	REST		EXERCISE	
	PCW	CO	PCW	CO
Pre	29±5(SD)	4.1±0.9	39±9	4.5±1.7
VD-acute	16±3	6.1±1.1	25±11	9.0±1.7
VD-chronic	19±4	5.8±0.8	29±6	9.1±1.4
Post	26±5	4.3±0.6	39±6	6.3±1.4

Initial and repeat PCW and CO on VD were similar and both were improved over pre-and post-VD (P<.01). The EX capacity of the 11 PTS increased from 7.7 ± 2.6 min. pre-VD to 8.9 ± 3.3 on acute-VD (.10 > p > .05) and further, to 10.2 ± 3.7 (p < .01) on chronic VD. However, it was unchanged in 3 PTS, each of whom had substantial increases in EX PCW between the 2 studies. These findings indicate that the combination of hydralazine and nitrates produces sustained hemodynamic improvement not only at rest but during EX and that this is accompanied by an increase in EX tolerance in most PTS.

ACTIVATION OF VASOCONSTRICTOR MECHANISMS DURING VASODILATOR THERAPY: A FACTOR MODIFYING DRUG RESPONSE IN HEART FAILURE

Milton Packer MD; Jose Meller MD, FACC; Norma Medina RN; Richard Gorlin MD, FACC; Michael V. Herman MD, FACC; Mount Sinai Medical Center, New York, New York.

The occurrence of rebound hemodynamic changes after the abrupt withdrawal of nitroprusside (NP) in patients (pts) with severe heart failure (CHF) is likely due to the activation of reflex vasoconstrictor mechanisms (RVM) during therapy which are left unopposed after its discontinuation. Exaggerated activation of RVM during vasodilator therapy may limit its effectiveness in certain pts. To test this hypothesis, we quantified the degree of activation of RVM in 33 pts with CHF by measuring the magnitude of NP rebound changes as the maximal % increase (↑) in systemic vascular resistance (SVR) after withdrawal of NP compared to pre-NP values. Vasodilator therapy consisted of NP (4.5 µg/kg/min) in all 33 pts and isosorbide dinitrate (ISDN)(40mg orally or 10 mg sublingually) in 21 of 33 pts.

After NP withdrawal, SVR rose to levels from 0 to 77% above the pre-NP SVR. The magnitude of rebound change was related directly to the control cardiac index (CI) (r=0.84) and inversely to the control SVR (r=-0.67).

During NP therapy, SVR decreased (↓) 24-65% and CI ↑ 7-130% of control values. The magnitude of rebound change post-NP was correlated inversely with the ↓ in SVR (r=-0.86) and the ↑ in CI (r=-0.84) during NP. The magnitude of NP rebound change subsequently predicted the % ↑ in CI (r=-0.86) and the % ↓ in SVR (r=-0.90) seen with ISDN to a better degree than did the pre-ISDN CI (r=-0.62) and SVR (r=0.49).

In conclusion, administration of vasodilators to pts with CHF and a mildly ↓ CI produces marked activation of RVM which counteract the drug mediated vascular effects and limit the responses observed. In contrast, pts with a severely ↓ CI have attenuated RVM so that marked responses are seen. Activation of RVM may be a key factor modifying the effects of vasodilators in pts with CHF.

INOTROPIC EFFECT OF AMRINONE IN SEVERE CONGESTIVE HEART FAILURE: LACK OF ATTENUATION WITH SEQUENTIAL DOSES.

Robert F. Malacoff, M.D.; Gregory D. Curfman, M.D.; Joshua Wynne, M.D., FACC; Jane Neill, R.T.; and Eugene Braunwald, M.D., FACC. Department of Medicine, Peter Bent Brigham Hospital, Boston, MA.

In order to evaluate possible tolerance to the inotropic effect of Amrinone, 5 patients with severe congestive heart failure received daily IV doses for 7 days. Four patients had idiopathic and one ischemic cardiomyopathy. Radionuclide ventriculography was performed before and at each hour after Amrinone on days 1, 4, and 7. Control global ejection fraction ranged from 11 to 35% and did not change significantly with IV placebo. Amrinone was administered in doses of 2.0-4.0 mg/kg and resulted in an increase in global ejection fraction averaging 31.0 ± 1.8%, i.e. global ejection fraction rose from 21 ± 3% to 29 ± 4%, $p<0.005$. There were no changes in heart rate or blood pressure. Inotropic effect was maximal within 1-3 hours of Amrinone administration, and persisted for up to 4 hours. Sequential observations during the 7 day study period showed no significant attenuation of inotropic effect. Left ventricular paradoxical wall motion assessed on a regional basis decreased significantly in 2 of 4 patients after Amrinone. We conclude that: 1) the inotropic effect of Amrinone can be quantitated non-invasively using radionuclide ventriculography; 2) inotropic effect appears to be maximal within 3 hours of IV administration; and 3) no significant attenuation of inotropic effect occurs with repeated administration of Amrinone for one week.

SYMPATHETIC AND RENIN RESPONSE TO ORTHOSTASIS IN CONGESTIVE HEART FAILURE.

T. Barry Levine, MD; Kathleen A. Gross, BS and Jay N. Cohn, MD, FACC ; University of Minnesota Medical School, Minneapolis, Minnesota 55455.

Assuming an upright position normally results in increased plasma catecholamines and renin activity (PRA). The orthostatic response of norepinephrine (NE) and PRA in congestive heart failure (CHF) is not known. Thirteen stable, hospitalized patients with severe CHF (NYHA Class III-IV) were studied while on digitalis, 43 mEq Na+ diets and 8/13 on diuretics. NE and PRA were measured supine (S). Patients were then tilted (T) to a 60° upright position and NE measured at 10 minutes and PRA at 45 minutes. NE (S) was elevated (average 616±75 pg/ml) compared to 20 normal subjects (177±15 pg/ml). NE rose 23% during T to 698±72 pg/ml (p=NS) in CHF while in normals NE rose 68% to 284±19 pg/ml ($p<0.001$). PRA (S) averaged 5.2±1.3 ng/ml/hr and was unchanged by T (5.2±1.3 ng/ml/hr) in CHF while in normals (n=7) PRA (S) was 1.8±0.5 mg/ml/hr and rose with T to 4.4 ng/ml/hr ($p<0.02$). In patients with CHF, cardiac output (CO_2 rebreathing or thermodilution) fell from 3.42±0.09 L/min (S) to 2.96±0.14 L/min (T) ($p<0.05$). NE % change and PRA % change during T in normals were significantly greater than in CHF ($p<0.01$). Therefore in CHF, PRA response to orthostasis is inhibited and appears to play no role in cardiovascular homeostasis. Furthermore, severe CHF stimulates cathecholamine activity to near maximal levels so that the ability of the sympathetic system to further respond to an orthostatic stress is markedly attenuated.

EFFECTS OF CHRONIC DIABETES ON CARDIAC PERFORMANCE AND METABOLISM IN RATS

Thomas F. Schaible, PhD, Somsong Penpargkul, MD, PhD, Alan Schwartz, Tada Yipintsoi, MD, PhD and James Scheuer, MD, FACC, Montefiore Hosp.-Albert Einstein Col. of Med., Bronx, N.Y.

To study the chronic effects of diabetes (D) on cardiac function and metabolism, male rats were made D with streptozotocin. At 9 weeks, D had blood glucose >600 mg/100 ml and heart and body weights were lower in D than in age-matched untreated control animals (C) ($p<0.001$). Hearts were then studied in an isolated working heart apparatus at atrial pressures (AP) 5-20 cm H_2O and at fixed heart rates using 5.5 mM glucose (G) without insulin (I) (group 1) and 15 mM G and I (10 mU/ml (group 2). Means of 8 hearts from group 1 and 2 at 15 cm AP were:

		PLVSP mmHg	+dP/dt mmHg/sec	-dP/dt mmHg/sec	SW[a] erg/min	MVO2[a] ml/min
group 1	C	101 *	4131 *	2864 *	1.47	1.29
	D	91	3600	2214	1.54	1.25
group 2	C	115 *	6097 *	3052	1.68	1.42
	D	100	5023	2640	1.95	1.47

(SW-stroke work, *=$p<0.05$ and a=per g dry LV wt.)

D hearts compared with C hearts from younger rats with the same heart size also showed depressed function. The ratio of lactate to pyruvate production was significantly greater ($p < 0.01$) in C than D in all groups. Therefore D was associated with abnormal contraction and relaxation. I and 15 mM G incompletely corrected these defects. The normal oxygen consumption and low lactate/pyruvate in D suggest that oxygenation and energy generation were normal. Thus myocardial energy utilization in D may be defective.

PAPILLARY MUSCLE FUNCTION IN RENOVASCULAR HYPERTENSION

Joseph M. Capasso, PhD; Fred Fein, MD, FACC; Laura B. Kornstein, MS; John E. Strobeck, MD, PhD; Edmund H. Sonnenblick, MD, FACC, Albert Einstein College of Medicine, Bronx, New York.

Renovascular hypertension, unlike other models of ventricular hypertrophy studied, has substantial clinical relevance. Left renal artery constriction was performed on female Wistar rats at 8 weeks of age. Animals became hypertensive (systolic blood pressure (BP) $\geq$ 150 mmHg) 2 to 3 weeks later. Ten weeks after surgery, left ventricular papillary muscles were studied isometrically in a muscle bath [(Ca^{++}) = 2.4 mM, Temperature = 30°C, stimulation frequency = 0.1 hz] and compared to age-matched controls. Hypertensives showed a 44% increase in heart weight (HW) over controls with no change in water content.

	Hypertensives (N = 12)	Controls (N = 12)
Systolic BP (mmHg)	179±9 (mean±SEM)	123±5*
Body Weight (g)	253±11	260±8
HW/Body Weight	.0036±.0001	.0024±.0001*
DT $(g/mm^2)^{1,2}$	7.80±.40	6.12±.60*
TPT $(msec)^{1,2}$	114±2.7	103±2.7*
T 1/2 R $(msec)^{1,3}$	115±4.9	99±4.8*

[1]Values at L_{max}, muscle length associated with peak developed tension (DT); [2]Time to DT; [3]Time from DT to fall to 50% DT.
*$p \leq .05$.

Despite marked hypertrophy, contractile force is not reduced early in hypertension. However, prolonged TPT and delayed relaxation (R) do occur, which may presage longer term changes.

DISCRETE SUBAORTIC OBSTRUCTION: TWO-DIMENSIONAL ECHOCARDIOGRAPHIC FEATURES

W. Dean Wilcox, MD; James B. Seward, MD, FACC; Donald J. Hagler, MD, FACC; Abdul J. Tajik, MD, FACC, Mayo Clinic, Rochester, MN.

M-mode echocardiographic and clinical features of discrete subaortic stenosis (DSS) are indirect and nonspecific. Cardiac catheterization and angiography are invariably necessary to substantiate the diagnosis. In this study, the usefulness of 2-dimensional sector echocardiography (2DE) for direct visualization of the obstructing lesion in DSS was investigated. Patients (pts) with hypertrophic obstructive cardiomyopathy were excluded. Eight pts with DSS (age 3-20 years, mean 10 years) had 2DE examination. All had subsequent confirmation by cardiac catheterization and surgery (gradient 65-130 mm Hg, mean 99 mm Hg). DSS was best appreciated with the parasternal long-axis view of the left ventricular (LV) outflow tract. A fine membrane (4 pts) or variable-appearing fibromuscular ridge (4 pts) was clearly visualized beneath the aortic valve in all. Although the circumference of the obstructing orifice could not be visualized in its entirety, the degree of LV outflow obstruction correlated with the distance between anterior and posterior edges of the obstructing lesion and the associated increase in LV muscle mass. The characteristics of the obstructing lesion were confirmed at surgery. Postoperative 2DE showed near-complete removal of the obstruction in each case. 2DE allows direct visualization and characterization (i.e., membranous vs. fibromuscular) of various types of DSS. Not only is the site of obstruction visualized, but the relative degree of outflow narrowing is readily appreciated. 2DE is at least as sensitive as angiocardiography in the recognition and characterization of the obstructive lesion and is the only noninvasive technique allowing direct visualization of lesions causing discrete subaortic obstruction.

PASSIVE STIFFNESS CHARACTERISTICS OF THE VOLUME-OVERLOAD HYPERTROPHIED MYOCARDIUM

Gangaiah Natarajan, MBBS, FACC; Alfred A. Bove, MD, PhD, FACC; Richard L. Coulson, PhD; Rita A. Carey, PhD; James F. Spann, MD, FACC. Temple University, Philadelphia, Pa.

Although the pressure-overload hypertrophied myocardium is shown to be stiffer than normal, whether such an increased passive stiffness is a result of hypertrophy is not known. This can be expected to be clarified by studying the muscle hypertrophied due to a different stimulus like volume overload. Accordingly, length-passive tension curves of right ventricular papillary muscles were studied in a group of 10 normal cats (N) and 6 cats with volume-overload cardiac hypertrophy (V) due to an atrial septal defect created 50 ± 5 days prior to the terminal study. Right ventricular hypertrophy was confirmed by increased RV/LV ratio (N=0.30 ± 0.01 g/Kg, V=0.46 ± 0.02 g/Kg). Active contractile function was normal in V (Peak active tension in g/mm^2: N=7.02 ± 0.28, V=6.57 ± 0.51). Stress-strain analysis was carried out with the equation $Ln\sigma = K\varepsilon + LnC$ where σ=stress, ε=natural strain (=Ln l/lo), and K and C are constants. The values of K and C were similar in the two groups.

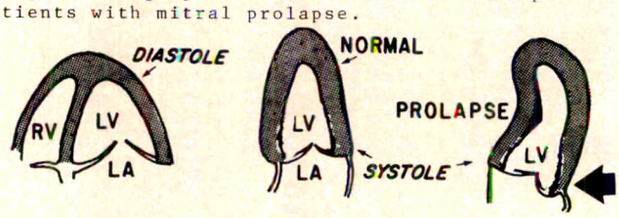
	K	LnC	r
Normal	15.01 ± 0.87	-4.33 ± 0.20	0.99
Volume-overload	17.00 ± 2.85	-4.45 ± 0.71	0.98

Elastic stiffness calculated as $\frac{d\sigma}{d\varepsilon} = K\sigma$ was also similar in the two groups at common stress levels.
CONCLUSION: 1. Myocardial passive stiffness is normal in volume-overload cardiac hypertrophy. 2. Hypertrophy process per se does not alter the myocardial passive stiffness.

ABNORMAL SYSTOLIC MOTION OF THE POSTEROLATERAL BASAL LEFT VENTRICLE IN MITRAL VALVE PROLAPSE: A NEW CROSS-SECTIONAL ECHOCARDIOGRAPHIC SIGN.

Ivan D'Cruz, MD, FACC, Shirish Shah, MD, Leroy Hirsch, PhD, Alberto Goldbarg, MD, FACC, Cardiovascular Institute, Michael Reese Hospital, Chicago, Illinois

In 8/26 (30%) of patients with typical mitral prolapse on M-mode echo, cross-sectional echo in the apical 4-chamber view revealed a characteristic (hitherto unreported) abnormality (see Fig): In mid to late systole, the ventricular septum contracted vigorously, forming a bend or convexity to the left, thus drawing the medial corner of the basal LV toward the transducer, while motion of the posterolateral corner of the basal LV toward the transducer was absent, or diminished and delayed (arrow). This finding was not encountered in 35 individuals with functional systolic murmurs but no detectable heart disease, nor in 15 patients with mitral regurgitation of etiologies other than mitral prolapse. We describe a new cross-sectional echo finding-impaired systolic motion of the posterolateral basal LV, compatible with previous reported angiocardiographic abnormalities in some patients with mitral prolapse.



A STATISTICAL COMPARISON OF THE M-MODE AND TWO-DIMENSIONAL ECHOCARDIOGRAPHIC DIAGNOSIS OF FLAIL MITRAL LEAFLETS
Gary S. Mintz, MD; Morris N. Kotler, MD, FACC; Wayne R. Parry; Bernard L. Segal, MD, FACC; Likoff Cardiovascular Institute, Hahnemann Medical College, Philadelphia, PA

We compared the sensitivity (SENS), specificity (SPEC), predictive accuracy (PA), and predictive value (PV) of the m-mode (MME) and two-dimensional (2DE) echocardiographic diagnosis of flail mitral leaflets (FML). MME and 2DE studies were evaluated prospectively in 45 consecutive patients (PTS) having surgery for pure mitral regurgitation (MR). 26 PTS had FML: 12 anterior and 13 posterior leaflet (LFT). 19 control PTS had MR from other causes: rheumatic disease (9 PTS), papillary muscle fibrosis (4 PTS), cleft anterior LFT (3 PTS), and mitral prolapse (3 PTS). 44 PTS had adequate MME; positive study showed systolic mitral flutter (SYS MV FLUT), diastolic flutter of the involved LFT (DIAS MV FLUT), paradoxic diastolic posterior LFT motion (PARA PML), or systolic left atrial echoes (SYS LA E). 45 PTS had adequate 2DE; positive study showed loss of systolic LFT coaptation.

POSITIVE MME	TP	TN	FP	FN	SENS	SPEC	PA	PV
SYS MV FLUT	6	18	1	19	24%	95%	86%	49%
DIAS MV FLUT	11	11	8	14	44%	58%	58%	44%
PARA PML*	6	9	1	7	46%	90%	86%	56%
SYS LA E	2	19	0	23	8%	100%	100%	45%
ONE OR MORE	15	10	9	10	60%	53%	63%	50%
POSITIVE 2DE	25	16	3	1	96%	84%	89%	94%

*Only PTS with flail posterior LFT are included
PTS with rheumatic disease are excluded

MME diagnosed only 60% of FML, and 9 control PTS had false positive MME. 2DE diagnosed 96% of FML. 3 PTS (2 rheumatic and 1 prolapse) had false positive 2DE; asymmetric chordal retraction or elongation caused loss of leaflet coaptation, and this may be the mechanism of MR in these PTS. Nevertheless, we conclude that 2DE is superior to MME in the diagnosis of flail mitral LFTS.

CLINICAL SPECTRUM OF LEFT VENTRICULAR MURAL THROMBI IN A LARGE CARDIAC POPULATION: ASSESSMENT BY TWO-DIMENSIONAL ECHOCARDIOGRAPHY.
Miguel A. Quinones, MD, FACC; Jean G. Nelson, RDMS; William L. Winters Jr., MD, FACC; Alan D. Waggoner, RDMS; Stephen P. Rosenfeld, MD; James B. Young, MD; Richard R. Miller, MD, FACC, Baylor College of Medicine and The Methodist Hospital, Houston, Texas.

To characterize the presence of left ventricular (LV) mural thrombi (MT) in a large patient (pt) population, wide angle (90°) two-dimensional (2-D) echocardiograms (echo) from 504 consecutive pts were reviewed. MT were present in 22 of 112 (20%) pts with segmental or diffuse LV dyssynergy (DYS) compared to none of 392 other pts. MT appeared as dense echoes attached to the LV wall most frequently (19/21) seen in apical views. Comparison of 2-D with LV angiography (presence of filling defects) by independent observers in 52/112 pts revealed a sensitivity of 2-D for MT of 89.5%(17/19 pts) and a specificity of 100% (33/33). MT were confirmed at surgery in 4/4 pts explored; all with (+) 2-D. Incidence of MT (2D & angio)as follows: total, 24/112 (21%); in coronary artery disease (CAD), 19/100 (19%); ejection fraction (EF) <.50, 23/101 (23%); EF<.35, 19/72 (26%); apical dyskinesis, 16/42 (39%) including discrete apical aneurysm, 7/14 (50%); primary cardiomyopathy (PCM), 3/10 (30%). Location of MT: 22 apical, 1 postero-inferior and 1 antero basilar wall. Electrocardiographic findings in MT: 18 infarcts (12 anterior, 6 inferior), 2 left bundle branch block and 4 LV hypertrophy. Clinical embolic episodes occurred in 3/24 pts (12.5% incidence). In conclusion, 2-D echo is both sensitive and highly specific for detecting MT when compared to angiography. MT are detected only in cardiac pts with DYS. MT relate directly to severity of LV dysfunction regardless of the etiology (PCM vs CAD). Further, despite multiple sites of DYS, most MT are localized to the apex suggesting that other factors unique to the apex determine MT formation.

TWO-DIMENSIONAL ECHOCARDIOGRAPHIC RECOGNITION OF MURAL THROMBI: IN-VIVO AND IN-VITRO STUDIES
Milutin Drobac, MD; Harry Rakowski, MD; Brian W. Gilbert, MD, FACC; Michael X. Glynn, MD; Malcolm D. Silver, MD; Toronto General Hospital, Toronto, Canada.

Mural thrombus was suspected by two-dimensional echocardiography (2DE) in 41 patients (pts) over a 2 year period, 32 with ischemic heart disease, 6 with cardiomyopathy, and 3 with mitral stenosis. Thirty-five of 41 thrombi were left ventricular (LV), 5/41 were in the body of the left atrium (LA), and 1/41 right ventricular. Of 16 pts who had either LV angiograms or pathological studies, thrombus was confirmed in 13. Seven of 41 pts had ischemic cerebral events or peripheral arterial emboli. Three of these 7 had pathological or angiographic confirmation of clot.

To assess the sensitivity of 2DE in detecting thrombi of various size and composition, an in-vitro study was carried out using a cadaveric left ventricle suspended in a water bath with clots of various types placed on the endocardial surface of the cadaveric LV and echoed. Four different types of clots were prepared and studied: (a) fibrin, (b) whole blood, (c) platelet, (d) an organized thrombus obtained at surgery from the LA of a patient with mitral stenosis. Two-dimensional echocardiography was able to detect all clots, regardless of composition and could visualize clots as small as 2mm in diameter.

We conclude that in-vivo, 2DE can reliably detect clots in various cardiac chambers. In-vitro, 2DE can detect very small clots of various compositions. False negative in-vivo studies would appear to be due to technical rather than theoretical limitations.

IMPROVED ECHOCARDIOGRAPHIC TECHNIQUE FOR EXAMINING THE LEFT MAIN CORONARY ARTERY
Lawrence D. Rink, MD; Harvey Feigenbaum, MD, FACC; Jane E. Marshall; Robert W. Godley, MD; Daniel Doty, MD; James C. Dillon, MD, FACC; Arthur E. Weyman, MD, FACC; Indiana University School of Medicine; Krannert Institute of Cardiology; Indianapolis, Indiana

Cross-sectional echocardiography (CSE) can record the left main coronary artery (LMCA) and at times LMCA obstructions (LMCAO) and LMCA aneurysms. Unfortunately, technical difficulties have made this examination impractical. To overcome these difficulties a commercial echograph with better resolution (3MHz), better gray scale (digitally processed), and strobe freeze-frame capability was used. The gray scale permitted one to judge echo intensity, as well as lumen diameter. The strobe feature permitted repeated visualization of the LMCA at a given time in the cardiac cycle thus eliminating extraneous echoes and allowing the LMCA to be studied repeatedly in real-time. Prospective and retrospective studies were done on 72 pts undergoing coronary angiography. The LMCA could be identified in 71 of the 72 pts. Seven of these pts had LMCAO. CSE detected the LMCAO in all 7 (2 prospectively, 5 retrospectively) as luminal narrowing by bright, thick echoes on repeated strobe mode recordings. Patients with coronary artery disease (CAD) but no LMCAO usually had bright LMCA echoes but no luminal narrowing. To further evaluate the technique, 28 random pts, 4 of whom had LMCAO, were blindly evaluated by 1 investigator. The LMCA was identified in all 28. All 4 pts with LMCAO were identified, i.e. no false negatives. There was 1 false positive in a pt with a proximal LAD lesion. In 2 pts with CAD but no LMCAO the observer diagnosed CAD but was undertain as to LMCAO. This new technique should greatly improve the practical use of CSE to examine the LMCA.

FIRST DERIVATIVE OF DIASTOLIC AORTIC ROOT MOTION AS A MEASURE OF TRANSMITRAL FLOW.

Louis Teichholz MD, FACC; Gary Caputo MD; John Ambrose MD, FACC; Bill Knopsler; Eulogio Martinez MD; Michael Herman MD, FACC. Mount Sinai Medical Center, New York, New York.

Aortic root (AoR) motion on echo has been shown to be related to left atrial volume changes. In order to study the usefulness of this relationship in estimating mitral valve flow, we examined the possible correlation between the first derivative of diastolic AoR motion (dAo/dt) and transmitral flow velocity (TMFV) in normals. M-mode echocardiograms were obtained in 5 normal subjects in the upright position using a digital tracking gate which allowed on-line acquisition and digitization of the posterior AoR echoes simultaneous with analog TMFV obtained with pulse-echo doppler techniques. Both signals were acquired by a PDP 11/70 computer, the TMFV doppler signal digitized, dAo/dt determined, and the results plotted. In normal subjects over range of heart rates 55-90, the curves of dAo/dt and TMFV during diastole showed a good visual correlation with similar shape and time-course. In order to further examine the relationship, simultaneous diastolic values of dAo/dt were plotted against TMFV and a linear relationship was found for each of the individual beats analyzed with r values from 0.81-0.90. Thus, dAo/dt during diastole appears to show a time-course and configuration similar to TMFV. The correlation between simultaneous values of dAo/dt and TMFV suggests the usefulness of dAo/dt as a measure of relative rate of transmitral flow.

REAL TIME TWO-DIMENSIONAL ECHOCARDIOGRAPHY IN RIGHT VENTRICULAR INFARCTION.

Brian J. D'Arcy, M.D., Bapineedu Gondi, M.D., Navin C. Nanda, M.D., F.A.C.C., Robert P. Gatewood, M.D., Theodore Biddle, M.D., F.A.C.C., University of Rochester Medical Center, Rochester, New York.

Five patients with typical clinical features (hypotension, neck vein distention, minimal or no pulmonary congestion, acute infero-posterior infarction) and hemodynamic findings (equalization of right atrial (RA) and pulmonary capillary wedge pressures) of right ventricular (RV) infarction were studied with a wide angle (90°) ATL mechanical sector scanner. The RV was imaged in standard long axis, apical four-chamber and sequential short axis views from precordial and subxiphoid positions. All patients showed RV enlargement in both long and short axis planes with RV/LV end-diastolic dimension ratio > 0.5. All also showed RV segmental wall motion abnormalities (RVMA). RVMA included hypokinesis of the RV anterolateral wall in 3 patients, akinesis of the RV anterolateral wall with minimal paradoxical motion of the RV apex in one, and a prominent RV lateral wall aneurysm seen in the apical 4-chamber view near the tricuspid ring in one case. Ventricular septal motion was paradoxical in 4 out of 5 patients in two of whom the entire septum bulged into the RV throughout systole. Echo contrast studies in 4 out of 5 cases utilizing RA catheter injections showed significant tricuspid regurgitation indicated by prominent reflux of contrast into the inferior vena cava (IVC) and hepatic veins in 2, and less marked insufficiency with minimal reflux into the IVC in the other two. Technetium 99m pyrophosphate scans were positive in 2, negative in 2, and technically inadequate in 1 patient. Autopsy confirmation of RV infarction was obtained in 1 patient in whom scan was negative. A comparison group of 5 patients with congestive cardiomyopathy showed diffuse RV and LV hypokinesis and chamber enlargement by echo but no RVMA were noted.

SENSITIVITY AND SPECIFICITY OF TWO-DIMENSIONAL ECHOCARDIOGRAPHY IN THE DETECTION OF LEFT VENTRICULAR ANEURYSMS

Maria Lengyel, MD; Abdul J. Tajik, MD, FACC; James B. Seward, MD, FACC; Donald J. Hagler, MD, FACC; and Hugh C. Smith, MD, FACC, Mayo Clinic, Rochester, Minnesota

We studied the effectiveness of two-dimensional echocardiography (2DE) in the detection of left ventricular aneurysm (LVA), defined as a well-demarcated bulge in diastole and systole with thinned, dyskinetic walls. In two years, 76 consecutive patients (60 males and 16 females, ages 34-87 years) were diagnosed by 2DE as having LVA. LVA was best visualized from apical four-chamber and apical long-axis views with a wide-angle phased-array sector scanner. LVA was located inferoposteriorly in five patients and involved the anteroapical wall in 71 patients; in 33 of the 71, the septum was also involved. Mural thrombi were visualized in 26 patients (34%); angiography was done in 44 of 76 patients. To determine the sensitivity and specificity of 2DE, we examined data on 78 patients (including the above 44) who had prior myocardial infarction and combined 2DE and angiographic studies. Forty-one of the 78 patients had LVA on angiography, and 38 of these were correctly diagnosed by 2DE (sensitivity 93%); three diagnoses were false negative. Thirty-seven of the 78 patients had no LVA on angiography, and 2DE was also negative for LVA in 31 of 37 patients (specificity 84%); six diagnoses were false positive. Thus, 2DE is a highly sensitive and specific technique for detection or exclusion of LVA.

TWO-DIMENSIONAL ECHO SECTOR ANGIOGRAPHIC DIAGNOSIS OF VENTRICULAR SEPTAL DEFECT FOLLOWING ACUTE MYOCARDIAL INFARCTION.

Jean-C. FARCOT,MD; Louis BCISANTE,MD; Michel RIGAUD,MD; Jean BARDET, MD; Jean-P. BOURDARIAS,MD,FACC; Ambroise Paré Hospital U.E.R. Paris Ouest (France).

Early and prompt diagnosis is essential in patients (Pts) with suspected ventricular septal defect (VSD) following acute myocardial infarction (AMI). To assess wether or not two-dimensional echo (2DE) can accurately diagnose VSD, we compared 2DE findings with perioperative (PO) or postmortem (PM) data obtained in 5 consecutive Pts hospitalized for anterior (4 Pts) or inferior (1 Pt) AMI, associated with sudden appearance of a loud systolic murmur . Using the apical (4-chamber) and subxiphoid approach, the entire left ventricle (LV) was analyzed, special attention being paid to the anatomical integrity of the interventricular septum (IVS). Echo contrast material (5-10 ml of Pts's own blood) was injected manually through a Swan-Ganz thermodilution catheter into the right atrium to investigate left-to-right shunt (L-R S). Negative contrast echocardiography (NCE) was considered to be present when an obvious washout of the microcavitations was seen in front of the defect and the contrast material filled this echofree space again during the following diastole. In all 5 Pts cardiac catheterization demonstrated a large L-R S with a pulmonic-to-systemic flow ratio of 3.2 ± 0.8/1 (mean ± SD). VSD size was expressed as a percentage of diastolic IVS thickness. Using apical approach 3 independent observers agreed in identifying 4 anteriorly located VSDs, and this correlated with PO (3 Pts) or PM (1 Pt) examination. On the opposite, a large inferior VSD could only be visualized using the subxiphoid view. NCE was noted in all 5 Pts. In all 4 anterior VSDs, IVS curvature was abnormally convex towards the LV outflow tract while it retained normal concavity in the single inferior VSD. Septal patches were visualized in the 2 Pts who survived surgery.

Conclusions : 1) 2DE is a highly reliable noninvasive technique for early diagnosis of VSD following AMI ; 2) 2DE provides direct anatomical information about location and approximate size of the VSD for the time of surgery; 3) while all 4 anterior VSDs were easily visualized on the 4-chamber view , the single inferior VSD was identified using the subxiphoid view only.

DOPPLERCARDIOGRAPHIC ASSESSMENT OF SEVERITY OF AORTIC AND MITRAL VALVE STENOSIS. Kent L. Richards, MD, FACC, Ernest R. Greene, PhD, David E. Hoekenga, MD, Jerry G. Davis, BA University of New Mexico & Veterans Hsp, Albuquerque, NM. Twenty patients [5 with aortic stenosis (AS), 7 with mitral stenosis (MS), & 8 normals (NL)] were studied by Dopplercardiography (D) & cardiac catheterization to assess D for detecting & quantitating valvular stenosis. A unique 3MHz range-gated D with variable sample volume (SV) width & a cardiac tracking device was utilized. The aortic orifice was studied with the transducer at the suprasternal notch & SV 2 cm above the aortic cusps; the mitral was studied with the transducer at the cardiac apex & SV within the orifice. Doppler frequency shifts were analyzed using a directional multifilter sonograph. From the 6 decibel envelope of the systolic (s) aortic record, temporal mean midsystolic velocity ($\bar{V}$) & systolic time-velocity integral (TV) were measured. Similar diastolic (d) parameters were measured from the mitral records. A velocity index (VI) which reflects the increased velocity, flow disturbance & prolonged ejection noted in stenotic orifices was calculated ($\bar{V}$ x TV). VI_s clearly separated 5 AS from 8 NL patients ($p<.01$), & VI_d clearly separated 7 MS from 8 NL patients ($p<.001$). Good correlation was noted between aortic valve area & VI_s ($r=.94$), & mitral valve area & VI_d ($r=.88$).

	Velocity Index (cm^2/sec)		Valve Area (cm^2)	
NL (Aortic)	191-648	(414)	-------	---
AS: Mild	687-879	(783)	1.0-1.2	(1.1)
Severe	1044-1797	(1463)	0.4-0.8	(0.6)
NL (Mitral)	76-435	(239)	-------	---
MS: Mild	-------	558	-------	2.9
Moderate	695-879	(804)	1.3-1.7	(1.5)
Severe	1216-1338	(1277)	0.4-1.0	(0.7)

The data support the usefulness of non-invasive D with improved spatial resolution and careful velocity waveform analysis in quantifying severity of AS and MS in adults.

PULSED ECHO DOPPLER MEASUREMENTS OF BEAT TO BEAT CHANGES IN STROKE VOLUME IN DOGS

Richard Steingart, MD, Jose Meller, MD, FACC, Julie Barovick, RN, Randolph Patterson, MD, FACC, Michael Herman, MD, FACC, Louis Teichholz, MD, FACC, Mount Sinai Medical Center, New York, N.Y.

Measurement of stroke volume (SV) by pulsed echo Doppler (PED) has not been validated against a reference method in vivo. Therefore, we compared Doppler systolic velocity integrals (DVI) with electromagnetic flowmeter SV in 7 open chest dogs. A PED transducer was held on the aortic arch with the sample volume in the ascending aorta. SV was varied by drugs and/or volume infusion and withdrawal. Linear regression analysis of SV v DVI reveals:

Dog #	N	SV† (cc)	DVI† (cm-sec)	r Value SV v DVI	Slope	Intercept
1	6	7-28	.311-.699	.89*	.018	.188
2	12	3-30	.107-.685	.96*	.020	.077
3	15	2-28	.041-.771	.95*	.026	-.028
4	5	3-23	.115-.947	.74*	.032	.239
5	9	3-21	.176-.748	.80*	.026	.217
6	12	1-16	.015-.189	.87*	.013	.048
7	10	1-11	.044-.485	.95*	.041	.002

N=# of interventions. †=range of values. *=$p<.001$

Strong correlations and intercepts close to zero are shown. Repositioning of the transducer between interventions did not influence DVI. Variability in slope is inherent in this system as different, uncalibrated PED settings are required for each dog. Variability of DVI within dogs may be due to zero crossing meter analysis of frequency shifts, turbulent flow, or changes in aortic cross sectional area. In conclusion, PED serves as an excellent measure of SV changes in this model.

REVERSAL OF PROPRANOLOL INDUCED MYOCARDIAL DEPRESSION DURING PARTIAL AND TOTAL CORONARY OCCLUSION BY NITROGLYCERIN

Shigehiko Hattori, MD; Vidya S. Banka, MD, FACC; Hajime Yamazaki, MD; Jai B. Agarwal, MD; John K-J. Li, PhD; Monty M. Bodenheimer, MD, FACC; Richard H. Helfant, MD, FACC, Presbyterian-University of Pa. Med. Ctr., Phila., Pa.

Usefulness of propranolol in acute myocardial infarction is limited by its cardiodepressant effects. To determine whether these cardiodepressant effects can be reversed by nitroglycerin (TNG), partial or total coronary occlusion (CO) was produced in 14 open chested dogs. Regional myocardial function was studied by implanting pairs of ultrasonic crystals subendocardially in the nonischemic (NZ) and ischemic zones (IZ). Propranolol (0.5 mg/kg) was given intravenously (IV) 30 min after CO, and TNG 0.4 mg IV was given 15 min after Inderal. During partial CO, systolic shortening (%ΔL) in the IZ decreased from 20.9±1.9 to 7.2±2.3 ($p<.001$). Propranolol produced small further decrease in %ΔL to 6.7±1.6. TNG increased %ΔL from 6.7±1.6 to 12.2±1.9 ($p<.001$). The NZ was unaffected by partial CO but showed decrease in %ΔL from 18.6±2.2 to 15.6±1.8 ($p<.01$) with propranolol. TNG increased %ΔL from 15.6±1.8 to 18.2±2.1 ($p<.01$). Following total CO, %ΔL in NZ changed from 17.8±1.2 to 18.3±1.2 and decreased to 15.4±0.8 ($p<0.02$) with propranolol. TNG increased the shortening to 19.1±1.0 ($p<0.05$). In the IZ, total CO replaced shortening by lengthening (%ΔL from 18.4±0.9 to -7.2±0.9). Propranolol and TNG had no significant effect on this. TNG caused a decrease in systolic pressure from 117.4±4.3 to 90.6±3.7 ($p<.001$) and in LVEDP from 5.9±0.5 to 4.1±.5 ($p<.01$). Heart rate remained unchanged. In summary, TNG reverses myocardial depressant effects of propranolol both in the partially ischemic and non-ischemic zones following acute coronary obstruction.

PULMONARY EFFECTS OF A "CARDIOSELECTIVE" BETA BLOCKER

Robert Di Bianco MD, Kenneth J Dickie MD, Steven Singh MD, FACC, Richard J Katz MD, Rebecca Bortz, Allan Simpson MD, Samuel V Spagnolo MD, Ross D Fletcher MD, James M Raver MD, Veterans Administration and Georgetown University Medical Centers, Washington, D.C.

Beta adrenergic blockers may produce adverse pulmonary effects. Cardioselective agents are possible therapeutic alternatives but may not be selective at clinical dosages. Each new agent must be evaluated for "nonspecific" beta effects at dosages used clinically. To assess acebutolol, a cardioselective beta blocker, for adverse pulmonary effects, we performed 104 pulmonary function studies on 26 male stable angina pts free of overt pulmonary disease. Pts were studied during each phase of a 20-week placebo controlled, doubleblind, randomized crossover trial. The mean of two studies while on placebo were compared with two on oral acebutolol (1.2 gms/day or 14 mg/kg/day) for each pt. Heart rates and rate pressure products at rest and peak exercise ($p<.005$) and frequency of angina attacks and NTG consumption ($p<.02$) decreased with acebutolol. A slightly decreased forced expiratory volume at 1 second (FEV1, 3.3%, $p<.05$) occurred, but flow volume loops, forced vital capacity(FVC), FEV1/FVC, maximum mid expiratory flow (MMF), arterial pO2, pCO2 and pH were not altered (pNS) on acebutolol.

	Placebo	Acebutolol	p-value
FVC	3.49 L	3.49 L	NS
FEV1	2.75 L	2.66 L	<.05
MMF	237 L/min	222 L/min	NS

Chronic oral acebutolol, in dosages effective for relief of angina provoked only minor and clinically unimportant changes in pulmonary function which supports a claim for cardioselectivity in the clinical setting.

ADRENERGIC RESPONSIVENESS FOLLOWING ABRUPT PROPRANOLOL WITHDRAWAL IN PATIENTS WITH ANGINA PECTORIS

JoAnn Lindenfeld, MD; Michael Crawford, MD, FACC; Robert O'Rourke, MD, FACC; Lawrence Horwitz, MD, FACC, University of Texas Health Science Center and Veterans Administration Hospital, San Antonio, Texas.

It has been suggested that propranolol (P) withdrawal phenomena may be due to sympathetic hypersensitivity. We have previously been unable to demonstrate enhanced adrenergic responsiveness following P withdrawal in conscious dogs and normal subjects. Accordingly, we studied 10 patients (pts) with angina pectoris before (C), during P therapy (160 mg/day X 14 days) and at 48, 96 and 144 hrs following abrupt withdrawal of P at rest, during an epinephrine (Epi) infusion (0.1 μg/kg/min X 5 min) and during treadmill exercise. Below is detailed heart rate (HR), systolic blood pressure (SBP) and plasma Epi levels at peak exercise; free fatty acid (FFA) response to Epi infusion; and resting total serum triiodothyronine (T_3) levels:

	HR (beats/min)	HRxSBP ($X10^3$)	Epi (pg/ml)	FFA (mEq/L)	T_3 (ng/dl)
C	136±16	22.9±6.6	59± 33	1050±356	151±27
P	106±14*	15.3±4.0*	126±129+	530±108*	137±23+
48	134±21	21.3±4.9	58± 27	817±155	132±12*
96	136±22	21.6±6.0	58± 28	911±249	137±23+
144	136±23	22.0±6.5	56± 34	926±173	129±20*

Mean ± 1SD +=p<.05 *=p<.01

All measures except T_3 differed from control only during P. T_3 was reduced for up to 144 hrs following P. Exercise duration was improved on propranolol therapy (454±128 vs 392±116 sec, p<.05), but returned to control levels during withdrawal. No patients experienced increased angina or other untoward events after P withdrawal. We conclude that enhanced adrenergic responsiveness in the 6 days following abrupt P withdrawal in patients with angina pectoris is unlikely to be the explanation for propranolol withdrawal phenomena.

BENEFICIAL HEMODYNAMIC AND ENERGETIC EFFECTS OF AFTERLOAD REDUCTION WITH PROSTAGLANDIN E-1 IN PATIENTS WITH SEVERE CHRONIC CONGESTIVE HEART FAILURE

John Hermanovich, MD; Najam A. Awan, MD, FACC; Mark Evensen, BS; Tom Evans, MD, FACC; Dean T. Mason, MD, FACC, University of California, Davis, California.

Although nitroprusside (NP) is recognized to be highly beneficial for vasodilator therapy of severe chronic congestive heart failure (CHF), the prostaglandins (PG) represent a more rationale physiological approach. Therefore, the hemodynamic effects of afterload reduction with PGE-1 infusion (0.04 μg/kg/min) were evaluated by cardiac catheterization in nine patients with refractory CHF. PGE-1 did not alter control (C) heart rate (HR) of 71 bpm, while mean blood pressure (BP) decreased mildly from 83 to 75 mmHg ($p<0.05$) and excessive left ventricular filling pressure (LVFP) fell from 22 to 17 mmHg ($p<0.005$). Concomitantly, lowered cardiac index (CI) was augmented from 1.8 to 2.3 L/min/M^2 ($p<0.01$) and stroke index rose from 25 to 33 cc/beat/M^2 ($p<0.01$). Moreover, PGE-1 raised stroke work index of 21 to 26 gm·m/M^2 ($p<0.01$) while total systemic vascular resistance declined from 2162 to 1412 dynes-sec-cm^{-5} ($p<0.01$) and HR·BP product of myocardial oxygen consumption (MVO_2) index was reduced from 8804 to 7952 ($p<0.05$). Thus PGE-1 is a potent systemic vasodilator with beneficial vasorelaxant actions on both the arteriolar resistance and venous capacitance beds causing substantially decreased LVFP and increased CI. Accordingly, PGE-1 infusion produces considerable improvement in LV function and energetics in patients with severe chronic CHF. Moreover, the marked concomitant platelet inhibitory actions of this potent agent indicate that PGE-1 is particularly suited for afterload reduction in patients with severe ischemic cardiac failure.

DO BETA BLOCKING AGENTS PREVENT THE MORE RAPID ONSET OF EFFORT ANGINA DURING THE POSTPRANDIAL STATE?

Gilles-R. Dagenais, MD, FACC; François Delage, MD; Jacques R. Rouleau, MD, FACC, Quebec Heart Institute, Quebec, Canada.

To answer the above question, metoprolol 100 mg (M) was given before an 800 calorie meal to 12 male patients with stable angina and documented coronary artery disease. Three graded treadmill exercise tests (GET) (Bruce protocol) were performed daily on 2 days. After an overnight fast, the first GET on each day was done after a placebo (P) to detect any daily variation. The second GET was done 90 min after M or a second P given orally in a double-blind randomized fashion. Immediately after, the patients ate their meal and 30 min later did their third GET. Angina or fatigue were used as endpoints for each GET. A positive ECG (ECG+) was defined as a 1 mm ST segment depression lasting 0.08 sec as compared to the resting tracing. There was no significant day to day difference in the first GET. After P, all patients had angina, while it occurred in 10 of the 12 patients after M. The results (mean±SEM) of the second (a.c.) and third (p.c.) GET for exercise duration, onset of ECG+ and maximal pressure-rate index (MPRI) were:

		DURATION (sec)	ECG+ (sec)	MPRI (Units 10^{-2})
P	a.c.	370±28	280±27	271±13
	p.c.	310±24	228±19	268±11
M	a.c.	405±26	335±25	188±11
	p.c.	386±30	317±29	191±11

After P, angina and ECG+ occurred sooner p.c. than a.c. at similar MPRI ($p<0.01$). After M, there was no significant difference between a.c. and p.c. results. Compared to P, M prevented the more rapid onset of effort angina and ECG+ during the postprandial state ($p<0.01$).

PHARMACOKINETICS AND PHARMACOLOGIC EFFECTS AFTER SINGLE AND CHRONIC DOSES OF ISOSORBIDE DINITRATE

Ho-Leung Fung, PhD; Edward F. McNiff, BS; Donald Ruggirello, BS; Andrew Darke, PhD; John O. Parker, MD, FRCP(C), Udho Thadani, MBBS, MRCP, FRCP(C), State University of New York at Buffalo, Amherst, NY.

The inter-relationships among oral isosorbide dinitrate (ISDN) dose, drug pharmacokinetics and pharmacologic effects were examined in 12 angina patients. Plasma ISDN concentrations were determined by gas chromatography at selected intervals after single oral doses of 15, 30, 60 and 120 mg and after chronic administration (qid for 1 week) of the same doses. Significant accumulation of intact ISDN in plasma was observed after chronic dosing at 30, 60 and 120 mg. The area under the plasma concentration vs. time curve, from 0-6 hr, (AUC) was shown to be approximately proportional to dose after single doses, but increased disproportionately with dose after chronic dosing. Apparent elimination of intact drug appeared more prolonged in the latter case, suggesting decreased ISDN plasma clearance after chronic dosing.

	AUC (0-6 hr) ng-hr/ml, (mean±S.E.)			
	15 mg	30 mg	60 mg	120 mg
single dose	15.6±3.4	26.7±3.8	49.8±5.9	93.2±12.5
chronic dose	18.6±1.6	43.7±4.8*	133 ±18*	304 ±34*

*Different ($p<0.001$) from corresponding single dose AUC.

In spite of elevated plasma ISDN concentrations after chronic dosing, responses in standing heart rate, systolic blood pressure, and exercise tolerance were considerably attenuated after chronic dosing. No apparent correlation between plasma concentration and effect was observed suggesting that ISDN at the site(s) of action might not be in rapid equilibrium with plasma drug and that ISDN tolerance in man was not a result of increased plasma drug clearance.

THE EFFECTIVENESS OF COMBINED VERAPAMIL AND NITRATE THERAPY IN PRINZMETAL'S VARIANT ANGINA

Albert E. Raizner, MD, FACC; William Gaston, MD, FACC; Robert A. Chahine, MD, FACC; Robert Fulweber, MD, FACC; Don Rochelle, MD, FACC; Richard R. Miller, MD, FACC; Robert J. Luchi, MD, FACC, Baylor College of Medicine and VA Medical Center, Houston, Texas.

Prinzmetal's variant angina which does not respond to nitrates (N) can pose a serious therapeutic problem. We studied the effectiveness of verapamil, a calcium antagonist, in combination with nitrates in 10 patients (pts), 4 males and 6 females, ages 42 to 74, (mean 57) years, who were refractory to nitrates alone. Angina frequency was 1-3 (6 pts), 3-5 (3 pts) and > 5 (1 pt) attacks per day. ST segment elevation during pain was documented in all. Serious arrhythmias during attacks included complete heart block (2 pts) and ventricular tachycardia (3 pts). Coronary arteries were normal in 7 and 3 had single vessel disease. Coronary artery spasm was documented in 7 pts during spontaneous (3 pts) or provoked attacks (4 pts). Verapamil, 40-120 (avg 80 mg) q 6 h was, initially, used alone in 3 pts. One became asymptomatic and 2 improved, but still had variant angina attacks (> 1/week). In 9 pts verapamil plus nitrates eliminated attacks in 7 pts, with marked improvement (< 1 attack/month) in 2 pts. Asymptomatic or improved status has been maintained during 3-12 month follow-up (mean 6.2). No episodes of ST elevation or serious arrhythmias have been noted on ambulatory 24 hour ECG obtained q 2-3 mos. Importantly, the only side effect was GI distress in 1 pt necessitating reduction in dosage of verapamil. Thus, verapamil in combination with nitrates is highly effective and safe in the treatment of Prinzmetal's variant angina.

SYSTEMIC AND CORONARY HEMODYNAMIC EFFECTS OF INTRAVENOUS DILTIAZEM IN PATIENTS WITH CORONARY ARTERY DISEASE

Julio F. Tubau, MD; Pierre Côté, MD, FACC; Martial G. Bourassa, MD, FACC, Montreal Heart Institute, Quebec.

The oral form of Diltiazem (D), a new calcium antagonist, seems to provide more benefit to coronary patients (pts) than the usual coronary dilators (nitroglycerin excepted). The effects of intravenous D in human are not well known. Therefore in 8 angina pts undergoing coronary arteriography, heart rate (HR), systolic blood pressure (SBP), stroke volume index (SVI), systemic vascular resistance (SVR) as well as coronary sinus blood flow (CSBF) and O_2 consumption by the heart (MVO_2) were measured at rest and throughout the infusion period. Two separate doses of D, 15 and 30 µg/kg/min, were administered for 10 min each with a 10 min interval in between.

	Rest (0 min)	D 15 µg (10 min)	D 30 µg (30 min)	(45 min)
HR(beats/min)	76±2	77±2	74±3	69±3**
SBP(mmHg)	133±6	130±5	121±6 *	122±7*
SVI(ml/beat/m^2)	38±2	44±3 *	45±4 *	
SVR(dyn.sec.cm^{-5})	1480±114	1336±99	1190±80***	
CSBF(ml/min)	142±24	158±23*	160±22*	
MVO_2(ml/min)	1470±269	1452±113	1300±87	

$\bar{X}$ ± SEM

*p<.05; **p<.02; ***p<.001 (compared to resting values)

These data show that D infused for a short period of time acts primarily as a peripheral and coronary vasodilator, decreasing SBP and SVR and increasing CSBF. However, 10 min after discontinuation of the drug, HR decreases significantly while SBP remains lower than at rest. Therefore D reduces HR in addition to its main vasodilator effect, but the onset of its negative chronotropic action is delayed significantly compared to afterload reduction. At this point D should induce a significant reduction in myocardial oxygen consumption.

EFFECT OF NIFEDIPINE ON EXERCISE TOLERANCE IN CORONARY ARTERY DISEASE

James V. Faris, MD, FACC; Richard H. Childress, MD, FACC; August M. Watanabe, MD, FACC, V.A. Medical Center and Krannert Institute of Cardiology, Indiana University School of Medicine, Indianapolis, Indiana

Nifedipine, a calcium-antagonist and arterial vasodilator, is known to be effective in treatment of Prinzmetal's angina, but may also be effective in angina due to fixed occlusive disease. To assess the effect of Nifedipine on treadmill exercise tolerance, nine stable angina patients with proven coronary disease underwent serial symptom limited exercise testing using a modified Balke protocol. Average exercise time, blood pressure response, double product and maximal ST-segment depression were compared for two control (placebo) treadmills versus the average of two Nifedipine treadmills. In a single-blind fashion, each patient received placebo or Nifedipine 10-20 mgm Q8H with a dose 1-2 hours prior to treadmill testing. All antianginal drugs except nitroglycerin were proscribed. The results are tabulated below:

	Control	Nifedipine	Sig.
Exercise Time(Seconds)	321±74.7	434±67.6	p<.001
Heart Rate	135±11.5	148±18.1	p<.01
Systolic BP(mmHg)	174±15.4	172±12.0	n.s.
Diastolic BP(mmHg)	105± 9.4	91± 5.9	p<.001
Mean BP(mmHg)	127±10.6	117± 6.7	p<.01
Double Product(HRxSBP/100)	235±24.6	259±28.3	p<.01
Maximal ST-Depression(mm)	1.9± 0.7	1.5± 0.8	n.s.

The data suggest Nifedipine significantly improves exercise tolerance, double product and peak heart rate achieved. The significant drop in mean and diastolic blood pressures may also play a role in the observed augmentation of exercise tolerance by reducing myocardial oxygen consumption.

EFFICACY OF DILTIAZEM IN VARIANT ANGINA

Steven Rosenthal, MD; Robert Ginsburg, MD; Irene Lamb, RN; Donald Baim, MD; John Schroeder, MD, FACC. Stanford University, Stanford, California.

Diltiazem is a new calcium "slow channel" blocker for the treatment of variant angina. Seven patients with variant angina documented to be secondary to coronary artery spasm completed a 10-week double blind study with three 2-week placebo periods and one 2-week period of Diltiazem 120mg per day and one 2-week period of Diltiazem 240mg per day. Response was assessed by number of episodes of pain and nitroglycerin consumption. There were 596 episodes of pain during 272 patient-days of placebo (2.19 per patient-day) with a significant reduction to 43 episodes during 95 patient-days of Diltiazem 120mg per day (0.45 per patient-day) (p<.05) and to 23 episodes during 93 per patient-days of Diltiazem 240mg per day (0.24 per patient-day) (p<.02). Nitroglycerin consumption was also significantly reduced from 2.01 per patient-day during placebo to 0.47 per patient-day during Diltiazem 120mg per day (p<.04) and to 0.24 per patient-day during Diltiazem 240mg per day (p<.03). Six of seven patients were complete or near complete responders; one of seven patients was an incomplete responder to 240mg per day. There were no complications or side effects. In conclusion, Diltiazem is an extremely effective drug in the treatment of variant angina.

HYDRALAZINE EFFECTS ON HEMODYNAMICS, CARDIAC CONTRACTILE FUNCTION AND MYOCARDIAL ENERGETICS IN ISOLATED MYOCARDIUM
Leigh D. Segel, PhD; Stephen V. Rendig, MS; Ezra A. Amsterdam, MD, FACC; Dean T. Mason, MD, FACC, University of California, Davis, California.

There is relatively little information regarding the direct cardiac effects of hydralazine (H), a vasodilator drug that has been applied in the treatment of cardiac failure. To clarify the direct cardiac effects of H, dose-response curves for this agent were evaluated in (1) isolated, working rat heart (IWRH); (2) isometric cat right ventricular papillary muscle (PM); and (3) isolated rabbit right atrium (RA). IWRH (n=6): there was a marked increase in coronary flow (72→99 ml/min/g, $p<.05$) at 10^{-6}M H, which remained significantly elevated at 10^{-5}M and 10^{-4}M H. Heart rate, cardiac output, left ventricular (LV) end-diastolic pressure and myocardial oxygen consumption (MVO_2) were not altered from control at 10^{-8}M - 10^{-4}M H. Cat PM (n=7): maximum developed tension (T), dT/dtmax and time to peak tension were unaltered by 10^{-7}M, 10^{-6}M and 10^{-5}M H but dT/dtmax was significantly elevated (34→36 g/sec/mm^2, $p<.05$) at 10^{-4}M and both T and dT/dtmax were increased (6.7→9.2 g/mm^2, 34→62, $p<.02$) at 10^{-3}M. Pretreatment with propranolol (10^{-6}M, n=7) abolished this positive inotropic effect. Isolated RA (n=5): spontaneous contraction rate was unaltered by 10^{-7}M - 10^{-5}M H, and diminished by 10^{-4}M and 10^{-3}M H (87→80→68 beats/min, $p<.005$). Thus, H was associated with unaltered pump performance and MVO_2, accompanied by augmented coronary flow in IWRH, while high concentration of H induced a positive inotropic effect mediated by beta-adrenergic stimulation in cat PM and elicited a negative chronotropic effect in rabbit myocardium. These data indicate that H has a primary coronary vasodilator effect and that at concentrations utilized clinically, its salutary circulatory actions are primarily related to extracardiac vasodilator actions.

AORTIC VALVE DISEASE
2:00-3:30

NATURAL HISTORY OF UNOPERATED AORTIC STENOSIS: HEMODYNAMIC PROGRESSION.
Stephen Wagner, MD, FACC; Arthur Selzer, MD, FACC, Pacific Medical Center, San Francisco, CA.

In order to examine factors that might predict progression rate in valvular aortic stenosis (AS) we reviewed serial hemodynamic studies in 50 adult pts of whom 7 had congenital, 22 rheumatic and 21 degenerative calcific aortic stenosis (CAS). Compared with the others those with CAS were older (62 ± 6 vs. 51 ± 9 yrs, $p < .001$) and had onset of murmur later in life (10 ± 4 yrs before first cath vs. 27 ± 9 yrs, $p < .001$). For all pts average values at first cath include age 54 ± 4 yrs, peak gradient 38 ± 27 mmHg, calculated aortic valve area (AVA) 1.3 ± .7 cm^2. A mean 3.5 ± 3 yrs later gradient was 57 ± 30 mmHg and AVA .8 ± .4 cm^2. Peak left ventricular (LV) pressure rose 9 ± 33 mmHg and cardiac output (CO) fell .5 ± .2 L/min. Pts appeared to distribute into rapid (n = 21) and slow (n = 29) progressors with respective rates of a change in AVA of .30 ± .21 vs. .02 ± .08 cm^2/yr. 76% of RP had CAS vs. 21% of SP ($p < .001$); they also differed in that 48% RP had serial fall in CO > 1 L/min vs. 17% of SP ($p < .05$). 6/21 RP developed critical AS with AVA ≤ .5 cm^2 and severe LV failure, all had CAS.

It is concluded that pts with CAS progress more rapidly than those with congenital or rheumatic etiology and in some reduction of calculated AVA is due to an impaired ability of the failing LV to move calcified leaflets rather than an anatomic reduction in valve orifice area.

THE ERGONOVINE STRESS TEST: A PROVOCATIVE TEST FOR DIFFUSE ESOPHAGEAL SPASM OR VARIANT ANGINA?
Kenneth L. Koch, MD, Ann Long, RN, R. Charles Curry, MD, and John R. Mathias, MD. University of Florida and the Veterans Administration Medical Center, Gainesville, Florida.

Intravenous ergonovine maleate (EM) during cardiac catheterization (CC) is used to evoke coronary artery spasm, resulting in chest pain (CP) and ST segment shifts. We have observed patients who experience CP in response to EM in the absence of spasm. The purpose of this study was to determine if EM produced esophageal dysfunction and CP. 15 patients were evaluated by routine esophageal manometry - 7 with CP(Group 1) and 8 without CP(Group 2). All patients had normal CCs. During esophageal manometry IV infusions of saline 10 ml or EM .2-.4 mg/10 ml were given. Following each infusion 25 dry swallows were analyzed. Means of the manometric responses are below:

	Group 1:Saline	vs EM	Group 2:Saline	vs EM
LESP[1] mmHg	18	28	19	20
% LESP ↑ w.EM		57[a]		6
% LESP relax	79	54[b]	48	49
% Repetitive	9	20[b]	10	16

[1]=Lower Esophageal Sphincter Pressure [a]=p<.05 EM vs EM
[b]=p<.05 Saline vs EM

During EM infusion Group 1 patients developed CP and significantly increased LESP, increased repetitive contractions, and decreased % LESP relaxation which resembled diffuse esophageal spasm. In contrast 4/8 Group 2 patients had CP with EM infusion but no changes in responses studied. In conclusion: 1) EM infusion induced both CP and esophageal motor dysfunction in Group 1 patients indicating esophageal disease. 2) Esophageal manometry with EM challenge may be a useful clinical test for angina-like CP by unmasking latent DES.

LATE SURVIVAL AFTER VALVE REPLACEMENT FOR SEVERE ISOLATED AORTIC INCOMPETENCE.
John Greves,MD; David Clark,MD; Barry Greenberg,MD,FACC; John McAnulty,MD,FACC; Albert Starr,MD,FACC;Shahbudin Rahimtoola,MD,FACC, University of Oregon Health Sciences Center, Portland, Oregon

Twenty-nine patients (pts) underwent aortic valve replacement (AVR) for severe, isolated aortic incompetence (AI) from 1973 to '78. Average (avg) age of the 23 men and 6 women was 42 yrs. Etiology for AI was aortic root disease in 11, congenital in 6, previous bacterial endocarditis in 6 and unknown in 6. Four had associated coronary artery disease; all received bypass grafts.

There were no hospital deaths; 5 yr survival is 61±10% (mean±SE). Of all 9 late deaths (LD), 5 (55%) were due to non-anticoagulation of mechanical prostheses.

In 24 anticoagulated pts, the 5 yr survival is 82±8%, avg mortality 3.6%/yr; 4 LD were due to heart failure, arrhythmia, sudden death, and unknown in 1 each. The 5 yr survival of pts with cardiac index (CI) >2.5 L/min/m^2 was 92±7% vs 57±19% in pts with CI <2.5 ($P<.02$);with mean Vcf ≥0.75 circ/sec was 91±8% vs 54±20% in mean Vcf<0.75($P<.05$) and with left ventricular (LV) ejection fraction (EF)≥0.45 was 94±6% vs 33±19% for EF <0.45 ($P<.001$). There were no deaths in pts with EF ≥0.50 at an avg followup of 5 yrs.

There were no significant differences in late survival between pts in Functional Class I & II vs III & IV, LV end-diastolic pressure of ≥20 vs <20 mmHg, LV end-diastolic volume of ≥210 vs <210 ml/m^2 , LV end-systolic volume of ≥110 vs <110 ml/m^2 and LV mass of ≥240 vs <240 g/m^2.

These data suggest that in pts with severe AI, AVR should be undertaken: 1) in all pts with impaired LV function at rest. The results will be better in those with mild impairment (e.g. EF as low as 0.45);and 2) in all symptomatic pts with normal LV function, even if symptoms are mild.

SEVERE VENTRICULAR ARRHYTHMIAS IN PATIENTS LATE AFTER AORTIC VALVE REPLACEMENT.

Alan H. Gradman, MD, FACC; Richard Shaw, MD; Harvey Berger, MD; Cynthia Crocco, BA; Mary Harbison, BA; Barry Zaret, MD, FACC, West Haven VAH and Yale University New Haven, Connecticut.

To gain insight into the issue of sudden cardiac death following aortic valve replacement (AVR), two 24 hour ambulatory ECG recordings and radionuclide left ventricular ejection fraction (LVEF) were obtained in 30 unselected patients (pts) with AVR an average of 4.5 years previously. Preoperatively, 38% had angiographically significant coronary artery disease, and 78% manifested left ventricular hypertrophy by ECG. Ambulatory ECG recordings were analyzed using the YALECG computer system which quantifies ventricular premature beats (VPB) by morphology and detects complex VPB patterns. Multiform VPB's were noted in all pts studied and ranged in average frequency from <1 to 72/15 mins. VPB's were infrequent (<10/15 min) in 21/30 pts and frequent (>10/15) in 9/30. These were associated with ventricular bigeminy in 25/30 (83%) and VPB couplets in 23/30 (77%). Strikingly, at least one episode of ventricular tachycardia (VT) was present in 14/30 pts (47%). Overall, LVEF ranged from 20 to 88%. Mean LVEF in pts with VT was 47±4%, compared to 62±4% in those without VT ($p<.005$). There was no difference in the incidence of coronary artery disease or left ventricular hypertrophy in pts with and without VT.

Conclusion: Advanced grades of ventricular arrhythmias, including a 47% incidence of VT, are common late after AVR and are associated with greater impairment in LV function. These arrhythmias may be related to the high incidence of sudden death after AVR.

AFTERLOAD REDUCTION THERAPY FOR CHRONIC SEVERE AORTIC INSUFFICIENCY: BENEFICIAL EFFECTS DURING REST AND EXERCISE.

Barry Greenberg, MD, FACC, Henry DeMots, MD, FACC, Edward Murphy, MD, FACC, Shahbudin Rahimtoola, MB, FACC, University of Oregon Health Sciences Center, Portland, Oregon.

The effects of isolated afterload reduction in patients (pts) with aortic insufficiency (AI) are uncertain. We evaluated the effects of hydralazine (H), a drug whose predominant effect is to reduce systemic vascular resistance (SVR), on cardiac performance both at rest and during exercise (ex) in 10 pts with chronic severe AI.

All pts had cardiac catheterization and angiography to document severe AI and exclude other significant valvular lesions. Ejection fraction was 0.52±.05(mean±SEM); it was reduced in 5 pts. Regurgitant fraction was 0.65±.03. Left ventricular end diastolic volume index was 191±12 cc/m^2.

At rest, optimal dose oral H (50-125mg) increased cardiac index (CI) from 2.7±.0 to 4.6±.3 L/min/m^2 ($p<.001$) and stroke volume index (SVI) from 34±3 to 46±4 cc/m^2 ($p<.001$); H reduced pulmonary artery wedge (PAW) from 14±3 to 9±3 mmHg ($p<0.10$) and SVR from 1409±103 to 896±71 dynes-sec-cm^{-5} ($p<.001$). Heart rate (HR) and mean arterial pressure (AP) did not change significantly.

Eight pts were also studied during maximal supine ex pre-H and at the same level of ex post-H. Although pre H ex alone reduced SVR from 1409±10 to 1105±166 dynes-sec-cm^{-5}, the addition of H caused a further reduction in SVR from 1105±166 to 644±56 dynes-sec-cm^{-5} ($p<.05$) and was associated with increased CI from 5.2±.6 to 6.8±.3 L/min/m^2 ($p<.05$) and reduced PAW from 21±4 to 12±2 mmHg ($p<.05$). HR did not change significantly; AP was reduced from 125±7 to 108±6 mmHg ($p<.05$).

We conclude that H improves cardiac performance both at rest and during ex and should be considered as alternative therapy in selected pts with chronic severe AI.

SYSTOLIC AND DIASTOLIC LEFT VENTRICULAR FUNCTION IN PATIENTS WITH AORTIC REGURGITATION BEFORE AND AFTER BIOPROSTHETIC VALVE REPLACEMENT

Ludger Goppel,MD; Serban Dacian,MD; Felicitas Kraus,MD; Donald Hall,MD; Werner Rudolph,MD,FACC, German Heart Center, Munich, Germany

To assess alterations in left ventricular function, studies were performed before and after valve replacement in 10 pts with aortic regurgitation. Determinations of mean systolic stress (MSS), the myocardial performance index (MPI), chamber stiffness (kp) and muscle stiffness (ks) were carried out as well as measurements of pressures, cardiac index (CI), end-diastolic (EDVI) and end-systolic (ESVI) volume indices, ventricular mass (VM) and the ejection phase parameters (EF, mVcf). Postoperatively the average pressure gradient was 13.7±6.2 mmHg with valve orifice area of 1.98±0.4 cm^2, pressures and CI were normal. EDVI decreased substantially in all pts (188 vs. 108 ml/m^2) but only in 50% to within normal limits. The VM also decreased markedly (238 vs. 143 g/m^2) but remained elevated in 8 of the pts. EF and mVcf, which were slightly diminished preoperatively, increased (0.54 vs. 0.58 and 0.58 vs. 0.63 circ/sec, respectively). MSS decreased markedly (326 vs. 185 g/cm^2) and the MPI decreased moderately (43 vs. 32 g/cm^2·sec). While all pts had normal kp (0.018 vs. 0.0175 ml^{-1}) there was a decrease in the preoperatively elevated ks (12 vs. 4.7). The results of this study show that the increase in EF and mVcf are not due to improved contractility but rather to a marked reduction in afterload. The further decrementation of the MPI can be explained by persistance of an elevated VM (wall thickness) in the presence of near-normal volumes and, subsequently, subnormal load conditions which lower ventricular contractility requirements. The normalization of ks negates irreversible fibrotic involvement.

EARLY DETECTION OF AORTIC ROOT ABNORMALITIES IN ANKYLOSING SPONDYLITIS BY TWO-DIMENSIONAL ECHOCARDIOGRAPHY.

Charles R. Tucker, MD; Robert Fowles, MD; Andrei Calin,MD; Richard L. Popp, MD, FACC; Stanford University, Stanford, CA.

Mild aortic root dilatation, cusp thickening and subvalvular fibrous ridges have been reported as characteristic in patients (pts) with ankylosing spondylitis (AnkSp) and aortic regurgitation. Thirty pts with AnkSp (7 also had Reiter's syndrome) without clinically apparent cardiac involvement were studied using phased array two-dimensional echocardiography (2DE) and sector-directed M-mode to determine the prevalence of aortic abnormalities. Aortic root dimensions were measured at the aortic annulus, the tip of the cusps and 0.5-1.5 cm above the cusps. The 2DE study was also analyzed for qualitative abnormalities. The dimensions were compared between pt subgroups separated according to age, duration of AnkSp, severity of AnkSp, and presence of qualitative abnormalities; and with 14 normals. No abnormally increased aortic dimensions suggestive of aortic dilatation were found in any of the groups, but 2 pts had aortic dimensions greater than 4.2 cm at the valve (normal 3.9 cm). Also, 8 pts had discrete areas of increased bright echoes below the right and/or noncoronary cusps suggestive of a subaortic "bump" and 2 pts had increased aortic cusp echoes suggestive of thickening and/or fibrosis. These changes tended to occur more commonly in older pts and with more severe disease. We conclude that aortic root changes suggestive of inflammation and/or fibrosis occur in asymptomatic AnkSp pts. Dilatation usually does not occur without aortic regurgitation.

MITRAL VALVE PROLAPSE
4:00-5:30

MITRAL REGURGITATION IN MITRAL VALVE PROLAPSE: DETECTION BY PULSED DOPPLER ECHOCARDIOGRAPHY VERSUS ANGIOGRAPHY AND CARDIAC AUSCULTATION. CORRELATION WITH CARDIAC ARRHYTHMIAS BY AMBULATORY MONITORING

Abid A. Shah, MD; Alan D. Waggoner, RDMS; James B. Young, MD; Richard R. Miller, MD, FACC; Miguel A. Quinones, MD, FACC, Baylor College of Medicine, Houston, Texas.

The presence of mitral regurgitation (MR) was assessed by pulsed Doppler echocardiography (PDE) in 88 patients (pts) with M-mode echo evidence of mitral valve (MV) prolapse (P). Pt's age averaged 42 yrs, range:12-84 yrs. PDE evidence of MR [systolic turbulence in the left atrium (LA) behind MV] was observed in 45/88 (51%) pts with MVP. Left ventricular (LV) angiograms in 31/88 pts [5 with, 26 without coronary artery disease (CAD)] revealed MR in 21, 19 with (+) PDE [91% sensitivity (Sn)] and no MR in 10, 9 with (-) PDE [90% specificity (Sp)]; predictive value of PDE=95%. Comparison with auscultation in 72/88 pts revealed isolated apical systolic murmurs typical of MR in 33 pts, 31/33 (94%) with MR by PDE; absent murmurs in 24, 20/24 (83%) without MR by PDE, and atypical systolic murmurs in 15 pts, 5/15 (33%) with MR by PDE (overall Sn of auscultation=90%, Sp-63%). M-mode predictors of MR severity (MV excursion >25 mm, LA dimension >40 mm, LV dimension>56 mm) were seen infrequently (40%, 42% & 36% respectively). Ambulatory 24-hr Holter monitor in 41 pts (31/41 with coronary angiography; 2 with CAD) revealed either ventricular (V) bigeminy (B), V multiforms (M), couplets (C), V tachycardia (T) or supra VT in 11/18 (61%) pts with MR versus 5/23 (22%) pts without MR ($p<0.01$). Incidence of VM, C or VT was greater with MR (4/18 or 22%) than without MR (0/23) ($p<0.02$). Thus, PDE is both accurate (90%) and superior to auscultation in detecting MR in MVP. Clinical recognition of this subgroup of MVP pts is important since they appear to be associated with a higher incidence of arrhythmias including VM, C & VT.

END-SYSTOLIC RETRACTION OF THE LEFT VENTRICULAR POSTERIOR WALL: A SPECIFIC ECHOCARDIOGRAPHIC MARKER OF PROLAPSING MITRAL VALVE.

James B. Young, MD; Alan D. Waggoner, RDMS; Miguel A. Quinones, MD, FACC; William L. Winters, Jr., MD, FACC; Richard R. Miller, FACC, Baylor College of Medicine and The Methodist Hospital, Houston, Texas.

An end-systolic posterior retraction (ESPR) of the basal left ventricular (LV) posterior wall(PW) may be seen by M-mode echocardiography (ECHO) in patients (pts) with mitral valve (MV) prolapse (P). In 100 random ECHO-studied MVP pts (78 late, 22 pansystolic MVP) 36 demonstrated ESPR. Pansystolic MVP was more frequent in ESPR (14/36, 39% vs 8/64, 13%; $p<0.002$). Mean (±SEM) posterior excursion of late prolapse was greater in pts with ESPR: 5.0±1 mm vs 3.6±1 mm ($p<0.002$). There were no differences ($p>0.05$) in ECHO LV shortening fraction, electrocardiographic findings or pt symptoms between groups. In a prospective review of 1697 subsequent consecutive ECHO, 113 (7%) had MVP; ESPR was noted in 35% of these pts. Only 5 pts without MVP had ESPR (3 with aortic insufficiency and one each with LV hypertrophy and mitral stenosis). Specificity of ESPR in MVP was therefore 99.6%. LV angiography (angio) in 42/213 ECHO MVP pts demonstrated 38 pts with definite MVP by angio (7 with ESPR) and 4 pts with equivocal MVP (none with ESPR). Elongated LV chambers were noted in 4/7(57%) ESPR pts vs 4/35(11%) without ESPR($p<0.02$). No differences were seen between groups in prevalence of mitral regurgitation (MR). Thus, ESPR is a highly specific marker of MVP associated with an increased duration and depth of prolapse by ECHO. Abnormalities of LV contour by angio are often seen in pts with ESPR without MR. It is postulated that ESPR may represent premature relaxation of LV PW segment due to pronounced MVP and altered LV geometry. Because of its high specificity this ECHO sign may be useful in assessing presence of MVP when MV motion is not entirely diagnostic.

CONCORDANCE BETWEEN MITRAL VALVE PROLAPSE AND ABNORMAL COLLAGEN SYNTHESIS IN PHENOTYPICALLY EXPRESSED AND OCCULT EHLERS DANLOS SYNDROME

Allan S. Jaffe, MD; Edward M. Geltman, MD; Michael E. Cain, MD; Jouni Uitto, MD, PhD, Washington University, St. Louis, Mo.

To determine whether mitral valve prolapse (MVP) is a consistent manifestation of the underlying derangement in type IV Ehlers Danlos (ED), we studied the family members of a propositus. Seven subjects were investigated prospectively for the presence of MVP and for defects in the synthesis of type III collagen, the characteristic biochemical abnormality in this form of ED. No subject had stigmata suggestive of Marfan's syndrome. To assess collagen synthesis, cultured skin fibroblasts were incubated with ^{3}H-proline. Types I and III collagen were separated by DEAE-cellulose chromatography or by SDS-polyacrylamide gel electrophoresis. The presence of MVP was determined by 2 blinded observers by analysis of 2-D echocardiograms (echo). Two subjects had entirely normal production rates of type III collagen and normal dermatologic examinations. Neither of these subjects had MVP by echo. In contrast, the remaining 5 subjects had MVP by echo and either a click, a murmur or both on physical examination. These subjects all produced significantly less type III collagen [28 to 73%, mean=48±5 (SE)], than controls ($p<.005$) and than subjects with normal echoes ($p<.005$). Despite abnormal collagen production in these 5 subjects, only 2 exhibited clinically apparent cutaneous abnormalities. These results demonstrate genetic concordance between abnormal collagen production and MVP in a kindred with type IV Ehlers Danlos syndrome. In addition they suggest that MVP may be the presenting feature or only evident manifestation (a form fruste) of the Ehlers Danlos syndrome.

PREOPERATIVE M-MODE ECHOCARDIOGRAPHY AS A PREDICTOR OF SURGICAL RESULTS IN CHRONIC MITRAL INSUFFICIENCY

Claudio L. P. Cunha, MD; Emilio R. Giuliani, MD, FACC; Valentin Fuster, MD, FACC; Robert O. Brandenburg, MD, FACC; Dwight C. McGoon, MD, FACC, Mayo Clinic and Mayo Foundation, Rochester, MN.

Long-term results of surgical treatment for chronic mitral insufficiency (MI) cannot be accurately predicted by preoperative clinical assessment. To determine whether preoperative M-mode echocardiography (echo) can help in predicting surgical results, we studied 96 patients (pts) who had operation for MI--83 for mitral valve replacement and 13 for valve repair--performed between 1973 and 1977. Ages ranged from 18 to 76 years, mean 56. Sixty-one pts were male and 35 were female. The interval between preoperative echo and operation was 1 day to 6 months, median 14.5 days. Evaluation of surgical results was based on curves of estimated probability of 5-year survival. The following echo parameters were associated with survival: (1) end-systolic left ventricular internal dimension (LVIDs) ($P<0.001$); (2) percent change in LV dimension (%ΔD) ($P<0.01$); (3) end-diastolic LV internal dimension (LVIDd) ($P<0.05$); and (4) percent change in septal thickness (%ΔThS) ($P<0.05$). Higher 5-year mortality was seen in pts with LVIDs >50 mm, %ΔD≤30%, LVIDd >70 mm, and %ΔThS ≤30%. Atrial fibrillation, which was related to larger left atrial (LA) dimension ($P<0.01$), was also associated with worse prognosis ($P<0.01$). LA dimension alone did not correlate with survival, but it improved the predictive ability of %ΔD ($P<0.05$). Cause of MI and functional classification were not related to postoperative results ($P>0.1$). In conclusion, preoperative left ventricular dimensions and function, as evaluated by M-mode echo, and cardiac rhythm are useful prognostic indicators in pts having surgery for MI.

MITRAL VALVE PROLAPSE SYNDROME: ANTHROPOMETRIC, SEXUAL AND CLINICAL FEATURES

Bernard King, MD; Harisios Boudoulas, MD, FACC; Mary E. Fontana, MD, FACC; Charles F. Wooley, MD, FACC; The Ohio State University College of Medicine, Columbus, Ohio

The spectrum of the mitral valve prolapse (MVP) syndrome is incompletely defined. Three hundred thirteen patients (86 M, mean age 34.4± 14 (SD) yrs and 227 F, mean age 34.3± 15 yrs) with auscultatory MVP were seen for symptoms (Sx) or murmur evaluation from 1963-1977. Height/weight ratio was greater in MVP compared to normals (M .46± .04 (SE) vs .42± .03, p<0.01, and F .54± .02 vs .47± .04, p<.01). Arm span/height ratio was 1.02± .03 in M and 1.01± .03 in F.

Mean age of Sx onset was the same in M and F (30.6 vs 29.9 yrs). Chest pain was the initial complaint in 50% M vs 36% F (p<.01). Conversely, 42% F presented initially with palpitations compared to 21% M (P<.01). Neurologic Sx (including syncope), an initial manifestation in 9.5%, were present sometime in 15% of all. Chest pain was noted by 60% of both sexes. Palpitation (75%), fatigue (48%), dyspnea (34%) and arrhythmias (54%) were more frequent in F than M (48%, 28%, 16%, 34%, respectively, p<.01). The number of Sx was greater in F than M (2.9± .1 vs 1.9 ± .1, p<.01); 10.5% of F and 16% of M were asymptomatic.

Distinctive anthropometric features; sexual differences in habitus, number and type of symptoms; previously documented (by this group) evidence of increased adrenergic activity; reported sleep disorders and autonomic dysfunction - permit definition of the systemic process, the MVP syndrome, and support the concept that MVP syndrome is a constitutional-neuroendocrine-cardiovascular process.

MITRAL VALVE PROLAPSE : POSSIBLE MANIFESTATION OF A CONGENITAL NEURO-ECTO-MESODERMAL HISTODYSPLASIA-

Philippe Jean-Louis -Chef de clinique -Service cardiologie Maurice Pont)-Hopital Croix-Rousse -Lyon 69317 - France.

The nosology of mitral valve prolapse (MVP) is as yet unknown.

To evaluate the possibility that MVP may be a manitestation of a congenital histodysplasia,We studied 130 men(M)and women(W)with MVP proved by phono(P) and echocardiography(E) without any other echocardiographic abnormality -I)Psychologicaltest-Rickels'rating scale(RRS)-was randomly administered to 60 MVP(MW) and 30(MW) with acquired valvular heart disease-MVP scored significantly higher on the depression, somatization, sleep disorder, anxiety scales of the RRS.The global psychopathological score was significantly higher in MVP(P<0,01).II)23% of the women with psychosomatic digestive disorders had MVP proved by P and E(prospective study). III) Dermatological examination was performed in 50 MVP(MW) : 28 had ichthyosis (xerodermia) and/or café au lait spots(24) and/or polythelia(2)and/or lentigines(31)and/or lipomatosis(3)(prospective research of MVP in patients with these epidermal manifestations is being performed)-IV)Vertebrothoracic abnormalities were comparable to those previously described and found in 100%(scoliosis and/or straight back and/or pectus excavatum etc.).Perhaps the link between MVP, dermatological, psychopathological and vertebrothoracic abnormalities could be explained by a single neural crest and mesodermal embryonic tissue defect during the 4th to 8th week of embryonic development.(MVP has an autosomal dominant mode of inheritance and is known to be associated with connective tissue disorders such as Marfan's syndrom, Ehlers Danlos syndrom etc.).This study suggests that MVP is a manifestation of congenital neuro-ecto-mesodermal histodys plasia-The neurogenic factor (central and peripheral) would explain many symtoms and features associa ted with MVP.

SUDDEN DEATH: TREATMENT OF VENTRICULAR TACHYARRHYTHMIA
2:00-5:30

RADIONUCLIDE VENTRICULOGRAPHY IN 121 SURVIVORS OF OUT-OF-HOSPITAL VENTRICULAR FIBRILLATION

James L. Ritchie, MD, FACC; Gene B. Trobaugh, MD; Alfred P. Hallstrom, PhD; Glen W. Hamilton, MD; Leonard A. Cobb, MD, FACC; Seattle Veterans Administration Hospital and Harborview Hospital, University of Washington, Seattle, Wa.

Radionuclide left ventriculography was performed at rest (R) in 121, and at R and maximal supine bicycle exercise (EX) in 66 survivors of out-of-hospital ventricular fibrillation (VF) attributed to coronary artery disease (CAD) (103 male, 18 female, mean age 58). Mean R ejection fraction (LVEF) overall was .41±.17 (n=121). Resting LVEF was below .30 in 36% of patients, .31-.50 in 31%, and >.50 in 33%. Regional dyskinesis was present in 14%, akinesis in 37%, and hypokinesis in 29%. Mean EX-LVEF was .39±.17 (compared to mean R-LVEF of .43±.17; n=66). At an average of 13.2 months of known followup, 10 of 118 (8%) patients had cardiac death or repeat VF. Mean R-LVEF in non-survivors was .30±.16 vs. .42±.17 (p<.015) in survivors. Non-survivors had more regions of akinesis or dyskinesis (7/8, 88%) than survivors (39/82, 48%; p<.001). The magnitude of LVEF depression with exercise was not greater in non-survivors (.03 vs. .04, p=NS).

We conclude that: 1) Marked depression of LV function is not the common denominator of out-of-hospital VF; two thirds of patients are either normal (EF>.50) or have moderate (EF>.30) LV dysfunction. Many such patients are thus possible candidates for further medical or surgical therapy. 2) Recurrent VF/death is associated with a low R-LVEF and more severe wall motion abnormalities, but not with the extent of EX-induced LV dysfunction.

LACK OF EFFECT OF ASSOCIATED MYOCARDIAL INFARCTION ON LONG-TERM SURVIVAL OF OUT-OF-HOSPITAL VENTRICULAR FIBRILLATION.

Bim Sharma, MD; Morrison Hodges, MD, FACC; Richard W. Asinger, MD; Gary Francis, MD, FACC. Hennepin County Medical Center & the University of Minnesota, Minneapolis, Minnesota.

Currently the prognosis of patients who survive out-of-hospital ventricular fibrillation (OHVF) is predicated on whether or not there is an attendant myocardial infarction. This report concerns the long term survival (1974-1978) of 90 patients (78 males and 12 females) who were discharged from the hospital ambulatory with full mental faculties after OHVF. Average age was 58.3 years (range 15-83). The occurence of acute myocardial infarction at the time of OHVF was determined by serial ECG, serial cardiac specific enzyme (CK-MB) and Tc pyrophosphate scans. Three groups emerged: 1) patients who sustained definite acute myocardial infarction (45 patients); 2) patients with no acute myocardial infarction (32 patients) and 3) an uncertain group (13 patients). Follow-up of the 90 patients from the period 1974-1978 revealed that 16 of 45 patients in acute myocardial infarction group (35.6%), 9 of 32 in no acute myocardial infarction group (28.1%) and 4 of 13 uncertain patients (30.8%) sustained sudden death. The survival curve of all 90 patients indicated the survival rate at 1, 2, 3, 4 yrs to be 78%, 64%, 53% and 43% respectively. The survival curves of acute myocardial infarction, no acute myocardial infarction, and uncertain groups were not different from each other.

This study differs from others in the following ways: a) There was no uncertain group in previous studies. In this study 13 pts (uncertain group) had no clear-cut evidence which allowed either diagnosis or exclusion of acute myocardial infarction; and b) The acute myocardial infarction group had as a high mortality as those without. Thus, in our study, the occurrence of acute myocardial infarction at the time of OHVF does not seem to affect long-term survival.

INDUCIBLE VENTRICULAR TACHYCARDIA IN PATIENTS WITH OUT OF HOSPITAL VENTRICULAR FIBRILLATION

Richard Kehoe, MD; Robert A. Bauernfeind, MD; Christopher R.C. Wyndham, MD, FACC; Sheridan Meyers, MD, FACC; James Talano, MD, FACC; Kenneth M. Rosen, MD, FACC, Northwestern University School of Medicine, Chicago, Illinois.

Electrophysiological studies (EPS) were performed in ten consecutive patients (pts) with resuscitated out of hospital (OOH) ventricular fibrillation (VF). Five (50%) had inducible ventricular tachycardia (VT), and are described herein. These five ranged in age from 53-56 yrs and four were male and one female. Four had coronary disease (triple in three and single in one), all with remote infarction eight weeks to 4 years prior to, and no acute infarction subsequent to OOH VF. One had primary myocardial disease and three episodes of OOH VF. None had VT documented prior to VF. EPS performed post OOH VF demonstrated replicable induction of sustained paroxysmal VT (PVT), utilizing V_2V_3 stimulation coupled to sinus or a driven ventricular rhythm. The cycle length (CL) of induced PVT ranged from 240-290 (274 + 20 msec) with QRS morphology of left bundle branch block pattern in two and right bundle branch block in three pts. Induced PVT was poorly tolerated, necessitating at least one cardioversion in four of the pts (two because of degeneration to VF and two because of inability to terminate PVT). Repeat EPS were performed in all five pts utilizing one or more interventions. In four of the pts, an intervention totally prevented induction of PVT (IV procaineamide in one, oral disopyramide in one, oral quinidine in one, and coronary bypass with aneurysmectomy in one). In the remaining pt, oral disopyramide increased CL of induced PVT from 290 to 400 msec. The pts have been followed on the drugs specified above (no drug in the surgical pt) for 2-9, 5.6 + 3 mos (28 pt mos of follow-up) with no recurrence of VF. In conclusion: 1) Replicable PVT is inducible in some pts with OOH VF. 2) This replicable PVT is fast, poorly tolerated, complicates organic heart disease, and is probably the inducing rhythm for OOH VF. 3) Chronic EPS of the induced PVT is difficult but feasible, and may allow demonstration of a favorable response to intervention. It is hoped that chronic EPS will allow prediction of therapy preventing subsequent VF.

SUDDEN DEATH AFTER MYOCARDIAL INFARCTION: RUNS OF VENTRICULAR PREMATURE BEATS AND R ON T AS HIGH RISK FACTORS

William Ruberman, MD, FACC; Eve Weinblatt, AB; Judith D. Goldberg, ScD; Charles W. Frank, MD, FACC
Health Insurance Plan of Greater New York, New York, NY

Risk of sudden coronary death over 5 years is examined among 1739 male MI survivors who were monitored for one hour at a baseline examination. High mortality associated with VPB, reported previously from the HIP study, persists in this extended observation period. Complex VPB (runs of 2 or more, R on T, multiform or bigeminal VPB) detected in the monitoring hour are associated with over twice the risk of sudden death found in the absence of such beats (5-yr mortality of 18.1% vs 7.7%, age-adjusted). Multivariate analyses confirm that the men with complex VPB have 2.4 times the sudden death risk of other men when the influence of other important prognostic features is controlled (congestive heart failure, ST depression, heart rate, elevated blood pressure). The longer observation period, with a total of 149 sudden coronary deaths, permits study of the role of specified types of VPB. The presence of runs or early VPB is uniquely related to excess risk of sudden death:

Findings in 1 hr of monitoring	No. pts.	5-yr probability of death (%) Sudden coronary	All causes
Runs/early VPB	202	24.8	37.0
Other complex VPB	260	13.4	33.0
Simple VPB only	433	11.9	25.6
No VPB	844	5.6	21.4

The gradient also seen for all causes of death reflects primarily the steeper gradient found for sudden deaths. Although VPB are relatively more common among MI patients with other indicators of myocardial dysfunction, the excess risk for sudden death in the presence of runs/early VPB among men with complex VPB (or with simple VPB only among other men) is independent of these other variables.

ECHOCARDIOGRAPHIC DETECTION OF PATIENTS AT HIGH RISK FOR RECURRENT VENTRICULAR FIBRILLATION

Jeffrey A. Werner, MD, FACC; David Salerno, MD; Leonard A. Cobb, MD, FACC; Gene B. Trobaugh, MD; Carolyn Janko; Max Hedgecock, Harborview Medical Center, University of Washington, Seattle, WA.

To establish the role of echocardiography (E) in the clinical management of patients (PTS) surviving out-of-hospital ventricular fibrillation (VF), E was performed in 124 PTS an average of 4.2 months after VF - M-mode (ME) in all and two dimensional (2DE) in 55 PTS. Coronary artery disease (CAD) was present in 98/124 PTS and documented by ECG Q waves, typical myocardial perfusion imaging abnormalities, coronary angiography and/or autopsy. Only 3/55 PTS undergoing 2DE did not have one or more of these diagnostic data. An E diagnosis of ischemic cardiomyopathy (ICM) was made if one or more akinetic (ASEG) or dyskinetic segments (DSEG), frank aneurysm (AN) and left ventricular dysfunction (LVD) was present. By 2DE, 34/55 PTS had at least one ASEG or DSEG and 17/55 PTS had AN. Of PTS with documented CAD, 34/39 PTS were diagnosed as ICM by 2DE compared to 3/13 PTS without CAD but diagnosed as ICM by 2DE ($p=.0001$). 1/52 PTS had normal 2DE but CAD. Severe ICM by E was present in 11/16 PTS having recurrent VF or other cardiac death compared to 16/108 PTS with this E diagnosis but without such clinical events ($p<.005$).
CONCLUSIONS: A diagnosis of ICM by E and particularly 2DE was sensitive for underlying CAD in survivors of VF. Furthermore, E may predict PTS at high risk for recurrence of VF.

AGE RELATED CHANGES IN PROPENSITY TO VENTRICULAR FIBRILLATION IN PUPPIES

Fany A. Kralios, M.D.; C. Kay Millar, M.D.; University of Utah, Salt Lake City, Utah

Developmental changes in propensity to fibrillation were studied in 46 puppies of 6 age groups between 1-6 weeks (wk) by ventricular fibrillation threshold (VFT) determinations, using the single pulse scanning technique. In each preparation 6 to 14 VFT determinations were obtained within a 3 hour period and averaged, since no systematic time effect was demonstrated. Analysis of variance of average values from each animal showed significant differences among age groups $p<0.005$. Mean group values showed a significant linear regression with age with $VFTmA = 8.4 + 2.35 \cdot wk$, $r = 0.98$, $p<0.001$. Similar study of 14 additional puppies 7-11 wk showed plateau of the VFT to age relationship at a level not differing significantly from that of a group of 10 adult dogs which averaged 26.5 ± 2.2 mA. Spontaneous defibrillation was the rule (96±2%) during the first wk and common (79±6%) during the second. However, it was less common during the third wk (46±9%) and rare during the subsequent weeks. Findings indicate that propensity to fibrillation is highest in the first wk and decreases linearly towards adult levels by the sixth. Whether this is due to changes in heart size and/or other developmental variable(s) is unclear. In contrast, maintenance of fibrillation is lowest the first wk and increases linearly towards the fourth. Thus there may be a critical time during development when the heart is both vulnerable to fibrillation and has the ability to maintain it. Since the incidence of sudden infant death (SID) in humans is highest the third month after birth, our finding may support the notion that interplay of factors responsible for initiating and for maintaining fibrillation may play a role in SID.

HOLTER 24 HR RECORDINGS IN POST MI PATIENTS IN DOUBLE BLIND TREATMENT WITH SULFINPYRAZONE

T.Edward Cuddy, MD, FACC; N.Donen, MD; H.Karlinsky, J.McManus, RN; H.Larson, University of Manitoba, Winnipeg, Canada.

Our participation in the Anturane Reinfarction Trial (ART) provided us the opportunity of studying the incidence of arrhythmias in patients with prior myocardial infarction treated in a double blind fashion with 800 mg sulfinpyrazone (S) or matching placebo (P). None were on antiarrhythmic drugs. For various reasons Holter 24 hr monitoring was not carried out at a uniform time post infarction, but 40 recordings on S and 37 on P were analyzed. The Lown Classification 0-V system was employed. Also, the frequency of VPC's was analyzed with cut points of < & > 30/hr. No difference was found with frequency analysis alone, but the Lown Classification revealed significant differences between S & P as seen below:

	S	P
Lown Class 0-III	27/40 (67.5%)	15/37 (40.5%)
Lown Class IV-V	13/40 (32.5%)	22/37 (59.5%)
*2 tailed chi square		*p<.05

The significant reduction in serious arrhythmias in patients treated with S could not be explained by any other identified differences in the patients, as to site of infarction, time of monitoring, or arrhythmias witnessed in the CCU. Although not designed as a trial to show an antiarrhythmic effect of S, the results are consistent with the reduction in sudden deaths reported in the ART studies and with animal studies showing pretreatment with S reduces serious ventricular arrhythmias after coronary occlusion.

TREATMENT OF PVCs WITH TOCAINIDE, QUINIDINE SULFATE, AND PLACEBOS

James E. Wasenmiller, MD; Wilbert S. Aronow, MD, FACC; University of California, Irvine

We performed a randomized study investigating the efficacy of tocainide 600 mg three times daily with placebos and quinidine sulfate 300 mg four times daily with placebos in 41 patients with at least 60 PVCs per hour during Holter monitoring. The 41 patients received placebo 1 during study weeks 1-2 and placebo 2 during study weeks 11-14. Tocainide was administered to 22 patients and quinidine to 19 patients during study weeks 3-10. Two 24 hour Holter recordings were obtained on placebo 1, four 24 hour Holter recordings on tocainide or quinidine (end of weeks 4,6,8, and 10), and two 24 hour Holter recordings on placebo 2 (end of weeks 12 and 14). Neither the subjects nor the interpreter of the Holter recordings (Anthropometrics, Inc.) knew which medication was being administered. Adverse effects occurred in nine of 19 patients (47%) on quinidine and in 14 of 22 patients (64%) on tocainide. Adverse effects caused six of 19 patients (32%) on quinidine and 13 of 22 patients (59%) on tocainide to discontinue medication. Reduction of PVCs at least 75% from placebos 1 and 2 occurred in six of 13 patients (46%) on quinidine and in one of nine patients (11%) on tocainide. Using Lown's classification, a reduction in one grade of PVCs occurred in eight of 13 patients (62%) on quinidine and in two of nine patients (22%) on tocainide. Neither quinidine sulfate nor tocainide suppresses PVCs with a high incidence of efficacy and a low incidence of adverse effects.

MANAGEMENT OF REFRACTORY VENTRICULAR TACHYCARDIA WITH APRINDINE.

Philip R. Reid, M.D., FACC, H. Leon Greene, M.D., FACC, Allen H. Schaeffer, M.D. and Ann R. Pendleton, M.S. Johns Hopkins University, Baltimore, Maryland.

Aprindine (Ap) was evaluated for symptomatic hypotensive ventricular tachycardia (VT), refractory to conventional antiarrhythmic agents, in 129 patients (pts): Coronary artery disease (68%), cardiomyopathy (16%), mitral prolapse (10%), rheumatic (4%), and congenital heart disease (2%). Forty seven pts (37%) were survivors of sudden death (SD). A good clinical response (CR) was defined as: elimination of VT and ➔ 75% reduction in ventricular premature beats on repeated Holter monitors prior to discharge with maintenance of therapeutic predose Ap levels. In 45 pts electrophysiologic testing evaluated intraventricular reentry phenomena (IVR) during Ap administration.

A good CR was present in 103 pts (80%) during a followup of 1.4±0.1 (SEM) yrs on 112±4 mg/d Ap with serum levels of 1.8±0.1 ug/ml. In 26 pts (20%) without good CR, followup was 0.3±0.1 yrs, on a dose of 144±10 mg/d with serum levels of 1.6±0.1 ug/ml. Recurrent SD occurred in 14/103 pts with otherwise good CR and in 9/26 pts with bad CR ($p < 0.03$). There were no differences in diagnoses, prior SD or serum Ap levels between good and bad CR. Testing for IVR after Ap correctly predicted the outcome of 7/11 with bad CR and 29/34 pts with good CR ($p < 0.003$).

Thus, pts who have good CR on Ap have a reduced incidence of recurrent SD compared to pts with bad CR. CR can be predicted by suppression of IVR and/or arrhythmias on Holter monitor.

CARDIAC OUTPUT DURING VENTRICULAR FIBRILLATION IN THE COUGHING DOG

John P. Rosborough, PhD; Mark Hausknecht, BS; J. Michael Criley, MD, FACC; Daniel Garner, BS; James T. Niemann, MD, Baylor College of Medicine, Houston, Texas

Observations in man have established that consciousness can be maintained by vigorous coughing during life threatening arrhythmias. The mechanisms by which cerebral and coronary perfusion are maintained by coughing have been studied in dogs by cineangiography and manometry, indocyanine green transit times, and flow measurements. Cineangiography (60 fps) with pressure measurements established that (1) left ventricular (LV), aortic (Ao), and airway pressures in excess of 100 torr can be produced by coughing; (2) outflow comes from the root of the Ao for 90 msec, then the Ao and mitral valves open for 400 msec, with flow from the vessels of the lung through the left atrium and left ventricle maintaining cerebral circulation; (3) flow out of the chest is confined exclusively to the brachiocephalic vessels with flow *from* the descending aorta going headward; (4) during the post-cough phase of the cycle there is a sufficient Ao pressure gradient to perfuse the coronary vasculature and there is forward flow down the descending aorta at this time. With indocyanine green, there is a mean transit time of 22 sec from the pulmonary trunk to the root of the Ao with a variety of coughs varying in force, duration, and frequency. Conventional, intravascular, electromagnetic fluid-velocity measurements in the coughing, arrested dog show that brachiocephalic flow may be up to 80% of control flow. Pressure gradients in the thorax produce flow of blood out of the thoracic reservoirs, by establishing a pressure gradient between the intrathoracic vessels and extrathoracic outlets in a manner not unlike a major aspect of conventional, basic CPR as described recently.

ELECTROPHYSIOLOGICAL CHARACTERIZATION OF MYOCARDIAL INJURY INDUCED BY DEFIBRILLATORY SHOCKS ON DOGS

Gary J. Anderson, MD, FACC, Joseph Reiser, Ph.D., and Hugh McAllister, MD., FACC. William Likoff Cardiovascular Inst, Hahnemann Medical College & Hospital, Philadelphia, Penna.

The purpose of this study was to characterize myocardial injury induced by defibrillation. Anesthetized mongrel dogs were given two transthoracic shocks, each 1 minute apart, at an energy level of 10 watt-sec/kg. Following the shocks, the animals were monitored for 2-3 hours. Of eight animals studied, transient AV block was observed in 2, ventricular tachycardia in 2, ventricular extrasystoles in 5, and no acute arrhythmias in 3. After 48 hours, animals were again anesthetized, the chest opened by lateral thoracotomy, and the heart was suspended in a pericardial cradle to allow for visual examination. Discrete visible dyskinetic segments and epicardial hemorrhage were observed. These areas and presumably normal areas were subsequently excised and studied utilizing conventional intracellular microelectrode techniques. Microelectrode studies of the injured segments showed the following: 1) altered action potential (AP) configuration with decreased resting potential (-57.6 ± 9 mV, n=17), shortened refractoriness (186 ± 5 msec) when compared to normal tissue (225 ± 6 msec) but increased time dependency and triangularization of the AP, 2) marked conduction delay and fragmentation in the involved areas, 3) reentrant excitation associated with premature stimulation, 4) discrete boundaries between injured and normal cells, 5) AP alternans, and 6) AP's resembling the slow response. Histologic studies of the impaled sites showed focal epicardial myocytolysis, interstitial edema and areas of contraction bands. These data suggest that high energy doses from defibrillators induce localized injury which provides an ideal setting for arrhythmogenesis.

CHRONIC CARDIAC CHANGES FOLLOWING TRANSTHORACIC VENTRICULAR DEFIBRILLATION IN THE DOG

Timothy B. Boone, MS.; Ted D. Pate, Ph.D.; John C. McMahon, Ph.D.; Ken D. Creamer, BS., University of Texas Health Science Center, Houston, Texas.

"Successful defibrillation" is commonly defined on the basis of the immediate electrical response to countershock, rather than chronic cardiac performance. Chronic hemodynamic and histologic changes following defibrillation at four current dosages (0.5, 1.0, 1.5, 2.0 A/Kg, peak current) were compared to control using 15 mongrel dogs (20-30 Kg). Left ventricular pressure (LVP), LV dP/dt, right ventricular pressure, aortic flow velocity (FV), dV/dt, and aortic pressure were measured with high fidelity catheter-tip transducers during light anesthesia (halothane:N_2O:O_2). Aortic diameter was measured dynamically with ultrasound. Stroke volume and cardiac output (CO) were calculated from measured parameters. Thirty seconds of ventricular fibrillation, induced by endocardial stimulation, 60 Hz, 2 msec, 4 v, was followed by a single-shock defibrillation of a specified current dose. Surviving animals were maintained chronically and re-evaluated 5 days post-defibrillation. Fibrillation was terminated in all experimental animals receiving dosages $\geq$ 1.0 A/Kg. No significant hemodynamic changes, or post-mortem histologic evidence of myocardial damage were found with 1.0 A/Kg. Significant ($p < 0.05$) decreases in FV and LV dP/dt, accompanied by minor microscopic myofibrillar edema, were found with 1.5 A/Kg. The 2.0 A/Kg group showed significant ($p<0.5$) decreases in heart rate, CO, FV, and LV dP/dt accompanied by substantial histologic damage, including myofibrillar fragmentation and hypercontraction bands. The results of this study suggest that current dosages in excess of 1.0 A/Kg (peak current) may result in graded histological damage and pump dysfunction.

USE OF AMBULATORY BLOOD PRESSURE MONITORING IN THE EVALUATION OF PATIENTS WITH BORDERLINE HYPERTENSION.

T.G. Pickering, M.D., G.A. Harshfield, Ph.D., and J.H. Laragh, M.D., F.A.C.C., Cardiovascular Center, The New York Hospital-Cornell Medical Center, New York, N. Y.

24 hour recordings of blood pressure (BP) and heart rate (HR) were made with an automatic non-invasive portable tape recorder (Avionics) in 30 ambulatory patients (pts) with untreated essential hypertension. Accuracy of the recorder was compared against both mercury sphygmomanometer and intra-arterial readings; correlation coefficients were 0.9 for both. For each patient comparisons were made between (a) previously recorded office BP and HR, (b) BP and HR recorded by the automatic recorder while being checked by a physician in the office (15 readings at the start of the recording, 15 at the end), and (c) BP and HR recorded by the automatic recorder at home while awake (30 readings). Pts were divided into a group of 17 with Borderline Hypertension (BH) and 13 with Established Hypertension (EH) according to whether their average diastolic BP in situation (a) was above (EH) or below (BH) 95 mmHg; BH and EH were comparable for age and number of previous visits. In the group with EH there were no significant differences between the 3 sets of readings for either BP (a=158/106, b=157/106, c=154/100 mmHg) or HR (a=84; b=86, c=86 per min). But in the BH group home pressures (c) were significantly lower ($p<0.001$) than either set of office pressures (a=150/92, b=149/100, c=130/86). Situation b provoked a tachycardia in BH pts (a=84, b=90, c=82 per min) ($p<0.05$ for b compared to c). All patients estimated the anxiety related to an office visit on a scale of 1 to 10; for BH there was a correlation ($p<0.05$) between this rating and the differences between home and office pressures (b and c), but not for EH.

It is concluded that ambulatory BP monitoring may be of particular value in pts with BH, where the anxiety of an office visit may elevate BP.

TIME COURSE STUDY OF BLOOD PRESSURE IN CHILDREN AFTER THREE YEARS--BOGALUSA HEART STUDY.

G. S. Berenson, MD, A. W. Voors, MD, L. S. Webber, PhD, Specialized Center of Research-Arteriosclerosis, LSU Medical Center, New Orleans, Louisiana.

For early diagnosis and prevention of essential hypertension we asked: "What is the time course of blood pressure (BP) of children in the upper BP decile? BPs were taken by mercury sphygmomanometer on 3524 children, ages 5-14 years, representative of an entire community. Age-specific systolic and diastolic (4th phase) deciles were assessed. All children, ages 5, 8, 11, and 14 years, were re-examined annually, and the mean intra-child standard deviation (SD) was computed to be 6 mm Hg systolic and 6 mm Hg diastolic. After three years all available children were re-examined, and the age-specific cross-sectional SDs were found to be 9-10 mm Hg systolic and 8 mm Hg diastolic. Hence the inter-child SD was computed and, using the Gardner-Heady model, the regression to the mean due to intra-child variation could be quantified for the upper decile BP. This enabled us to measure precisely the tracking of the group of children in the upper decile after three years. We observed that these children had on the average 1 mm Hg lower systolic and 1 mm Hg lower diastolic BP than expected after adjusting for regression to the mean observed and mean expected). This finding of remarkable tracking in childhood is much higher than indicated by previous studies. We ascribe this difference to: (a) six repeat measurements during each visit; (b) rigidly protocolized, near-basal measurements of children who were relaxed and free of anxiety; and (c) painstaking attention to optimal instrumentation including cuff sizes and a continuous training program for the small, exclusive, and permanent team of observers. Similar measurements can be obtained in a setting of office practice and are useful to detect early hypertension.

CIGARETTES, COFFEE, AND OTHER ASSOCIATIONS WITH HDL CHOLESTEROL IN THE GENERAL POPULATION

Russell V. Luepker, MD, FACC; David R. Jacobs, PhD; Peter Hannan, MS; Elizabeth Brewer, BS, Henry L. Taylor, PhD; University of Minnesota, Minneapolis, MN

High density lipoprotein cholesterol is consistently related inversely to coronary heart disease (CHD) in numerous prospective studies. HDL is also associated with physiologic and health behavior characteristics. To evaluate those relationships, 632 adults (age 20-59) from a geographic based random sample were surveyed. Measures included fasting plasma, blood pressure (BP), height, weight, treadmill performance (ET), and questions about nutrition and health habits.

Participation rates in this population sample were consistently high (>80%). In univariate analysis, HDL was positively and significantly related to female sex (F), and exogenous hormone use (H), and negatively related to cigarette usage (CIG), body mass index (BMI), triglycerides (TG), very low density lipoprotein cholesterol (VLDL), and low density lipoprotein cholesterol (LDL). HDL was not related to total cholesterol (TC), BP, reported physical activity (PA), fitness by ET or reported alcohol (EtOH), tea, or coffee usage.

Multivariate analysis demonstrated HDL independently related positively to F, H, age, heavy PA, EtOH, heavy coffee intake (>8 cups/day), and negatively to BMI, CIG, TG, VLDL, and LDL. It was not related to moderate coffee usage, ET, TC, or moderate PA.

HDL is related to many modifiable health characteristics in these epidemiological data. Causal connections cannot be evaluated from these data; however, they must be considered in postulating mechanisms, evaluating patients, or planning intervention strategies.

ANGIOGRAPHIC CORRELATION OF CORONARY ARTERY DISEASE WITH HIGH DENSITY LIPOPROTEIN CHOLESTEROL IN ASYMPTOMATIC MEN

Gregory S. Uhl, M.D., R. George Troxler, M.D., James R. Hickman, Jr., M.D., and Dale Clark, Ph.D., USAF School of Aerospace Medicine, Brooks Air Force Base, Texas.

There appears to be an inverse relationship of high density lipoprotein cholesterol (HDL) and the risk of coronary artery disease (CAD). Fasting serum cholesterol (Chol) and HDL were determined on 572 asymptomatic (Asx) aircrew screened for CAD. Of these, 132 had an abnormal treadmill (TM) and underwent coronary angiography. CAD, defined as >50% narrowing in any major vessel, was found in 16 with the rest having minimal (N=14) or no CAD (N=102). The mean ±SEM for Chol, HDL, and Chol/HDL are presented below:

	Normal (N=102)	CAD (N=16)
Chol mg%	216 ± 3.6	286 ± 16.3**
HDL mg%	50 ± 1.1	39 ± 2.9*
Chol/HDL	4.4 ± 0.1	7.5 ± 1.6***

*p <0.02 **p <0.001 ***p <<0.001

The mean ±SEM values in the cath normals did not differ significantly from those values in the whole population. The 14 men with minimal CAD had Chol and Chol/HDL values that differed from the normals ($p < .001$). Only 2/16 CAD patients had Chol/HDL <6.0 while 4 cath normals had a ratio > 6.0. Only 42/440 men with normal TM had a Chol/HDL >6.0. That is, only 9.5% of patients with a normal TM had a ratio >6 while 87% of those with CAD had Chol/HDL >6. The sensitivity for detecting CAD of Chol/HDL >6.0 was 87% (14/6), specificity 96% (98/102) and a predictive value of 77% (19/18) in an asx population with prevalence of 12% (16/132). Thus (1) Asx men with CAD have significantly lower HDL and higher Chol and Chol/HDL than normals, (2) A Chol/HDL >6.0 in Asx men with abnormal TM is an accurate predictor of CAD and (3) Even minimal CAD (lesions <50%) are identified by Chol/HDL above the norm.

TOTAL CHOLESTEROL/HIGH DENSITY LIPOPROTEIN RATIO CORRELATES WITH THE PRESENCE BUT NOT SEVERITY OF CORONARY ARTERY DISEASE

Gordon L. Pierpont, MD, John O. Swanson, MD, and Arnold Adicoff, MD, FACC, VA Medical Center and University of Minnesota, Minneapolis, Minnesota

Elevated serum low density lipoprotein is considered a risk factor for developing coronary artery disease (CAD), whereas elevated high density lipoprotein (HDL) appears to have a protecting effect, and total cholesterol (C) to HDL ratio has been suggested as an improved method for assessing risk. We determined C, HDL, and triglycerides (trigl) in 189 patients (pts) undergoing diagnostic cardiac catheterization to determine if they correlate with the severity of CAD assessed as number of vessels (# ves) involved with >70% stenosis. Results (mg/dl±SEM):

# ves	0	1	2	3
# pts	32	40	51	66
age	52± 1.8	53± 1.6	56± 1.2	56± 1.2
C	212± 7.7	250±10.7	244± 8.5	250± 6.2
HDL	54± 2.3	43± 1.8	45± 1.8	41± 1.2
C/HDL	4.1± 0.2	6.1± 0.3	5.7± 0.2	6.4± 0.3
Trigl	140±12.3	212±28.8	204±21.4	231±14.7

Using analysis of variance, pts with no CAD differed from those with CAD in HDL ($p<.005$), trigl ($p<.01$), C ($p<.005$), and C/HDL ($p<.005$), but no significant differences were found between pts with CAD having different # ves involved. There were no significant differences between the groups in age, and although the 0 ves group had more females than the others, there were no differences in C, HDL, C/HDL or trigl between males and females with no CAD. We conclude that C/HDL correlates with the presence but not severity of CAD.

FOLLOW-UP OF PATIENTS WITH CHEST PAIN AND NORMAL CORONARY ARTERIOGRAPHY

Ira S. Ockene, MD, FACC; Marilyn Shay, RN; Bonnie H. Weiner, MD; Joseph S. Alpert, MD, FACC; James E. Dalen, MD, FACC, University of Massachusetts Medical Center, Worcester, Massachusetts.

Approximately 10% of pts referred for coronary arteriography (CA) because of chest pain are found to have angiographically normal coronary arteries. The good prognosis of these pts has been well documented, but their functional and sociological status has been less well studied. 56 pts (26 M, 30 F, mean age 47) referred for CA because of chest pain and found to have normal coronary angiography with no other heart disease were followed up at a mean interval of 15.2 ± 9.9 months. 17 pts (30%) were pain free. 29 (52%) had fewer episodes, and in only 10 (18%) was the pain unchanged or more frequent. 15 (27%) were still on propranolol and 22 (39%) remained on nitrates.

	Pre Cath	Post Cath
Work disability	35 (63%)	22 (39%)
Pt feels heart disease present	43 (77%)	21 (38%)
Pt feels heart is normal	9 (16%)	24 (43%)

All of these pts had been told that they had normal hearts, and noncardiac chest pain. Despite this, 39% remain disabled, and 38% still feel they have heart disease. These pts represent a large, poorly dealt with health problem, and might benefit from further rehabilitation.

LATE RESULTS OF RECONSTRUCTION OF THE RIGHT VENTRICULAR OUTFLOW TRACT WITH VALVED EXTERNAL CONDUITS IN CHILDREN.

George S. Bisset, III, MD. David C. Schwartz, MD. FACC, George Benzing, III, MD. FACC, James Helmsworth, MD. FACC, Samuel Kaplan, MD. FACC. University of Cincinnati, Children's Hospital Medical Center, Cincinnati, Ohio.

The long-term results of reconstruction of the right ventricular outflow tract (RVOT) with a porcine valve heterograft (Hancock sizes 16-35 mm) was studied in 33 children 1-5.8 yrs. ($\overline{3.3}$ yrs.) post-operatively. Ages ranged from 2.5-17.5 yrs at the time of surgery ($\overline{8.3}$ yrs.). Intraoperative pressure measurements of right ventricle (RV) to pulmonary artery (PA) peak systolic (PS) pressure in 25 patients showed gradients which ranged from 0-38 mm. Hg. ($\overline{10}$ mm). RVPS pressure in 7 other patients revealed 5 with RV/LV pressure <0.5. Nineteen children had hemodynamic evaluation 1 mo. to 3 yrs. post-operatively ($\overline{1.4}$ yrs.). The RV-PA gradients ranged from 8-70 mm. Hg ($\overline{29}$ mm). Seven of the patients (21%) demonstrated gradients >40 mm.Hg. and have undergone or are awaiting reoperation. Two other patients have clinical evidence of prosthetic valve incompetence. Each of the 4 porcine valves which have been replaced were thickened and calcified. No vegetations were visible and in the remainer of the study group infectious endocarditis has not been indentified. We conclude that the long-term performance of the porcine heterograft remains uncertain in children and should be used cautiously in reconstructing the RVOT when an alternate surgical method is available.

INTRAATRIAL REPAIR OF TRANSPOSITION OF THE GREAT ARTERIES IN INFANCY, EARLY AND LATE RESULTS

Kevin Turley, MD; Barry Vinocur, MD, Michael Heymann, MD, FACC, Abraham Rudolph, MD, FACC, Paul A. Ebert, MD, FACC, University of California, San Francisco, CA

Intraatrial repair of transposition of the great arteries (TGA) in the past has been delayed until the 2nd year of life in the hope of improving survival. An approach of early intraatrial repair (< 6 mos.of age) or emergency intraatrial repair, if the Rashkind procedure was unsuccessful, has been employed at the UCSF from 1975-79. During this period 65 infants < 2 yrs. of age underwent intraatrial repairs. The early corrective approach was employed in 42 with 34 of these in the first 3 mos. of life. Twenty-three patients had either multiple attempts at palliation prior to referral, or late referral following successful palliation. Overall hospital survival was 98.5%. The single mortality was in the late corrected group. Complications included phrenic nerve palsy in 2 (1 secondary to previous Blalock-Hanlon) and chylothorax in 1 and retarded neurologic development in 1 infant who had experienced a preoperative arrest. There have been no late mortalities in 64 survivors. Thirty-seven patients a minimum of 18 mos.postoperatively (mean 36 mos.,range 18-56 mos.) were reviewed. Twenty-three had early or emergent repairs. There was a lower incidence of both rhythm disturbances and neurologic sequelae in the early corrected group. There were no symptomatic systemic or pulmonary obstructions. Echocardiographic and catheterization data revealed no significant (NS) difference in RV function between the 2 groups. Early intraatrial repair of TGA with intact septum can be performed with a low operative mortality avoiding the interim mortality and complications of extended medical management and palliative attempts. A low incidence of late complications is noted with early correction.

RIGHT VENTRICULAR GROWTH IN PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

F.J.Fricker, M.D.; J.R.Zuberbuhler, M.D., FACC; W.H. Neches, M.D.,FACC; R.A. Mathews, M.D.; S.C.Park, M.D., FACC; C.C. Lenox, M.D.,FACC; L.B. Beerman, M.D. Children's Hospital, University of Pgh., School of Medicine, Pittsburgh, Pa.

Right ventricular growth was assessed by serial catheterizations in 8 surviving patients with pulmonary atresia with intact ventricular septum. Their ages at the time of follow up catheterization ranged from 7 mo. to 12 yrs. Initial surgical management included either a closed or open pulmonary valvotomy in 4 patients; valvotomy combined with a systemic to pulmonary artery shunt in 2; and in one an aorta to pulmonary artery shunt alone. One patient with a patent ductus has had no operative intervention.

The degree of right heart hypoplasia was estimated by measuring the inlet(RVI) and outlet(RVO) dimensions of the RV from cineangiogram, and comparing these dimensions with corresponding left heart measurements (LVI and LVO). The ratio of measurements taken from serial cineangiograms (RVI x RVO/LVI x LVO) was plotted against BSA (body surface area M^2), giving an estimate of relative growth of the right ventricle. An increase in this ratio occurred in those patients who survived open or closed pulmonary valvotomy indicating definite RV growth. The ratio decreased in the 2 patients in which RV decompression was not accomplished.

We conclude that the degree of RHH can be accurately estimated by cineangiography and forms an important basis for selecting patients for valvotomy. Factors affecting RV growth potential include size of RV, successful decompression, absence of inflow obstruction to the RV, and the presence of pulmonic or tricuspid regurgitation.

TRANSPOSITION OF THE GREAT VESSELS WITH VENTRICULAR SEPTAL DEFECT: LONG TERM SURGICAL RESULTS

Paul S. Damus, MD; Constance J. Hayes, MD; Robert A. Boxer, MD, Carl N. Steeg, MD, FACC; Frederick O. Bowman, Jr., MD James R. Malm, MD, FACC; Welton M. Gersony, MD, FACC, Columbia-Presbyterian Medical Center, New York, N.Y.

Various approaches to surgical treatment of transposition of the Great Vessels (TGV) and ventricular septal defect (VSD) have been employed with diverse results. The long term effects of right ventriculotomy remain unknown. Thirty-three patients, age 7 months - 18 years, with TGV-VSD, have undergone open heart surgery at CPMC between 1966 and 1978. Twenty patients had a Mustard procedure (MP) and VSD closure via a right ventriculotomy. Twelve patients have expired, most as a result of poor right ventricular function. Eight patients have survived 1-9 years postoperatively; two show poor RV function and 4 have rhythm abnormalities. Thirteen patients had a MP with VSD closure without right ventriculotomy. There were 5 early and 1 late death. Four of 7 survivors have had arrhythmias.
Eleven older patients with TGV, VSD and PS had a Rastelli procedure (RP) and 10 survived with 1 late death. Eight survivors are in NSR.
Rhythm disturbances and poor RV function have been significant problems following the MP and VSD closure. The RP, after PA banding, may offer significantly better long term survival.

EARLY FAILURE OF PORCINE VALVES IMPLANTED IN CHILDREN
Stephen P. Sanders, MD; Michael D. Freed, MD; William I. Norwood, MD; Aldo R. Castaneda, MD; Alexander S. Nadas, MD
Children's Hospital Medical Center, Boston, Ma.

Between 1/74 and 12/78, 34 patients (pts), ages 10/12 - 20 years (yrs) (median 14 yrs), underwent mitral (M) or aortic (A) valve replacement (VR) at Children's Hospital, using Hancock Porcine xenografts (xeno).

Among 26 pts who underwent MVR, there were 5 operative deaths and 3 late deaths, occurring 2, 2, and 34 months (mo) after surgery. Nineteen pts were followed 4 - 64 mo (mean = 26 mo) postoperatively. Four required repeat VR 34 - 49 mo after implantation because of xeno failure. Calcific stenosis occurred in 2, while cusp rupture caused regurgitation in 2 others. Mild calcification was found in the regurgitant xeno as well. There were no operative or late deaths among 8 pts undergoing AVR. The duration of follow-up was 7 - 37 mo (mean = 23 mo). One xeno calcified, causing severe stenosis and requiring replacement 31 mo after implantation.

Xeno failures began presenting 30 mo after implantation, and of 13 valves followed 30 mo or longer, 5 (38%) have been replaced. Although confidence limits were broad due to the small number of pts, actuarial analysis by life table showed only 37% of xeno remaining intact after 50 mo of follow-up.

Since xeno failure is rare in adult pts, we examined the relationship between age at VR and incidence of xeno failure. The 5 pts, in whom xeno failed, were significantly ($p = .008$) younger at initial VR than the other 8 pts followed 30 mo or longer (10.8 $\pm$ 3.0 yrs vs 15.2 $\pm$ 2.0 yrs). Valve failure occurred in all 3 xeno implanted in pts under 11 yrs of age, in 2 of 7 in pts 11-14 yrs of age, but in none of 3 in pts over 15 yrs of age.

Xeno failure in children is a serious problem and further study of the incidence and mechanism is required.

HEMODYNAMIC RESULTS OF REPEAT VALVULOTOMY FOR AORTIC STENOSIS IN CHILDREN.
Thomas Hougen, M.D.,; David Fulton, M.D.; William Bernhard, M.D.; Amnon Rosenthal, M.D., FACC; John Keane, M.D.
Children's Hospital Medical Center, Harvard Medical School, Boston, Massachusetts.

A second aortic valvulotomy (AV) is sometimes considered in young patients (pts) with severe residual valvar aortic stenosis (AS). This study was undertaken to assess our results of repeat AV in children. From 1958-1977, 171 pts underwent AV of which 21 (12.2%) required a second operation for residual AS. Repeat AV was performed in 13 (8%) and valve replacement in the other 8 (5%). Of these 13, 7 (Group A) were $<$ 1 year of age at first AV (average 8 months), while the other 6 (Group B) were older (average 8 years). After the first AV the peak systolic ejection gradient (PSEG) was 104 mmHg (range 60-140, n=6) in Group A and 97 mmHg (80-113, n=6) in Group B.

Following repeat AV, the PSEG was $<$ 40 mmHg in 2 of the 4 recatheterized and unchanged in the other 2 in Group A. Mild aortic regurgitation (AR) was present in 6 of the 7 children. In Group B, of 5 pts recatheterized the PSEG was $\geq$ 70 mmHg in 4 and 12 mmHg in the other. AR was present in 5 of the 6, at least of moderate degree in 4.

Our data indicate that repeat AV may be of value only in those children in whom the first AV was done in the first year of life. In those in whom the initial AV was performed $>$ 1 year of age, valve replacement is probably the preferred operation.

EXTENDED RESULT AFTER OPERATION FOR CONGENITAL AORTIC STENOSIS
N. Okike, MD, D. C. McGoon, MD, FACC, G. K. Danielson, MD, FACC, R. B. Wallace, MD, J. R. Pluth, MD, F. J. Puga, MD, W. H. Weidman, M.D., Mayo Clinic, Rochester, Minn.

An additional 12 years of follow-up are now available since our previous report (maximum 23 years). Also since then, 144 more patients have been operated. Of the total 313 patients, 183 (59%) had congenital valvular stenosis, 64 (20%) subvalvular, 29 (9%) supravalvular and 37 (11%) had a combination of two or all three levels of stenosis. The overall hospital mortality rate was 4%, and actuarial probability of being alive at 10 and 20 years was 84% and 69% respectively. The principal causes of early death were endocarditis (BE), dysrhythmia and sudden death. The overall likelihood of reoperation was 8% and 11.8% at 10 and 20 years. Causes for reoperation were recurrent stenosis, regurgitation, or BE. Valve replacement (VR) was performed at the original operation or later in 45 (14%) patients. LV apico-aortic conduit was performed at reoperation in 1 patient. Heart size, hemodynamics, type stenosis and other factors were correlated with early and late results. At final follow-up the clinical status of patients (NYHA) was 86% I, 8% II, 3% III and 3% IV. The study is the longest available and large enough to allow comparison between the four subtypes.

SUBAORTIC STENOSIS: A THIRTY YEAR EXPERIENCE. Gregory B. Wright, M.D., John F. Keane, M.D., Alexander S. Nadas, M.D., FACC, Aldo R. Castaneda, M.D., FACC, William F. Bernhard, M.D., Children's Hospital Medical Center, Boston, Massachusetts

The purpose of this study was to observe the course of 1) obstruction, as determined by the peak systolic ejection gradient (PSEG), and 2) aortic regurgitation (AR) pre- and post-operatively in 85 patients (pts.) (35 female) with subaortic stenosis (SAS). Only pts. with fixed left ventricular SAS and left ventricles of normal size were studied. Total follow-up was 625 pt.-yrs. (mean = 7.4 yrs.). Mean age of first catheterization was 7.4 yrs. (1 day-24 yrs.) whereas mean age at detection of an LV outflow gradient was 9.7 yrs. (11 mos.-26 yrs.). Forty-six pts. had 104 other cardiac lesions, 31% of which were right-sided. Among 29 pts. catheterized more than once pre-op, the PSEG increased by $\geq$40mmHg in 11 (38%). AR appeared spontaneously in 41 (48%), being mild in 38, moderate in 3.

Resection of SAS was performed in 74 pts. (on two occasions in 11 pts.) with 11 early and late deaths. In 37 pts. catheterized post-op, mean PSEG was reduced from 80 mmHg (S.D.=32mmHg) to 22mmHg (S.D.=26mmHg). Eight pts. required valve replacement (4 aortic (AVR), 4 mitral (MVR)), mainly for iatrogenic regurgitation. AR (present in 39 pts. pre-op) remained mild in 28, disappeared in 3, remained or became moderate in 7, and became severe in 1.

Bacterial endocarditis (BE) occurred in 11 pts. (13%) (5 pre-op, 6 post-op), but only when PSEG $\geq$40mmHg or when other lesions were present.

Our data indicate: 1)SAS is often progressive; 2)AR is common, acquired, and usually does not progress after SAS resection; 3)BE is a frequent complication; 4)SAS resection adequately reduces PSEG in most pts.; 5)AVR is usually not required in pts. less than 25 yrs. of age.

MANAGEMENT OF THE INFANT WITH COARCTATION OF THE AORTA AND VENTRICULAR SEPTAL DEFECT

Maureen A. Strafford, MD; Constance J. Hayes, MD; Sylvia P. Griffiths, MD, FACC; Allan J. Hordof, MD; Richard N. Edie, MD; Frederick O. Bowman, Jr., MD; James R. Malm, MD; Welton M. Gersony, MD, FACC, Columbia-Presbyterian Medical Center, New York, N.Y.

In the management of infants with coarctation of aorta (CoA) and ventricular septal defect (VSD), pulmonary artery banding (PAB) may be carried out at CoA repair, or primary repair of the VSD may be performed later without PAB initially. Twenty-four infants with CoA and VSD were operated on at CPMC from 1972 to 1979. All presented between one week and 5 months of age (mean =4 weeks). Cardiac catheterizations revealed CoA with large VSD and severe pulmonary hypertension. Seven had PAB at CoA repair One died at initial operation. Five had had debanding with 2 deaths. One required debanding with VSD closure within 3 months. Seventeen infants had no PAB at CoA repair. One died at initial operation. Three required VSD closure within 3 months with 1 operative death. Four have had elective VSD closure prior to 2 years of age with 1 death. Three have closed the VSDs spontaneously. Six have shown decreased pulmonary artery pressure and have improved clinically. We conclude that the infant with VSD and CoA can be successfully managed without PAB. A significant number of these patients will not require a second operation.

COR TRIATRIATUM (SUBDIVIDED LEFT ATRIUM) ANATOMY, HEMODYNAMICS, SURGERY, AND LATE FOLLOWUP OF TWENTY-ONE PATIENTS

James V. Richardson, MD; Donald B. Doty, MD, FACC; Ralph D. Siewers, MD, FACC; James R. Zuberbuhler, MD, FACC; The University of Iowa, Iowa City, Ia.

Cor triatriatum sinister (CT) is a rare, congenital anomaly consisting of a subdivided left atrium, the result of abnormal partitioning of the left atrium by a fibromuscular membrane. Hemodynamically this lesion usually mimics total anomalous pulmonary venous connection, due to left to right shunting at the atrial level or mitral valve stenosis due to pulmonary venous inflow obstruction. During the period 1955-1978, 21 patients (pts) (age 1 day - 156 months) with CT were treated in a combined series at The University of Iowa Hospitals and Pittsburgh Children's Hospital. Twenty (95%) pts had classical CT with normal pulmonary venous connections. In 17 (81%), the fossa ovalis (FO) was located above the obstructing membrane, in 3 (14%) the FO was below the membrane and in one pt the atrial septum was absent. Surgical correction was performed in 13 pts (62%) of whom eight (62%) survived. Long-term results from 1 month to 7 1-2 years (m 41 months) were excellent in seven (88%) survivors. Surgical correction consists of excision of the obstructing membrane. In infants and small children, correction through the right atrial-transseptal approach is advised, while the left atrial approach is preferable in older children.

TRUNCUS ARTERIOSUS WITH PULMONARY VASCULAR OBSTRUCTIVE DISEASE - MEDICAL VS SURGICAL MANAGEMENT

Valentin Fuster, MD, FACC, Douglas D. Mair, MD, FACC, Donald G. Ritter, MD, FACC, Dwight C. McGoon, MD, FACC, Mayo Clinic, Rochester, MN.

Between 1960 and 1978, 175 patients (pts) with truncus arteriosus (without pulmonary artery stenosis or agenesis) were catheterized. Eighty-one (46%) pts, 41 female and 40 male, had a total pulmonary resistance (TPR) higher than 7 Um^2. Of these pts 35 had surgical treatment (ST) and 46 had medical treatment (MT). All pts were followed between 1 and 19 years (yrs) (mean 9 yrs) and 43 had followup catheterization study at a mean of 5 yrs after initial catheterization.

Of 25 pts with TPR 7-9 Um^2 (mean age 4.9 yrs), the 3 MT have died or clinically deteriorated (TPR has progressed in 1 restudied pt). In contrast, 10 out of the 22 ST pts have clinically improved (TPR has not progressed in the 6 restudied pts); but the remaining 12 pts died early postoperatively. Of 26 pts with TPR 10-13 Um^2 (mean age 6.9 yrs), the 13 MT pts have died or are clinically deteriorated (TPR has progressed in the 11 restudied pts). In contrast, 6 out of the 13 ST pts have clinically improved (TPR has not progressed in the 5 restudied pts), 6 died at operation and 1 died late postoperatively. The 30 pts with TPR $\geq$ 14 Um^2 (mean age 10.4 yrs) all had MT and they have died or are clinically deteriorated (TPR has progressed in the 20 restudied pts).

In conclusion, the operative risk in truncus pts with TPR $>$ 7 Um^2 is high. However, pts with elevated TPR who do survive operation have a better prognosis than do those medically managed.

THE PULMONARY VASCULATURE IN PULMONARY VALVAR STENOSIS

Nadiv Shapira, MD, Kathleen Heidelberger, MD, Douglas M. Behrendt, MD, FACS, Amnon Rosenthal, MD, FACC, University of Michigan, Ann Arbor, Michigan 48109

The pulmonary vascular morphology in surviving patients (pts) with simple valvar pulmonary stenosis (PS) has not been previously described.

We studied lung biopsies obtained at surgery from 9 pts with PS. Detailed histologic quantitative morphometric changes in intraacinar pulmonary vasculature were studied using 4 structural features: (1) % wall thickness (%WT), (2) muscularity of vessel walls (musc), (3) Alveolar-arterial ratio (A/a) and (4) vessel size.

Pts ages ranged from 3½ mos. to 34 yrs. Right ventricular pressures ranged from 66 to 150 mmHg (mean 108). Pulmonary vascular changes on each pt were compared to biopsy (n=7) or necropsy (n=9) findings on age matched controls. Controls had biopsy at operation for trivial heart lesions or died from noncardiac or nonpulmonary disease.

The %WT and vessel size in pts with PS were comparable to the matched controls. Seven of nine pts had a 10-57% decrease in the number of intraacinar arteriolar vessels when compared to biopsy or to autopsy controls ($P<.01$). Only the youngest 4 pts in the group had abnormal extension of muscle towards the small peripheral arteries. Intimal proliferation was present in 2/9 pts. It was diffuse in the oldest pt.

Four pts had a more protracted postoperative course than might be expected after simple pulmonary valvotomy. Each of these had abnormalities on biopsy.

We conclude that patients with PS may have a decreased number and/or abnormal muscularity of small pulmonary arteries. We speculate that these abnormalities may influence pts' recovery from operation.

PARADOXICAL ACCELERATION OF VENTRICULAR TACHYCARDIA BY GROUP II ANTIDYSRHYTHMICS

Geoffrey O. Hartzler, MD; David R. Holmes, MD; Michael J. Osborn, MD, Mayo Clinic, Rochester, MN

Lidocaine is the most commonly used antidysrhythmic drug for the treatment and prophylaxis of ventricular tachycardia (VT). Although lidocaine and other group II antidysrhythmics reduce automaticity of Purkinje fibers, other electrophysiologic properties (increased conduction velocity and decreased effective refractory period) theoretically could lead to acceleration of reentrant ventricular tachycardias. Acceleration of previously stable, sustained ventricular tachycardia occurred immediately following administration of phenytoin in 1 pt, lidocaine in 2 pts, and mexiletine in 3 pts. All were men, ages 34-77 years, undergoing invasive study and electrophysiologic-pharmacologic (E-P) testing of recurrent VT. Diagnoses included coronary artery disease with prior myocardial infarction-4 pts (LV aneurysm-1 pt), congestive cardiomyopathy-1 pt, hypertrophic cardiomyopathy-1 pt. During extensive programmed ventricular stimulation (PVS) and initial E-P testing, multiple stable, sustained VT episodes (mean 45, range 20-150 episodes) were induced and terminated. Immediately following infusion of phenytoin and lidocaine or oral mexiletine (mean dose 1,000 mg), PVS induced sustained VTs which were accelerated by 30-50 beats per minute in 2 pts and by 100-150 beats per minute in 4 pts. DC cardioversion was required in 4 pts. Following discontinuation of group II antidysrhythmics, accelerated VT did not reoccur despite extensive continued PVS and E-P testing (mean 40, range 20-100 induced VT episodes). We conclude that 1) group II antidysrhythmics may unpredictably accelerate VT, 2) E-P testing may identify acutely susceptible pts, and 3) the chronic risk of continued group II drug therapy in these patients has not been established.

PREDICTION OF EFFECTS OF ORAL APRINDINE UTILIZING INTRAVENOUS APRINDINE

Edwin Palileo, MD; Thomas Smith, MD; Boris Strasberg, MD; Christopher R.C. Wyndham, MD, FACC; Wilfred Lam, MD; Ramesh C. Dhingra, MD, FACC; Kenneth M. Rosen, MD, FACC, University of Illinois, Chicago, Illinois.

Aprindine (AP) is an antiarrhythmic drug which may be utilized either intravenously (IV) or orally. Because of long half life (13-50 hrs) and slow onset of action orally, a 1-2 week trial is necessary for assessment of efficacy of oral AP. In this study, we tested the hypothesis that response to IV AP would predict the subsequent response to oral AP. The study group consisted of 15 pts (13M, 2F), ages 20-60 (mean ± SD, 56 ± 12 yrs), with organic heart disease and recurrent drug resistant (3 or more drugs) paroxysmal ventricular tachycardia (PVT). PVT was incessant in six pts and sporadic in nine (4-15, 7 ± 3 sustained PVT's/yr), necessitating two or more cardioversions in all pts. PVT rates ranged from 125-210, 166 ± 21 beats/min. IV AP was administered in a dose of 5 mg/min (to a total dose of 200 mg) during PVT. In eight pts (53%), PVT converted to sinus rhythm after 25-200, 132 ± 55 mg IV AP. Total cure of PVT was achieved in these eight pts with oral AP (100-175, 140 ± 20 mg/day) (follow-up of 1-33, 15 ± 9 mos). In the remaining seven pts (47%), IV AP produced slowing of PVT from a mean rate of 167 ± 18 to 131 ± 16 beats/min, without conversion to sinus rhythm (range of slowing of 20-70, 36 ± 22 beats/min). Short term cure of PVT with oral AP (100 mg/day) was achieved in two of these pts (follow-up of 4 and 2 mos). The remaining five pts have had PVT occurring two to six weeks after starting oral AP (150 ± 50 mg/day). In conclusion, conversion of PVT to sinus rhythm with IV AP is highly predictive of cure with oral AP. In contrast, slowing of PVT without conversion to sinus rhythm with IV AP, predicts probable failure of oral AP for prevention of PVT. Testing IV AP during PVT is thus relevant to choosing pts for trial of oral AP.

EFFECT OF LIDOCAINE ON THE RATE OF ATRIOVENTRICULAR JUNCTIONAL ESCAPE PACEMAKERS

Chien-Suu Kuo, MD, FACC, and C. Pratap Reddy, MD, FACC, University of Kentucky Medical Center and Veterans Administration Hospital, Lexington, Kentucky.

We have previously reported that Lidocaine (L) may cause exit block (EB) of ventricular (V) escape pacemaker (EP) in patients (pt) with complete (C) atrioventricular (AV) block (B) distal to the His bundle (HB). In this study, we tested the effect of L administered intravenously (1.5 mg/Kg/2 min followed by a constant infusion of 3 mg/min for 10 min) on AV junctional EP in 9 pt (age 14 - 83 yr) with CAVB proximal to HB following insertion of temporary pacemaker. CAVB was congenital in 1, chronic acquired in 5 and due to acute inferior myocardial infarction (IMI) in 3 pt. EP rate was 44 ± 12 beats/min (bpm) (range 28 - 56). QRS duration of EP was ≤ 0.10 sec in 8 and 0.13 sec in 1 pt (congenital AVB). HB electrogram obtained in 8 pt showed block proximal to HB in all with an HV interval of 43 ± 9 msec (range 30 - 55). Blood L levels ranged from 2.1 - 10.8 µg/ml (mean 5.9 ± 4). Of 6 pt without IMI, L did not change EP rate in 4 and gradually decreased EP rate by 3 - 7 bpm in 3, presumably by decreasing automaticity. Of 3 pt with IMI, L did not change EP rate in 1 and abruptly slowed EP rate by more than half in 2, presumably due to EB or depressed conduction. These results are consistent with selective depression of conduction in ischemic myocardium by L in concentrations which caused either slight or no effect on automaticity and/or conduction in non-ischemic myocardium. This may be the first clinical evidence that L exerts greater effect on ischemic than on normal myocardium.

ABOLITION OF VENTRICULAR ARRHYTHMIAS DURING CHRONIC ORAL THERAPY WITH ENCAINIDE IN MAN.

Dan M. Roden, MD; Stots B. Reele, MD; John A. Oates, MD; Raymond L. Woosley, MD, PhD; Vanderbilt University, Nashville, TN.

The pharmacokinetics and pharmacodynamics of the new antiarrhythmic agent encainide (E) were evaluated in 11 patients (pts) with high frequency chronic ventricular arrhythmias (VA). E therapy was started at low dosages and was increased every 48 hours to the point of efficacy or side effects. A previously-validated computer method analyzed 12-24 hours of ambulatory ECG data at each steady state level. Increasing dosages produced increasing antiarrhythmic effect and ultimately >99% VA suppression in 10/11 pts; this response was then confirmed in a single-blind comparison of placebo to E each given for 3 days in random sequence. Dosages (50-300 mg/day) and minimal plasma concentrations (1.3-56 ng/ml) required to maintain VA abolition were highly variable. Elimination was rapid ($T_{\frac{1}{2}}$=2.7±0.2 hrs, $\bar{X}$±SE) in the 10 pts responding to E. The single pt whose VA did not respond had plasma concentrations >11-fold higher than the other 10 and a $T_{\frac{1}{2}}$=7.6 hrs; this suggests that a metabolite may contribute to E's activity. Effective therapy was accompanied by marked PR and QRS lengthening ($\bar{X}$=+46%), but no evidence could be adduced from prolonged ambulatory monitoring, exercise testing or radionuclide ventriculography that these changes were deleterious. Despite rapid elimination, the margin between effective and excessive plasma concentrations was wide enough to allow outpatient therapy on a 6-12 hourly basis (median=8) without recurrent VA at the dosing interval in all 10 pts responding to E. Transient side effects (primarily blurred vision) requiring minor dosage adjustments have occurred in 6/10. Treatment continues in all 10 with maintenance of VA control at 2-8 months ($\bar{X}$=4). E is a highly effective antiarrhythmic agent suitable for chronic therapy and requires further clinical study.

LONG TERM THERAPY WITH TOCAINIDE

Philip J. Podrid, MD; Bernard Lown, MD, FACC, Harvard School of Public Health, Boston, Massachusetts.

Tocainide (TOC), oral methyl lidocaine, was evaluated in 61 patients (PTS) with recurrent ventricular tachycardia (VT) that was refractory to conventional agents. Maximal tolerated dosage was utilized in all patients. Drug efficacy as evaluated by both exercise testing and repeated ambulatory monitoring was defined as total abolition of VT and couplets and a greater than 60% reduction in total number of ventricular premature beats. TOC was effective in 29 PTS (47.7%). The average daily dose was 1800 mg and average peak blood level was 8.6 ug/ml (3.8-15.1 ug/ml). Dosage and peak blood level were similar in the nonresponders. Seven PTS had side effects (neurologic or gastrointestinal) and were not continued on TOC. Twenty-two PTS were placed on long term therapy with TOC. Four PTS discontinued the drug after 1-3 months because of side effects. Two PTS had recurrent VT after 1 month and one PT died suddenly after 4 years of treatment. The remaining 15 PTS continued TOC and have been treated for an average of 13 months (2-27 mos). Follow-up has been monthly. Blood levels have been stable in all and no adverse reactions have occurred. Repeat ambulatory monitoring and exercise testing has been performed every 3-6 months. Arrhythmia remains controlled in all PTS. We conclude that TOC is useful for long term therapy in selected PTS with VT.

EFFECT OF PROCAINAMIDE ON EXCITABILITY IN MAN

Allan M. Greenspan, MD; Joseph S. Camardo, MD; Sc Spielman, MD; Leonard N. Horowitz, MD,FACC; John Kastor, MD,FACC; Mark E. Josephson, MD,FACC, Hosp the University of Pennsylvania, Philadelphia, Pa.

Threshold (Th_d) and refractoriness (RP) are impor measurements of excitability. Since RP is curren strength (I) dependent, evaluation of RP requires ation of the relation between RP and I. Procaina (PA) has been shown to prolong ventricular (V) RP at twice late Th_d, but its effect on Th_d itself a multiple I have not been investigated. We theref evaluated the relationship between VRP and I befo after PA infusions in 18 patients undergoing clin electrophysiologic studies for various indication lowing standard VRP determinations during right v lar pacing (cycle length 600 msec) at Th_d, I was creased by 0.25 to 0.5 mA increments up to 10 mA, redetermined at each I. The procedure was repeat IV PA infusions of 500 to 1000 mg. PA increased .78±.34 mA to .90±.5 mA (p NS) at the serum level achieved (8.1±1.2 µg/ml). PA did not alter the h figuration of the excitability curve which was ch ized by a progressive decrease in VRP with increa showing a gradual slope at longer coupling interv (CI), and a steeper slope at shorter CI as it app absolute refractoriness (RP-A). However, PA shif excitability curve upward and to the right such t at Th_d, the mid portion of the curve (twice Th_d) steep portion of the curve (3 times Th_d) all occu longer CI. We conclude that PA suppresses excita in the intact human ventricle by increasing the I sary to elicit a propagated response at each poir diastole up to the RP-A and by shifting RP-A late astole, rather than by significantly altering Th_d

MODIFICATION OF VENTRICULAR TACHYCARDIA BY PROCAINAMIDE

Toby R. Engel, MD, FACC; Jerry C. Luck, MD; Steven G. Meister, MD, FACC; William S. Frankl, MD, FACC, The Medical College of Pennsylvania, Philadelphia, Penna.

Fifteen consecutive patients had sustained ventricular tachycardia (VT) or fibrillation (VF) remote from myocardial infarction. VT was induced by right ventricular extrastimulation before and after procainamide (PA). Twelve patients, six of whom were survivors of sudden death, were evaluated prior to a comprehensive clinical trial of drugs because they had tachycardias that required resuscitation. In the basal state, induced VT was rapid (average 211 beats/min±30 SD) and required external countershock in 10 of 15 patients because of poorly tolerated VT or VT degenerating to VF. Traditional doses of PA infusion (plasma concentrations >4mcg/ml) consistently slowed VT, but failed to prevent the induction of sustained VT in 13 of the 15 patients. In fact, VT induction was facilitated in 10 patients after PA. The two patients who responded to traditional doses of PA had the slowest VT rates (188 and 158 beats/min) and their VT cycle length increased 34% and 50% respectively. In contrast, the increase in VT cycle length of non-responders was only 23%±15 SD after 1 gm of PA. Eight of 13 non-responders at traditional doses of PA were retested at higher doses. Peak plasma concentrations ranged from 11.3 to 42.1 mcg/ml (average 20.2±9.7 SD). Higher dose PA prevented induction of sustained VT in only one additional patient. There were no clinical features other than VT rate that predicted a successful response to PA. In conclusion, traditional and higher doses of PA failed to prevent induction of sustained VT in a subset of patients with coronary heart disease truly at risk for sudden death. Responders were characterized by slower VT rates (<210 beats/min) and marked slowing after PA infusion.

CONTROL OF VENTRICULAR RATE IN PAROXYSMAL SUPRAVE LAR TACHYCARDIA AND ATRIAL FLUTTER-FIBRILLATION W TRAVENOUS VERAPAMIL: A DOUBLE BLIND RANDOMIZED C OVER STUDY

Harvey L. Waxman, MD; Robert J. Myerburg, MD, FAC Appel, RN; Ruey J. Sung, MD, FACC, University of School of Medicine, Miami, Florida.

Although several studies have examined the effect Verapamil (V) for treatment of paroxysmal suprave lar tachycardia (PSVT) and atrial flutter-fibrill (AFF), no randomized double blind (RDB) investiga has been reported. To evaluate the effectiveness we studied two groups of patients(pts) (Gr A and Gr A consisted of 30 pts with PSVT and Gr B of 2(with AFF and a ventricular rate of greater than 1 beats/min. All pts were given an initial dose of mg/Kg of V (V_{ID}) and placebo in a RDB cross-over Response was defined as conversion to sinus rhyth for Gr A, and slowing of the ventricular rate to than 100 beats/min for Gr B. If there was no res to either, an additional higher dose of 0.15 mg/k (V_{HD}) was given 30 min later. In Gr A: 14/30 pts converted to SR after V_{ID} and 1/30 (3%) converted after placebo. Of the 15 pts who failed to respc V_{ID} or placebo, 6 (40%) responded to V_{HD}. In Gr pts (50%) responded to V_{ID}. Six of the 10 pts ((failed to respond to V_{ID} responded to V_{HD}. In 1 with atrial flutter and Wolff-Parkinson-White (WI drome, administration of V_{HD} resulted in an incr heart rate from 150 to 300 beats/min due to a cha atrioventricular conduction from 2:1 to 1:1. We clude that: (1) V is significantly superior to p for conversion of PSVT and for slowing of the ver rate in AFF (both P values < 0.01); and (2) V may contraindicated in pts with WPW syndrome associat a propensity to AFF.

"We thought selecting the best central station would be difficult, but this system is clearly in a class by itself."

Hewlett-Packard's new 500 Series Patient Information Center is a substantial advance in patient monitoring.

All quotations in this brochure are a summation of comments made by medical, engineering, and administrative professionals during extensive clinical tests, trials and seminars on the 500 Series.

While the 500 Series incorporates virtually every monitoring function required of a modern microprocessor based central station, it also provides important innovations in four specific areas:

☐ It has noticeably reduced false HR alarms.
☐ It has simplified system operation to 10 function keys.
☐ It has improved the detail, display, recall and accuracy of monitoring information.
☐ It has increased system reliability through a comprehensive four-level system of self-test and self-diagnosis.

In addition, the 500 Series is so compact that it requires less than half the working space needed by most other central stations. It is modular in design so that it can be economically expanded and upgraded. And its inherent flexibility provides a broad range of price and performance features as well as functional capabilities. In short, the 500 Series is a total Patient Information Center which can serve your unit or institution for years to come.

"Now when I hear that alarm I know it's serious."

In an actual hospital test, the 500 Series showed more than an 85% reduction in false HR alarms. By using sophisticated computer techniques to identify "R" waves, the 500 Series seldom miscounts the muscle artifact and extraneous noise that account for most false alarms.

"10 major function keys make it far easier to use."

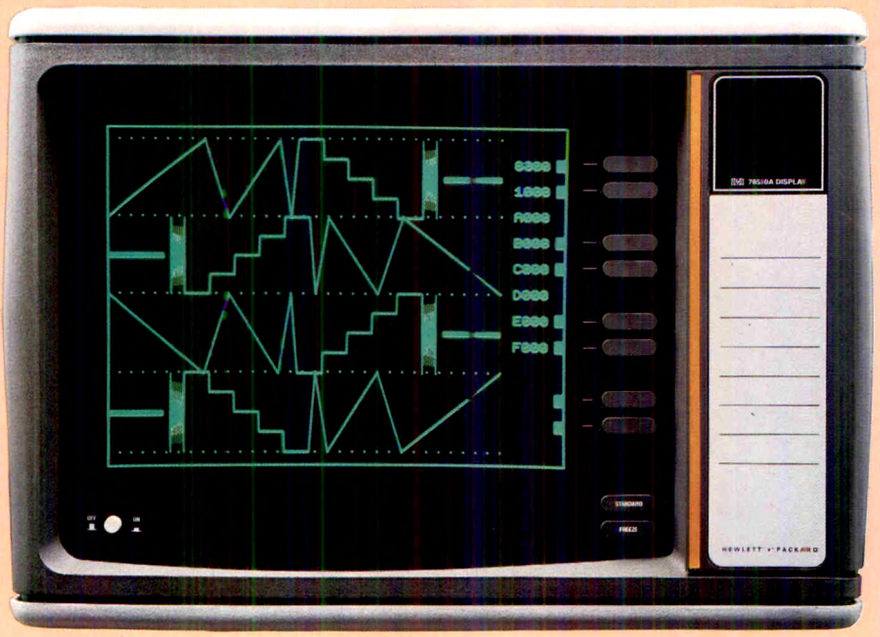
While most central station systems carry as many as 50 or 60 major function keys, the 500 Series requires only 10, since each "softkey" is a multiple function key. This means a more compact control panel with less clutter and less confusion. And the operation of the 500 Series is simplicity itself – it actually guides the staff through the use of English-like cues.

"For the first time, I've got a sharp, bright QRS right next to my patient's vital signs."

Using such techniques as a high resolution 1200 line raster scan and a 10-bit sample, the new "superaster" display in the 500 Series delivers bright QRS detail on ECG waves. In addition, words and numbers can both be displayed anywhere on the screen.

Reliable

The 500 Series is designed and built to provide the highest level of on-line consistency. Advanced circuit design, thoroughly tested parts and components, and a rigorous 14-step environmental and quality control testing procedure give the 500 Series an inherent reliability.



Dependable

Should a malfunction in the 500 Series occur, four distinct levels of self-test and self-diagnosis are available to quickly and easily detect and correct it.

Level 1 is an automatic continuous fault monitor, invisible to the operator unless a malfunction occurs.

Level 2 is a self-test that generates an internal system check as well as a list of diagnostic codes to aid in the correction. It provides a recorder strip, conveniently annotated with error codes so the operator has a hard copy of virtually any fault.

Level 3 is an extended self-test that does everything in Level 2 with the addition of a display check.

Level 4 fault detection employs a circuit analyzer board which takes command of the microprocessors and data buses facilitating component level trouble shooting using digital signature analysis.

Self-test with the 500 Series Patient Information Center is not an idle claim. It was designed and built-in at the inception, and it is a major advancement in system serviceability, convenience and cost effectiveness.

Adaptable

The modularity of the 500 Series Patient Information Center permits a variety of system configurations as well as options and functions. This "building block" approach to patient monitoring allows you to custom configure a system to best meet your individual needs.

A Choice of Systems. The 500 Series Patient Information Center is available in a Basic and a Comprehensive system. The 78501 Basic system is primarily intended for progressive care and telemetry units and provides 8 ECG traces on a single scope.

The 78502 Comprehensive system is primarily intended for intensive care and surgical units. It provides 4 six-second ECG traces. It also provides display of all monitored vital signs, other monitored waveforms, or freeze of ECG data. Optionally, 48 trend lines and eight channels of pressure processing may be added to each four-bed unit.

The 78520 is an arrhythmia monitoring system with a separate computer and arrhythmia data display. It can be added to either the Basic or Comprehensive system. The 78525 adds storage, recall and edit plus data management functions to either system.

Recorder Capabilities. Hewlett-Packard recorders may be dedicated to four patients or shared by as many as 32. In either case, simultaneous alarms from several patients will automatically be captured, and stacked in an electronic memory. Annotation of bed ID, time, date, alarm cause and heart rate from the time of alarm accompany the waveform on the strips.

Bedside Options. Available HP bedsides include "telemetry," "ECG only," "ECG and pressure," or "multi-parameter." Each system accommodates any combination of bedsides.

Custom Options. Both systems also offer custom configuration. Such parameters as recorder run and delay times, and bed identification may be defined for each installation.

Mounting Options. Displays may stand alone or be stacked, or be mounted on racks, swivels, tabletops, walls, or ceilings.

The Hewlett-Packard approach to critical care.

The 500 Series Patient Information Center is a tangible end product of the Hewlett-Packard approach to patient monitoring. An approach that is committed to the innovative use of new technology and the on-going design, development, manufacture and support of reliable, dependable critical care products.

Careful attention to compatibility between the 500 Series and older as well as new bedside products is another example of the HP approach. Compatibility adds longer life and utility to an institution's investment.

In addition, Hewlett-Packard returns more than 8% of every medical sales dollar to research and development. Hewlett-Packard's engineers also maintain perhaps the industry's toughest quality control standards – standards that include 14 separate environmental tests. As part of its support services, Hewlett-Packard is committed to timely installation, user and bioengineer training, as well as preventative maintenance and repair.

In every aspect of patient monitoring, Hewlett-Packard is dedicated to responsible technological advances and clinically tested procedures. You can depend on it.

DIFFERENTIAL EFFECT OF VERAPAMIL IN OVERT AND CONCEALED WPW SYNDROME: NEW EVIDENCE FROM INTRACARDIAC RECORDINGS

Marc Platt, MD, Tom Peter, MD, William Mandel, MD
Cedars-Sinai Medical Center, Los Angeles, California

The effects of Verapamil (V), a slow channel blocker, on accessory pathway (AP) tissue is unclear; a bypass tract (BT) functioning solely in the retrograde (RET) direction (concealed WPW [WPWc]) may be electrophysiologically dissimilar to an AP with anterograde (ANT) and RET conduction (WPWo). V, 0.15 mg/kg IV was given to 20 pts with supraventricular tachycardia (PSVT) (8 Type A WPW, 12 left-sided WPWc) and studied with programmed intracardiac stimulation. Ventriculo-atrial (VA) BT conduction was proven by earliest atrial activation at the septal RA or the coronary sinus during PSVT or RV pacing. 14/16 pts converted with prolonged atrial echo to His time (Ae-H; mean pre 255 msec - post 360 msec) - and AV block; RET H-Ae time did not change (mean 230 msec). In 8/8 with WPW: 1) ANT AP effective refractory period (ERP) decreased or did not change (NS p <0.5); 2) RET AP ERP decreased or did not change (NS p <0.5). In WPWc, mean RET APERP increased (p <0.05) post V.

	PRE V		POST V	
	WPW	WPWc	WPW	WPWc
ANT APERP (msec)	338±10	-	326±11	-
RET APERP (msec)	256± 8	273±11	250± 6	295±9

(Mean±SEM)

Thus, the response of the BT in WPW and WPWc is qualitatively different and suggests electrophysiologically different tissue. These observations may in part explain the different clinical course and response to therapy in those two types of WPW.

QUINIDINE DECREASES BOTH RENAL AND METABOLIC CLEARANCE OF DIGOXIN.

Piet Hooymans, Pharm D; Nicholas Holford, MRCP; Barry Massie, MD, FACC; Michael Witt, Pharm D; Ben Pluym, MD; Frans Merkus, PhD. University of Amsterdam, The Netherlands, and University of California and VA Hospital, San Francisco, CA.

Recently it has been shown that quinidine (Q) increases plasma digoxin concentration ([D] mg/ml) by decreasing D volume of distribution and renal D clearance (C-R L/Hr) in normal subjects. We have examined the changes C-R, as well as the non-renal clearance (C-NR), of D in cardiac patients (PTS) given Q. Five PTS were studied before and 21 hours after starting Q. [D] increased from 1.0 ± .5 (SD) to 1.4 ± .5 and C-R fell from 3.9 ± 1.7 to 2.3 ± .0. Twelve PTS were studied during steady state D therapy, on and off Q. In these, total D clearance (C-T) was estimated from daily D dose, [D] and an assumed D bio-availability of 65%. C-NR was calculated as C-T minus C-R. Simultaneously measured creatinine clearance was unchanged.

	[D]	C-R	C-NR
Off Q	1.0 ± .5	5.7 ± 2.4	2.1 ± 1.9
On Q	1.7 ± .9	3.7 ± 1.9	.6 ± .8
Change (*p<.05)	↑70%*	↓35%*	↓71%*

These findings suggest that although the acute rise in [D] after Q probably results from a change in volume of distribution, the decrease in C-R is also rapid. The sustained rise in [D] during chronic D and Q therapy can be explained by the decrease in digoxin clearance. Of note is that C-R and C-NR decreased by similar amounts, suggesting that Q decreases D metabolism as well as renal excretion in PTS. Therefore, changes in both metabolic and renal clearance should be considered in predicting D dose requirements following the addition of Q.

EFFECTS OF ORAL DIGOXIN ON VENTRICULAR ECTOPY AND ITS RELATION TO LEFT VENTRICULAR FUNCTION.

Alan H. Gradman, MD, FACC; Harvey Berger, MD; Moira Cunningham, PA; Mary Harbison, BA; Barry Zaret, MD, FACC, West Haven VAH and Yale University School of Medicine, New Haven, Connecticut.

The effect of oral digoxin on ventricular ectopy was assessed in 13 cardiac patients with frequent (>60/hr) ventricular premature beats (VPB). Continuous 24 hr electrocardiograms were obtained during 2 control days and one day each during maintenance dosing with digoxin 0.25 mg and digoxin 0.375 mg daily; electrocardiograms were analyzed using the YALECG computer system which quantifies VPB's and detects complex VPB patterns. No significant change in VPB frequency occurred between control (219±39 VPB/hr) and the digoxin 0.25 mg dosing period (177±42 VPB/hr). However, at the higher digoxin dose of 0.375 mg, VPB frequency decreased to 106±28 VPB/hr, a mean reduction of 52% (p<.05). During the control period, multiformity was observed in 12/13 patients, bigeminy in 13/13, coupling in 12/13 and ventricular tachycardia in 4/13. The incidence of complex VPB patterns did not change after digoxin.

Radionuclide left ventricular ejection fraction ranged from 37 - 74% (mean 54±3%) during the control period. Left ventricular function was normal (ejection fraction ≥ 50%) in 8/13 and abnormal in 5 patients. On digoxin 0.375 mg, patients with normal ejection fraction had a mean reduction in VPB/hr of 65% (p<.05), while in patients with abnormal ejection fraction only a 12% reduction occurred (pNS). Thus, digoxin 0.375 mg daily is moderately effective in reducing VPB frequency but ineffective in suppressing complex VPB patterns. This effect is present predominantly in patients with normal left ventricular function.

DIGOXIN-QUINIDINE INTERACTION: INCREASED DIGOXIN BRAIN CONCENTRATION

James E. Doherty, MD, FACC; David Straub, MD, Joe Bissett MD, FACC and Marvin Murphy, MD, FACC, VAMC-UAMC, Little Rock, AR

The mechanism of increased digoxin serum levels and toxicity with concomitant quinidine administration is poorly understood. We studied tritiated digoxin (D) in tissues of 6 dogs given digoxin alone (DA), and 5 given D and quinidine (DQ) for 48 hours after steady state was achieved. Serum D levels increased from 1.6 ng/ml to 2.35 ng/ml in dogs given digoxin-quinidine and some animals vomited and some developed cardiac irregularities. Animals were sacrificed and tissues and serum were analyzed for D. Data revealed D content of brain (white matter) was increased by 51%. D content of skeletal muscle, a major depot for D, was reduced. D concentration of adrenals, bladder, colon, small intestine, liver, lung, pancreas, spleen and gall bladder was not changed.

Canine Tissue Digoxin (ng/gm)

	DA	DQ	
Brain	9.42	19.93	p < 0.05
Skeletal muscle	25.1	17.65	p < 0.025
Heart	104.00	83.63	p < 0.05

Redistribution of digoxin from major depots is the basis of the digoxin-quinidine interaction. Increased brain digoxin levels and reduced myocardial levels indicate toxicity may be neurally mediated in this drug interaction.

CORONARY ARTERY DISEASE: ROLE OF VASOSPASM
8:30-10:00

INCREASED LEVELS OF THROMBOXANE A_2 IN PERIPHERAL AND CORONARY CIRCULATION IN PATIENTS WITH ANGINA PECTORIS

T. Kuzuya, MD; M. Tada, MD; M. Inoue, MD; K. Kodama, MD; H. Takeda, MD; M. Mishima, MD; M. Inui, MD; H. Abe, MD, FACC, Osaka University School of Medicine, Osaka, Japan

Thromboxane A_2 (TXA_2), a vasoconstrictive prostanoid, is known to induce spasm of isolated coronary vessels and to increase platelet aggregability. To define role of TXA_2 in the pathogenesis of angina pectoris, plasma levels of TXB_2, a biologically inactive product of TXA_2, were determined in coronary sinus (CS) and aorta (AO) as well as antecubital (peripheral) vein of anginal patients by radioimmunoassay employing anti-TXB_2 antisera and [^{3}H]TXB_2 after acidic lipids were extracted from plasma of EDTA- and indomethacin-treated blood. Of 18 patients with effort angina whose stenotic lesions (≧ 75 %) were angiographically documented, 12 exhibited a marked increase in peripheral TXB_2 (494 ± 191 pg/ml plasma, $P < 0.01$), compared with normal subjects (251 ± 98 pg/ml, n = 20). When AO and CS TXB_2 levels were determined in 11 cases with simultaneous measurements of CS blood flow during atrial pacing stress, 7 cases exhibited marked increases in CS TXB_2 efflux at rest (46.5 ± 19.7 ng/min ; normal value = 38.6 ± 11.9 ng/min) with further increases (117 ± 50 %) during pacing-induced anginal attack. All of 11 patients with variant angina exhibited marked increases in peripheral TXB_2 (637 ± 162 pg/ml, $P < 0.01$); 3 cases were subjected to cardiac catheterization and showed increased TXB_2 efflux in CS during spontaneous and ergonovine-induced anginal attack, which were accompanied by coronary vasospasm and fluctuation of CS blood flow. These results indicate that increased TXA_2 production in coronary circulation may be at least partly responsible for anginal attack or coronary vasospasm, possibly due to altered blood platelet-vascular wall interactions; measurements of TXB_2 in patient blood are thus of possible diagnostic value.

INCREASED PLATELET PROSTAGLANDIN GENERATION AND ABNORMAL PLATELET SENSITIVITY TO PROSTACYCLIN AND THROMBOXANE A_2 IN ANGINA PECTORIS

Jawahar Mehta, MD, FACC; Paulette Mehta, MD; University of Florida and VA Medical Center, Gainesville, Fl.

To define the role of platelet function in myocardial ischemia, we studied 22 patients (pts) with angina pectoris (AP) and 14 normal subjects. Of 22 pts, 10 were studied during episode of AP (group A) and 12 several hours after AP (group B). Platelet prostaglandin generation (malondialdehyde levels) (MDA) was measured as index of thromboxane A_2 (TXA) synthesis. Platelet sensitivity to vasodilator-platelet aggregation inhibitor prostacyclin (PGI_2) and vasoconstrictor-platelet aggregation stimulant TXA analog EMA were also evaluated. MDA production was significantly higher in AP pts compared to controls (2.50±0.30 and 1.70±0.13 nM/10^9 platelets, respectively, $P<0.02$). AP pts required more PGI_2 for 50% platelet aggregation inhibition than controls (1.90±0.35 and 0.68±0.04 ng, $P<0.001$). Group A AP pts required more PGI_2 than group B pts for similar degree of aggregation inhibition (2.90±0.60 and 1.30±0.12 ng $P<0.005$). Furthermore, platelets from AP pts had greater sensitivity to pro-aggregatory actions of EMA than from controls (EMA required for 50% platelet aggregation, 135±8 and 194±16 ng, $P<0.001$). Platelet sensitivity to EMA was similarly increased in both group A and group B pts (131±12 and 137±11 ng, P-NS). These data show enhanced MDA generation, decreased sensitivity of platelets to PGI_2 and increased sensitivity to EMA in AP pts. Previous studies have suggested decreased synthesis of PGI_2 by atheromatous vessels. Imbalance between PGI_2 and TXA production in favor of TXA, and altered sensitivity of platelets to PGI_2 and TXA may be important mechanisms in the genesis of enhanced platelet aggregation and myocardial ischemia in certain pts.

RESPONSIVENESS OF ATHEROSCLEROTIC RABBIT AORTA TO ADRENERGIC AND CHOLINERGIC STIMULATION

Mitsuhiro Yokoyama, M.D.; Philip D. Henry, M.D., FACC, Washington University, St. Louis, Mo.

Both adrenergic and cholinergic agents can induce coronary spasm in patients with Prinzmetal's angina. To determine whether altered autonomic responsiveness is related to atherosclerosis, helical strips from aortae of control rabbits and rabbits fed a 2% cholesterol diet were mounted in an organ bath for the recording of isometric force under basal conditions and in response to selected agonists. Concentrations of norepinephrine and ergonovine evoking half-maximum contractions (ED_{50}) averaged 4 x 10^{-7}M (n=10) and 10^{-6}M (n=10) in normal arteries. In atherosclerotic arteries, corresponding values for the two α-agonists were significantly ($P < 0.01$) lower, averaging 10^{-7}M (n=11) and 2 x 10^{-7}M (n=12). Acetylcholine and methacholine evoked minor relaxations at low concentrations (< 5.10^{-8}M), and contractions at higher concentrations in both control and atherosclerotic arteries. ED_{50} for acetylcholine- and methacholine-induced contractions averaged 2 x 10^{-6}M and 10^{-6}M in atherosclerotic arteries (n=20) and did not differ significantly from values obtained in control arteries (n=20). In both groups of arteries, muscarinic blockade with 10^{-7}M atropine abolished all responses, whereas prejunctional nicotinic blockade with 10^{-7}M β-bungarotoxin or postjunctional α-adrenergic blockade with 10^{-7}M prazosin had no inhibitory effect. In contrast, contractions produced by nicotine (10^{-5}-10^{-4}M), an agent that acts by releasing norepinephrine from vascular nerves, were abolished by 10^{-7}M β-bungarotoxin or 10^{-7}M prazosin in all arteries. Thus, compared to control arteries, atherosclerotic aortae were supersensitive to α-adrenergic agonists but exhibited normal muscarinic responses to acetylcholine.

FREQUENCY OF MYOCARDIAL INFARCTION AND SUDDEN DEATH IN 44 VARIANT ANGINA PATIENTS: A HIGH RISK ISCHEMIC HEART DISEASE SUBSET

R. Charles Curry, Jr., MD, FACC; Carl J. Pepine, MD, FACC; Robert L. Feldman, MD; James L. Whittle, MD; C. Richard Conti, MD, FACC, University of Florida, Gainesville, FL.

Variant angina is thought to be associated with an increased risk of myocardial infarction and death. To test this hypothesis we tabulated the clinical course of 44 patients (pts) with variant angina documented by transient episodes of rest pain with ST segment elevation occurring spontaneously (28 pts) or following ergonovine (16 pts). The group consisted of 36 men and 8 women, age 51 years (mean, range 19-69 years). Chest pain was present for 15 months (mean, range 1-100 months). All pts underwent coronary angiography with significant (>50% diameter narrowing) coronary artery disease (CAD) present in 29 pts (multivessel in 19 pts, single vessel in 10 pts). Treatment included: short and long-acting nitrates (44 pts), propranolol (37 pts), perhexiline (21 pts), and coronary artery bypass graft surgery (13 pts).

FREQUENCY OF CLINICAL EVENTS IN VARIANT ANGINA

	No. Pts.	MI	SUDDEN DEATH
CAD	29	11(38%)	7(24%)
No CAD	15	3(20%)	2(13%)
Totals	44	14(31%)	9(21%)

MI = myocardial infarction

Conclusion: Patients with variant angina, especially those with CAD, appear to be at high risk for MI and sudden death. These results support a need for improved treatment.

MYOCARDIAL CELL DAMAGE DURING VASOSPASTIC ANGINAL ATTACKS WITH PROMPTLY REVERSIBLE ELECTROCARDIOGRAPHIC CHANGES.
A.Biagini,MD; C.Carpeggiani,MD; G.Mazzei,MD; G.C.Zucchelli; G.Buzzigoli; A.L'Abbate,MD; A.Maseri,MD,FACC. CNR Laboratory of Clinical Physiology and University of Pisa, Pisa, Italy.

Since recent reports indicate that coronary vasospasm may be involved in the genesis of acute myocardial infarction, we have investigated whether vasospastic anginal attacks might be associated with myocardial cell damage also in the absence of permanent QRS or ST-T changes. We obtained the serum time activity curves of creatine kinase MB and of myoglobin (both by radioimmuno assay method) in 15 patients (pts) admitted to our CCU with documented vasospastic angina. We reasoned that the relatively large experimental errors in the low range of values to be expected in our pts could be overcome by detecting a consistent rise and fall in the time activity curve of multiple indices of cell damage (even within the normal range). The pts were studied following an ischemic attack lasting from 10 to 30 minutes associated with typical transient ST-T changes completely reversible at the end of the episode (12 pts had ST↑ and 3 pts had ST↓). Peripheral blood sampling was begun within 3 hours from the onset of the ischemic episode and was followed at four-hour intervals in the first day and at six-hour intervals in the next two days. A consistent rise and fall (with a significant difference in the mean activity of the first 12 hours relative to the subsequent hours) of all 2 indices was observed in 7 pts, while the remaining 8 pts showed changes of only 1 index or no consistent changes.
In conclusion, the consistent, coherent rise and fall of multiple curves in some pts with vasospastic angina indicates that episodes of ischemia may cause cell damage even in the absence of persistent QRS and ST-T changes.

CORONARY ARTERY DISEASE: EVALUATION OF MEDICAL AND SURGICAL THERAPIES
10:30-12:00

THE EFFECT OF CROSSOVERS ON ESTIMATES OF SURVIVAL IN MEDICALLY TREATED PATIENTS WITH CORONARY ARTERY DISEASE
David B. Pryor, M.D.; Phillip J. Harris, M.D.; Kerry L. Lee, Ph.D.; Frank E. Harrell, Jr., M.D.; Robert A. Rosati, M.D.; Duke University Medical Center, Durham, North Carolina.

Estimating survival in medically managed patients with coronary artery disease is complicated by the crossing of some patients to aortocoronary bypass surgery. The purpose of this study was to evaluate the effect on estimating survival of medically managed patients, when those subsequently requiring surgery are withdrawn from the medical group. Of 1488 patients with significant coronary artery disease who were treated medically, 151 subsequently underwent aortocoronary bypass. The median time of crossover from initial catheterization was 15.5 months (range 2-89 months). The crossover and noncrossover patients were compared with respect to 13 prognostically important descriptors of symptoms, coronary anatomy, and ventricular function. Significant ($p<.03$) differences were found in 6 of the descriptors. The crossover group had a lower prevalence of severe congestive heart failure (0 vs. 8%), abnormal left ventricular contraction (45% vs. 62%), anterior left ventricular asynergy (23% vs. 34%), intraventricular conduction defects (0 vs. 4%), arteriovenous oxygen difference >5 vol% (22% vs. 31%) and left ventricular end diastolic pressure >17mmHg (7% vs. 18%). Therefore, at the time of initial catheterization, the crossover patients had a better prognosis. We conclude that survival of this medically managed group may be made worse, not better, by withdrawal of the crossover patients.

INFLUENCE OF ERGONOVINE-INDUCED CORONARY ARTERY SPASM ON VULNERABILITY TO VENTRICULAR FIBRILLATION
Basil Margolis, MB, MRCP; Richard L. Verrier, PhD, FACC; Bernard Lown, MD, FACC, Cardiovascular Laboratories, Harvard School of Public Health, Boston, Mass.

Although coronary spasm has been extensively studied, its influence on ventricular electrical properties has not. We therefore examined the effect of ergonovine-induced spasm on coronary blood flow, coronary sinus oxygen saturation and ventricular fibrillation threshold (VFT). Coronary spasm was induced in anesthetized dogs by ergonovine maleate (0.1 mg iv). Coronary blood flow was measured by an electromagnetic flow probe around the left anterior descending artery, and VFT was determined using the single stimulus method. Catheters in the coronary sinus and aorta allowed measurement of anteriovenous oxygen difference ($A\text{-}VO_2$ Δ %) across the coronary bed. The subsequent effect of intravenous Nifedipine 1 μg/kg as a coronary vasodilator was also studied. Coronary spasm was induced with ergonovine in 6 out of 10 dogs and the results are as follows (mean values ± SE) where *=$p<0.05$ compared to control values:

	Control	Ergonovine	Nifedipine
Peak Coronary Flow (ml/min)	41±4	29±3 *	40±4
$A\text{-}VO_2$ Δ %	47±6	57±8 *	47±8
VFT (milliamps)	28±2	21±2 *	28±3

In another 5 dogs nitroglycerine was also shown to annul ergonovine's effect on coronary blood flow and ventricular vulnerability. We therefore conclude that: (1) ergonovine-induced coronary spasm substantially lowers the VFT, and (2) this effect is mediated through an action on the coronary vasculature rather than directly on the myocardium.

INFLUENCE OF BYPASS SURGERY ON MORTALITY AND MORBIDITY IN STABLE ANGINA: A PROSPECTIVE RANDOMIZED STUDY
Frank Kloster, MD, FACC; Cynthia Morris,BS; Paula Kanarek, PhD; U of Oregon Health Sciences Center, Portland, Oregon.

To evaluate the influence of coronary bypass surgery on chronic, stable angina 100 patients were randomized to medical (M, n=49) or surgical therapy (S, n=51). On entry the groups did not differ in age, sex, prior myocardial infarction (MI), extent of coronary disease or ejection fraction. All were in Functional Class III without previous heart failure; left main disease was excluded. Prospectively defined critical events requiring termination from the study include death, MI and high risk unstable angina requiring surgery (UA-S). Unstable angina responding to medical therapy (UA-M) and other cardiac events are tabulated. Current followup is from 1 to 94 months (mean 49.5) with 20 in each group at risk 5 years or longer after entry.

Critical events: death--5 in M, 4 in S (all cardiac); new MI--11 in M, 13 in S; UA-S--10 in M, 4 in S. Three additional M and 1 S died after termination for MI or UA-S (total deaths--8 in M, 5 in S). The probability of survival after 5 years is 87±5.1% in M vs 90±4.6% in S. Using life table analysis there are no significant differences between M and S in death, MI, UA-S or all events combined.

Stratified by vessel disease the only difference in terminating events is in patients with 3-vessel disease having UA-S (5 in M, 1 in S $p\leq.05$). UA-M is no different in the two groups (12 in M, 5 in S, p=n.s.). However, UA-M and UA-S combined are more frequent in M ($p<.01$) and in M with 3-vessel disease ($p<.01$). The probability of developing unstable angina within 5 years is 51% in M vs 34% in S.

After 4 years average followup there is no difference between M and S therapy in survival, MI, UA-S or UA-M. However, overall UA is less frequent following bypass surgery and in the S subgroup with 3-vessel disease.

THE PREDICTIVE AND PROGNOSTIC VALUE OF EXERTIONAL HYPOTENSION

Karl E. Hammermeister, MD, FACC; Timothy A. DeRouen, PhD; Harold T. Dodge, MD, FACC; Veterans Administration Medical Center and University of Washington, Seattle, Wash.

We examined the data files of the angiography registry of Seattle Heart Watch to determine the ability of exertional hypotension to predict three vessel disease, left main coronary disease, severe left ventricular dysfunction with ejection fraction ≤30%, or poor prognosis. The mean followup in 1241 patients with coronary arteriography and maximal treadmill testing was 5.5 years. Exertional hypotension (present in 93 patients) had poor sensitivity in detecting three vessel disease (15%), left main stenosis ≥50% (15%), or ejection fraction ≤30 (12%), but had relatively high specificity (95%, 93%, and 92% respectively). Using Cox's regression analysis to study 493 medically treated patients, exertional hypotension is univariately predictive of survival (p=0.006); but when examined multivariately to adjust for the effects of age and a history of congestive heart failure, is no longer significantly predictive of survival (p=0.075). Maximum systolic blood pressure (MSBP) during exercise appears more predictive of survival in medically treated patients, retaining its significance (p=0.001) when examined multivariately with age and history of CHF. Among 653 surgically treated patients, MSBP was not even univariately predictive of survival, suggesting that the abnormal physiology and poor prognosis in patients with MSBP ≤130 had been altered by surgery. We conclude that exertional hypotension is an insensitive technique to identify patients with three vessel disease, left main coronary disease, or severe left ventricular dysfunction. It adds little to prediction of prognosis over a history of CHF and age. MSBP is a better predictor of survival in medically treated patients.

USE OF NONINVASIVE CLINICAL PARAMETERS TO CHARACTERIZE PROGNOSIS IN PATIENTS WITH ANGINA PECTORIS, TREATED MEDICALLY OR SURGICALLY

The VA Cooperative Study Group for Surgery for Coronary Arterial Occlusive Disease

Since CHD patients with symptomatic left main disease exhibited improved survival following surgical treatment, identification of other high risk groups was sought using simple noninvasive variables present at entry and known to be risk factors from other natural history studies. Accordingly, for 508 male patients randomized to medicine in 1970-1974, a risk function was developed using 4 noninvasive variables (in descending order of importance, ST segment depression on resting EKG, history of myocardial infarction, history of hypertension, NYHA Class III or IV) by applying the Cox life table regression model to their 5-year survival data. The 5-year risk distribution obtained by the function showed a sharp gradient of risk between the high and low terciles. The terciles appeared to be independent of angiographic descriptors, since the distribution of patients with disease of 1, 2 or 3 vessels was approximately the same in each. The low risk tercile included patients with none or only one risk factor, except ST depression; the high tercile included those with any 2, except NYHA, and those with any combination of 3 or more; all other patients were in the middle risk tercile. The same risk function was used to classify all patients randomized in 1972-74 into approximate terciles.

Five-year cumulative survival rates (CSR) by treatment and tercile are shown for the 595 patients without left main disease in all hospitals and for the 511 patients at the 10 hospitals with an average operative mortality of 3.3%:

	All 13 Hospitals			10 Hospitals		
Risk Group	n	Med.	Surg.	n	Med.	Surg.
Low	238	.93	.82**	207	.93	.82*
Mid	175	.79	.81	148	.76	.83
High	182	.64	.82***	156	.63	.88†

*P < .05; **P < .01; ***P < .005; †P < .0005 based on Mantel-Haenszel χ^2

We concluded that, in contrast to patients in the low and mid terciles, for whom survival is not improved by surgery, a new high risk subgroup has been identified among angiographically confirmed CHD patients whose survival is significantly improved by coronary bypass surgery.

EVALUATIONS OF PRE- AND POSTOPERATIVE MYOCARDIAL PERFUSION BY THALLIUM 201 GRADED EXERCISE TESTING

James M. Jones, Gary S. Niess, James L. Taylor, Santosh Kansal, David I. Roitman, L. Thomas Sheffield, Joseph R. Logic, Nicholas Kouchoukos, Robert B. Karp. UAB Medical Center, Birmingham, Alabama.

We studied the effect of coronary artery bypass grafting (CABG) on coronary perfusion in 62 patients (PTS) of mean age 53 years with coronary artery disease using exercise thallium scintigraphy (TS) pre- and post-operatively. Most PTS were exercised 1 day prior to and 3 months post surgery which included aneurysmectomy in 7 PTS. 3 PTS had perioperative MI defined by new Q waves on the EKG and CPK MB criteria. Immediate and 3 hour delayed (TS) was obtained.

On the treadmill post-op the mean treadmill time was longer (406 vs 267 sec, $p < 0.001$) and the mean double product was higher (256 vs 180 mg Hg beat/min x 10^2, $p < 0.001$) than pre-op. Post-op fewer PTS had angina (9 vs 45, $p < 0.001$) or EKG evidence of ischemia (8 vs 39, $p < 0.001$) detected by treadmill testing. However, post-op we found no marked difference in the number of PTS with TS showing reversible defects (RD) with exercise (41 vs 43) or fixed defects (FD) (29 vs 30). Also, we found no difference in the area of RD (28% vs 27%) or FD (30% vs 29%) expressed as percent of total myocardium using computer assisted planimetry.

Thus, we conclude that CABG 1) improves PTS clinically 2) is associated with longer treadmill time and higher double product post-op 3) reduces number of PTS with EKG evidence of ischemia on exercise testing 4) does not reduce number of RD or FD detected by exercise TS and 5) therefore, does not exert its effect exclusively by restoration of coronary perfusion.

CORONARY COLLATERAL CIRCULATION –" A FUNCTION–LESS - QUIRK? "

Wolfram Kupper, MD, Walter Bleifeld, MD,
Department of Cardiology, University Hospital-Hamburg
W.- Germany.

Recent work gave evidence that similar appearing collaterals (collats) may have a different reserve capacity (CRC). To test the hypothesis that left ventricular segmental wall motion (LVWM) in areas supplied by collats depends on CRC we measured great cardiac vein flow (GCVF), (continuous thermodilution, constant atrial pacing rate) in 17 patients (pts) with a proximal occluded LAD and collats from the right coronary artery (RCA) to the LAD. Measurements were taken at rest and during reactive hyperemia after intracoronary injection of 8 ml of contrast medium into the RCA. CRC was determined as % increase of GCVF during contrast induced hyperemia. Anterior LVWM was quantitated by % systolic halfaxial shortening from cine ventriculography (30° RAO, at rest and after nitroglycerin: hypokinetic < 35 %, akinetic < 10 %). Quality of collats was grossly examined from the coronary angiogram by first and maximal contrast appearance time (CAT) within collats.

Results: Arterial pressure did not change significantly after contrast injection into the RCA. 10/17 pts (I) had irreversible LVWM abnormalities, their CRC was 19 % (GCVF: 70 ⟶ 83 ml/min). 7/17 pts (II) showed normal LVWM after nitroglycerin, their GCVF increased significantly more during contrast hyperemia from 62 to 126 ml/min (CRC: 103 %, $P < 0.001$). Mean CAT in group I and II was not significantly different (3681 ± 961 vs 4100 ± 1327 ms).

Conclusion: Collats in both groups had similar CAT at rest but their CRC differed significantly with a much higher CRC of collats to regions with reversible LVWM abnormalities. After LAD occlusion regional LVWM seems to depend on CRC.

THERAPEUTIC USE OF PACING
8:30-10:00

PULMONARY VENOUS REGURGITATION: ETIOLOGY OF HEMODYNAMIC DETERIORATION DURING VENTRICULAR TACHYARRHYTHMIAS AND PACING

Masahito Naito, MD, T. Joseph Mardelli, MD, Daniel David, MD, James Kmetzo, Joel Morganroth, MD, FACC, Leonard S. Dreifus, MD, FACC, Lankenau Hospital, Jefferson Medical College, Philadelphia, PA

To determine the mechanism of deterioration in cardiac output (CO) that may occur in ventricular (V) tachycardia or pacing, 23 dogs with intact pericardium underwent V and atrial (A) pacing at cycle lengths (CL) of 400 and 300 msec with AV interval=100 msec, simultaneous A and V pacing (AV=0 msec) and V to A conduction (AV= -100 msec). Simultaneous systolic left ventricular (LV) and left atrial (LA) pressures (P) were correlated with M-mode echo LV size (LVD), LA size (LAD), and mitral valve (MV) motion and LA and LV angiograms. Results:

	A-V = 100		A-V = 0		A-V = -100	
CL (msec)	400	300	400	300	400	300
CO (L/min)	2.8	3.7	2.0	2.9	1.8	2.4
LVP (torr)	129	121	120	101	112	88
LAP (torr)	15	18	21	30	23	27

A significant ($p<0.02$) progressive reduction in LVP and CO occurred with loss of normal AV sequencing but was most marked during VA sequencing. This was associated with a decrease of 10% in LVD and an increase in LAP correlating with an increased LAD. Remarkably, the duration of MV opening and size excursion of MV was unchanged at all AV and VA intervals and there was a complete absence of MV regurgitation by LV angiogram. In contrast, atrial regurgitation into the pulmonary veins resulted from VA sequencing. Hence, it appears that the major determinant of decreased CO and LVP during V tachycardia or pacing with VA conduction is a decreased LV preload due to reversal of atrial flow.

EVALUATION OF AN IMPLANTABLE PROGRAMMABLE MULTIMODAL (DVI; DVI-DVO; DOO SEQUENTIAL; AND DOO SIMULTANEOUS) PACEMAKER FOR THE CONTROL OF SUPRAVENTRICULAR TACHYCARDIAS

Agustin Castellanos, MD,FACC; Harvey L. Waxman, MD; Barouh V. Berkovits, EE,FACC; Ruey J. Sung, MD,FACC, Univ. of Miami School of Medicine, Miami, Florida.

The efficacy of a recently developed implantable programmable pacemaker (PP) in the control of recurrent, or incessant, supraventricular tachycardias (SVT) was evaluated during intracardiac electrophysiological studies.When attached to atrial (A) and ventricular (V) electrodes, this PP, in seven of its eight possible program states,is capable of performing demand sequential A-V (DVI) pacing at varying rates and A-V intervals.In the program setting of "700 + 150" it provides double demand A-V sequential (DVI-DVO) pacing. Moreover, by placing the tip of the ventricular electrode in a position from which it did not perceive an adequate intraventricular signal we were also able to perform continuous asynchronous A-V sequential (DOO SE) pacing and, by magnet application, continuous asynchronous A-V simultaneous (DOO SI) pacing.Programmed A and V stimuli were delivered before,and after, connection to the PP in 5 patients (pts); 3 with dual A-V nodal pathways(2 of the slow-fast, and 1 of the fast-slow type) and 2 with left sided accessory pathways. Following connection to the PP,the SVT were abolished in 4/5 pts with DVI-DVO, DOO SE, and DOO SI pacing. However, in 2/5 pts, DOO SE stimulation also induced the arrhythmias. The patient in whom the SVT could not be abolished had a short $\bar{P}$ — R and a long R — $\bar{P}$ and probably required sequential ventriculo-atrial pacing. The present study proves the usefulness of this multimodal PP, but raises the possibility that V-A sequential pacing might be required in some cases of SVT.

TERMINATION OF RECURRENT VENTRICULAR TACHYCARDIA BY PATIENT-ACTIVATED RAPID VENTRICULAR STIMULATION

Geoffrey O. Hartzler, MD; Michael J. Osborn, MD; David R. Holmes, MD, Mayo Clinic, Rochester, MN

When recurrent sustained ventricular tachycardia (VT) proves refractory to antidysrhythmic drug therapy, treatment options are severely limited. Five men, ages 34-59 years, received permanently implanted transvenous radiofrequency ventricular stimulators (RFVS) for termination of refractory, recurrent ventricular tachycardias. Diagnoses included coronary artery disease with prior myocardial infarction-3 pts, congestive cardiomyopathy-1pt, and hypertrophic cardiomyopathy-1 pt. Prior to invasive investigation and RFVS implantation, pts required an average of 7 hospitalizations (range 5-8) in a 14 month period (range 2-42 mos) for 23 episodes (range 6-75) of recurrent sustained VT. Each patient underwent extensive electrophysiologic study including programmed ventricular stimulation (PVS) and electrophysiologic-pharmacologic (E-P) testing during which sustained VT was repeatedly induced and terminated. Antidysrhythmic drugs preventing induction of VT could not be identified. In 4 pts, repeated PVS and E-P testing at subsequent hospitalization yielded identical results. Subsequent to RFVS implantation, 3 pts have terminated multiple VT episodes (respectively, $>1,000$ episodes at 17.5 mos, 35 episodes at 8 mos, 5 episodes at 4 mos followup). A fourth pt successfully terminated 1 VT episode but subsequently died from an arrhythmia unrelated to the use of RFVS. The fifth pt has had no sustained VT recurrence at 4 mos followup. All pts continue to require multiple antidysrhythmic drug combinations to reduce the frequency and rate of spontaneous VT. We conclude that pt activated RFVS can be used effectively in selected pts with thoroughly investigated and characterized recurrent ventricular tachycardia.

REFRACTORY SUPRAVENTRICULAR TACHYCARDIAS: SUCCESSFUL THERAPY WITH DOUBLE DEMAND SEQUENTIAL PACING.

Samuel Lévy, MD, FACC, Barouh Berkovits, EE, FACC, William Mandel, MD, FACC, Jean-Paul Broustet, MD, Israël W.P. Obel, MD, FACC, Henri Bricaud, MD, FACC Departments of Cardiology, University of Bordeaux, France, and Cedars-Sinai Medical Center, Los Angeles, CA

Refractory recurrent supraventricular tachycardias (SVT) have been treated with a variety of permanent pacemakers with variable results. This report details the use of a double demand sequential (DDS) pacemaker modified to function in a dual demand (DVI-DVO) mode. The unit has a sense circuit which identifies a tachycardia (5 consecutive ventricular complexes with a cycle length <395msec.). The generator then switches to the DVO mode with a fixed rate of 77/min. and delivers stimuli (atrial and ventricular) with a 60msec. AV interval. Upon termination of the SVT, the unit switches to the DVI mode. Three pts. had this pacing mode employed for the control of SVT. All pts. had been extensively evaluated and therapeutically failed to respond to all available antiarrhythmic agents. One pt. (57 y.o. female) had concealed WPW; one pt. (40 y.o. male) had overt WPW and one pt. (65 y.o. female) had sinus node reentry and severe COPD. All pts. had preimplantation studies of the efficacy of the DVI-DVO unit. Subsequent to implantation (6-16 mos.), all pts. have been unaware of significant arrhythmias and have had Holter monitor recordings. Antiarrhythmic agents have been continued in 2 of the 3 pts. but at much lower dosages. In summary, a DVI-DVO DDS pacemaker was successfully implanted in 3 pts. with intractable SVT. In an automatic mode, AV fixed rate pacing has repeatedly terminated PSVT. This device offers a new means of managing intractable PSVT.

IMPLANTED AUTOMATIC BURST PACEMAKERS FOR TERMINATION OF VENTRICULAR TACHYCARDIA.

John D. Fisher, MD, FACC, Seymour Furman, MD, FACC, Soo Gyum Kim, MD, Montefiore Hospital and Medical Center, Bronx, New York

Automatic burst pacemakers for termination of ventricular tachycardia (VT) are needed because of three major limitations with manual systems, i.e., 1) syncope may occur before the pacemaker can be activated; 2) VT may exist unnoticed for long periods until hemodynamic decompensation occurs; 3) patients (pts) develop psychologic syndromes due to responsibilities of managing manual systems. We implanted automatic burst pacers in four VT pts; two Medtronic (Medt) 2404 and two Intermedics Cybertach (Cytach). The Medt units are custom prescription units with bursts at a fixed rate or adaptive as a % of the VT cycle length (CL). The Cytach is a programmable pacer with tachycardia criterion, burst rate and duration, and other features adjustable. Both pacers can be disarmed to work as ventricular demand pacers only.

Pt.	Pacer	VT rate	Burst rate	# stimuli
1	Medt	180-220	(75% VT CL)	7
2	Medt	125-190	232	8
3	Cytach	140-150	206	8
4	Cytach	140-155	206	8

Results: over a follow-up period of 0-12 months there have been no major complications, no malfunctions, no evidence of inappropriate bursts, and no further hospitalizations for VT. Atrial fibrillation with a rapid pulse led to disarming one unit which is rearmed when needed for termination of VT. In carefully selected pts automatic burst pacemakers open new horizons for control of VT.

THE MANAGEMENT OF PAROXYSMAL VENTRICULAR TACHYCARDIA AND FIBRILLATION ASSOCIATED WITH THE LONG QT SYNDROME

Elio Di Segni, MD; Herman O. Klein, MD; Daniel David, MD; Elieser Kaplinsky, MD, FACC, Department of Cardiology, Meir General Hospital and Tel-Aviv University, Israel.

Prolongation of the QT interval is known to be associated with repetitive paroxysms of a particular ventricular tachycardia called also "torsade de pointes". It is a typical complication of quinidine but may occur in various other conditions. Antiarrhythmic medications are ineffective and treatment is empirical. We have utilised transvenous right ventricular endocardial pacing in 12 patients with marked prolongation of the QT interval suffering from bouts of ventricular tachycardia and fibrillation. In six patients the syndrome was due to quinidine. Acceleration of the heart rate resulted in immediate suppression of all arrhythmias. Pacing was continued until the condition producing the QT prolongation disappeared. In one case a permanent pacemaker was implanted as the QT prolongation was congenital and permanent. The actual QT interval was shortened by overdrive pacing in all patients (< 0.5 seconds) but the corrected QT interval remained prolonged (> 0.6 seconds). The arrhythmia was therefore clearly dependent upon the actual QT interval and overdrive pacing could suppress it by decreasing the actual interval without shortening the corrected interval. All 12 patients survived and in 11 pacing was discontinued following the return of both the actual and corrected QT intervals to normal. In conclusion, overdrive pacing is an effective, safe, expeditious and reliable mode of treatment in paroxysmal ventricular tachycardia and fibrillation associated with prolongation of the QT interval.

CARDIAC PACEMAKERS
10:30-12:00

RADIONUCLIDE ANGIOGRAPHIC EVALUATION OF LEFT VENTRICULAR PERFORMANCE DURING VENTRICULAR PACING

Charles A. Boucher, M.D., FACC, Gerald M. Pohost, M.D., FACC, Frederick K. Poulin, M.D., H. William Strauss, M.D., Robert D. Okada, M.D., J. Warren Harthorne, M.D., FACC, Massachusetts General Hospital, Boston, MA.

To determine the effect of ventricular pacing (VP) on global and regional left ventricular (LV) function, gated cardiac blood pool scans were performed in 15 patients (pts) with permanent transvenous ventricular pacemakers. In all, the heart rate during VP was within 15 beats/min of the rate during sinus rhythm (SR). LV ejection fraction (EF) was derived and the synchrony and synergy of LV regional wall motion (WM) was evaluated. WM was scored in 3 LV segments each in the anterior and left anterior oblique views on a 5 point scale from 3 = normal to -1 = dyskinesis. Ten pts had a normal (NL) EF (>.50) and 5 pts had an abnormal (ABN) EF (<.35). Seven of the pts with NL EF had scans both at rest and during exercise. At rest, NL pts had a small but statistically significant mean decrease in EF of 0.03±.04 (± 1 S.D.), $p<.05$, during VP, compared with SR. In addition, contraction became asynchronous, beginning in the anterolateral and posterobasal walls and ending at the apex. The septum, apex, and inferior walls showed significant reduction in WM during VP, compared with SR, whereas the anterolateral and posterobasal walls remained NL. During exercise, there was no longer a difference in EF between SR and VP, and the contraction pattern became nearly synchronous. In ABN pts, EF and WM were the same with SR and VP.

In conclusion: 1) NL pts demonstrate reduction in global and regional LV function during VP at rest, but demonstrate no significant differences during exercise; 2) In ABN pts, there was no difference in EF and WM during VP, compared with SR.

ARE AN EXCESSIVE NUMBER OF PERMANENT PACEMAKERS BEING INSERTED?

Atul B. Chokshi, M.D.; Howard S. Friedman, M.D., FACC; Monte Malach, M.D., FACC; Balendu C. Vasavada, M.D.; Sheldon J. Bleicher, M.D. The Brooklyn Hospital and Downstate Medical Center (SUNY), Brooklyn, NY

Almost 100,000 pacemaker generators were inserted in 1978 at an estimated cost of at least 500 million dollars. Between 1973 and 1976 permanent pacemaker(PP)insertions at The Brooklyn Hospital increased by 71%. Accordingly, it is our purpose to review our experience for this period to determine whether some of these PP may have been unnecessary and to show the impact of peer-review on reducing such operations. The average age of patients was 75 years(range 24-95). The indications for a PP in 169 patients was sick-sinus syndrome in 92(54%),intraventricular conduction abnormality in 44(26%)and complete or advanced heart block in 28(17%). In 1976 heart block was the indication in only 8% of the patients. Of the 92 patients with sick-sinus syndrome 10 were receiving alphamethyldopa and 29 digitalis and/or propranolol; thus, in 42% of the patients receiving a PP for bradycardia an iatrogenic cause may not have been excluded. Preliminary review of patients receiving a PP for indications other than heart block showed that in at least 22 of141(15.6%)symptoms persisted and that 23(16.3%)died less than 1 year after PP had been inserted. A more critical policy and the institution of a pacemaker-review committee which provided guidelines and a means for ongoing retrospective review produced a decline in PP insertions by 46% from 1976 in both 1977 and 1978. It is concluded that peer-review can improve patient selection and thereby result in a substantial reduction in PP operations. If our experience can be extrapolated nationally, the result could be an estimated health-care savings of ¼ of a billion dollars per year.

TEMPORARY TRANSVEOUS PACING AND FEMORAL VEIN THROMBOSIS
Andre J. Nolewajka, MD; Michele D. Goddard, MD; Thomas C. Brown, MD, University of Western Ontario, London, Canada.

The true incidence of deep vein thrombosis with subsequent pulmonary embolism in patients requiring temporary transvenous pacing via the femoral vein is unknown. Thirty consecutive patients, mean age 66± 10 years (38-79) requiring temporary transvenous pacing were studied by bilateral contrast venography and perfusion lung scans within 4 hours of removing the pacing wire. The patients were subdivided into two subgroups based on their hemodynamic status. There was no statistical difference between the two groups with respect to mean age or the length of time the pacer wire was in place and all patients were placed on subclinical heparin therapy. Eleven or 37% of the patients had venogram evidence of thrombosis with 6 (55%) showing lung scan evidence of pulmonary emboli. The hemodynamically compromised subgroup (7 patients) had 6 (85%) patients with thrombosis with 3 (50%) having subsequent pulmonary emboli. The hemodynamically stable subgroup (23 patients) had a 22% incidence of thrombosis and a 40% incidence of emboli. Deep venous thrombosis with subsequent pulmonary emboli is a serious complication of temporary transvenous pacing using the percutaneous femoral approach, despite prophylactic heparin anticoagulation.

AN ANALYSIS OF MALFUNCTION AND COMPLICATIONS OF TEMPORARY PACING
Joseph L. Austin, MD; Lehman K. Preis, MD; Richard S. Crampton, MD, FACC; Randolph P. Martin, MD, University of Virginia, Charlottesville, VA.

Temporary pacing is a common treatment for bradyarrhythmias, but few studies have dealt with pacer malfunction (MF) and complications. We reviewed the medical records of 100 consecutive patients (pts) who received 113 temporary pacemakers (PM). MF was defined as failure to capture and/or sense, and occurred in 37% (42/113) of PM. The initial MF occurred within 48 hrs in 86% (36/42) and within 24 hrs in 50% (21/42). The incidence of MF was 35% (32/91) in femoral catheters and 42% (8/19) in brachial (p=not significant (NS)). In pts with acute myocardial infarction (AMI), 50% (9/18) of PM developed MF vs 35% (33/95) of PM in pts without AMI (NS). Thirty-seven complications occurred in 20% (23/113) of PM: ventricular tachycardia during insertion:7, bleeding or hematoma at the site:4, cardiac perforation:4, fever: 7, sepsis:3, phlebitis:6, local infection:3, and pulmonary embolus (PE) :3. No deaths resulted from these complications. In pts with AMI, 28% (5/18) of PM produced complications vs 19% (18/95) of PM in pts without AMI (NS). While the incidence of total complications, especially perforation, was signigicantly higher in brachial (7/19) vs femoral (16/91) PM ($p < .05$), sepsis, local infection, and PE were seen only in femoral PM. In all pts with sepsis, local infection, and PE, and in 5/6 pts with phlebitis, the PM were in place $\geq$ 72 hrs ($p < .0005$). We conclude: 1) Since MF is common after pacemaker insertion and tends to occur early, close monitoring is advisable. 2) The incidence of MF does not seem influenced by site of insertion or presence of AMI. 3) Complications are also not infrequent and in pts prone to thromboembolism and/or infection, sites other than femoral should be considered. It may be advisable to terminate temporary pacing by 72 hrs.

THE RHYTHMS UNDERLYING THE FIXED RATE PACING OF LONG-TERM TRANSTELEPHONE MONITORING
Doris J.W.Escher, MD, FACC; Seymour Furman, MD, FACC; John D. Fisher, MD, FACC, Montefiore Hospital and Medical Center, Bronx, New York

The natural history (Nhx) of the underlying rhythm (UR) of paced (P) patients (pts) on long term transtelephone monitoring (TTM) is unknown, particularly when always paced on TTM (apparent pacemaker (PM) dependence), as is the level of risk for syncope (real PM dependence) in event of sudden failure. One hundred consecutive pts (48 male, 52 female; usual age distribution) with VVI pulse generators (PG) on TTM were reviewed for Nhx of UR. Duration of pacing was 2-122 (av 50) months; duration of TTM the last 1-63 (av 16) months of followup. Forty six pts were 100% P on day of entry to study; 32 of these, always P on TTM, revealed on PM inhibition UR of 3^{o} block (B) 10, atrial fibrillation (AF)without bradycardia (BA) 5, with BA 5, Sick Sinus Syndrome (SSS) with BA 5, incomplete B5, other 2. Of 36 pts initially P for 3^{o}B, the 28 always P on TTM had UR of 3^{o} B 14, AF 7, intermittent B 5, sinus BA 2. Of 31 pts initially P for SSS, UR broke through intermittently or regularly in 14, 7 were always P. Those pts not P on entry to study ran gamut from original UR of SSS, AF with bradycardia and 3^{o} B to RSR.

Many pts apparently shift UR post implantation, often, in the short run of brief inhibition, to less serious patterns. To evaluate the relatively small but significant (10% or less) true risk for syncope in event of recalls, traveling, scheduling of PG changes, etc., pacemaker center visits, with inhibition of pacing to reveal UR must be interpolated with long term TTM. A schedule of Q 6-12 months will provide a good Nhx of the UR.

ATRIO-VENTRICULAR NODAL "MEMORY" STUDIED BY RANDOM ATRIAL STIMULATION
Frederik M.A. Harms, MD; Robert M. Heethaar, PhD; Etienne O. Robles de Medina, MD, FACC; Frits L. Meijler, MD, FACC, University Hospital, Utrecht, the Netherlands.

To study AV junctional function, ventricular responses were correlated with atrial intervals during random atrial stimulation.
Methods: Five patients with normal AV conduction -documented by incremental atrial pacing- were studied during random high right atrial stimulation (interval range 350 to 700 msec) using a computer controlled stimulator. Right atrial and His bundle electrograms were used to document the AV nodal transmission characteristics. In all patients random atrial stimulation was repeated following 1 mg atropine i.v. and 20 minutes after 5 mg propranolol i.v. Cross-correlograms were computed between atrial intervals and AH conduction times, before and after drug administration.
Results : 1) The first correlation coefficient showed a strong negative correlation (-0.8) between the last atrial interval preceeding the conducted atrial complex and AH conduction time.

2) Second and higher order coefficients showed no significant correlation between atrial intervals and AH conduction times.

3) In spite of observed changes in AV nodal refractoriness similar results were obtained after atropine and propranolol administration.
Conclusions: 1) Adaptation of AV nodal conduction to random changes in atrial intervals does not exceed two cycles, suggesting no, or a minimal effect of AV nodal "memory" on AV transmission characteristics.

2) This AV nodal behaviour was not affected by the autonomic nervous system.

MYOCARDIAL INFARCTION: ELECTROPHYSIOLOGY OF ARRHYTHMIAS
8:30-10:00

PATHOPHYSIOLOGY OF EPICARDIUM OVERLYING TRANSMURAL MYOCARDIAL INFARCTION

Ronald R. Hope, MD, FACC; Benjamin J. Scherlag, PhD, FACC; Ralph Lazzara, MD, FACC, Vet. Adm. Medical Center and University Hospital, University of Oklahoma, Oklahoma City, OK

Reentrant ventricular arrhythmias (RVA) arise in epicardium (epi) overlying the transmural infarction zone (IZ) in the dog 4-5 days after left anterior descending coronary artery ligation. Effects of pacing at various heart rates (HR) (30-330/min) from epi in normal zone (NZ) and IZ were studied in 20 dogs using ECG leads and epi recordings. Pacing in the NZ at any stimulus strength (SS) showed no change in QRS morphology at these HR. During pacing at IZ sites, QRS morphology changed with HR in association with conduction delays in the IZ. This effect was reversed by increasing the SS. Refractoriness in the IZ was tested by programmed pacing. Abnormally short refractoriness ($\leq$130 msec) and prolonged refractoriness ($\geq$330 msec) coexisted within the IZ. This marked dispersion of refractoriness was related to the occurrence of RVA. In 10 dogs a 3x4 cm section of epi was removed which included NZ and IZ. Action potentials were recorded during superfusion with Tyrode's solution at 37° C. Rate-dependent RVA were initiated in 90% of tissued studied. At a constant SS, action potentials close to the stimulation site showed progressivley shorter (100 msec), diminutive responses as the HR was increased. Intermittent failure of excitation was noted at higher rates. Rate-sensitive changes in conduction, refractoriness, and excitation are determinants of RVA, originating in the IZ epi.

ROLE OF ELEVATED EXTRACELLULAR K^+ ACTIVITY IN CONDUCTION SLOWING DURING ACUTE MYOCARDIAL ISCHEMIA

Jeffrey L. Hill,Ph.D.; Leonard S. Gettes, MD, FACC, University of North Carolina, Chapel Hill, N.C.

Transmural electrodes capable of simultaneously recording local extracellular K^+ activity and ventricular activation at subepicardial, midmyocardial and subendocardial sites were used to determine if the rise in extracellular K^+ induced by acute ischemia causes the associated conduction slowing. In 10 open-chest pigs the distal LAD was cannulated and perfused with femoral arterial blood using a roller pump. A transmural K^+ electrode was inserted in the center of the anticipated ischemic zone and in the non-ischemic zone. Acute ischemia was produced for 5-10 minutes by stopping the perfusion pump; extracellular K^+ and transmural conduction were continuously recorded. One hour following reperfusion, isotonic KCL was added to the arterial perfusate to raise extracellular K^+ to ischemia-induced levels at rates equivalent to and twice that recorded in the ischemic subendocardium (which always demonstrated the greatest K^+ rise, $[K^+]$ = 11-16 meq/L).
Conduction slowing at the same level of K^+, with and without ischemia, were compared: 1) conduction slowing induced by ischemia was always greater and occurred at lower K^+ levels than that produced by K^+ infusion.
2) doubling the rate of K^+ infusion produced greater conduction slowing at the same level of K^+ but still did not equal the conduction slowing caused by acute ischemia.
Thus, the rate of K^+ change contributes significantly to conduction slowing. However, the ischemia-induced conduction slowing cannot be entirely explained by either the rate or magnitude of the extracellular K^+ rise occurring in the ischemic zone.

THE LETHAL LATE CONSEQUENCES OF SMALL INFARCTS.

Eric L. Michelson, MD; Joseph F. Spear, PhD, FACC; E. Neil Moore, DVM, PhD, FACC; University of Pennsylvania and Lankenau Hospital, Philadelphia, Pennsylvania

A canine model of chronic infarction has been developed in which ventricular fibrillation (VF) can be reproducibly initiated with routine methods of programmed electrical stimulation (PES). At 3-30 days after 2-stage occlusion of the distal left coronary artery 1-2 cm from its termination, modified by a reperfusion stage, 12/13 dogs (vs. 1/8 with proximal occlusion, $p < 0.005$) had VF inducible with 1-3 ventricular extrastimuli during ventricular pacing at a cycle length of 300 msec. Infusion of 15-60 mg/kg procainamide prevented reinitiation of VF, using identical methods of PES, in all 13 dogs previously susceptible. Following PA, 2 effects were observed with PES: (a) 7 dogs: inducible sustained ventricular tachycardia(rather than VF, with cycle length 120-250 msec and with fractionation of local electrograms) which could be terminated (in 4 dogs) by PES or rapid ventricular pacing, and with characteristics suggesting a reentrant mechanism; (b) 3 dogs: self-terminating ($\leq$ 5 sec duration) ventricular fibrillation-flutter; (c) 3 dogs: both (a) and (b). All 13 dogs had small ($\leq$ 2 cm^2) mottled infarcts confirmed histopathologically. These results suggest (1) the potentially lethal late consequences of small mottled infarcts (2) the potential salutory effects of high dose procainamide on the initiation of inducible VF, and (3) that a common reentrant mechanism may explain both inducible VF and inducible sustained VT.

CORRELATION OF THE INCIDENCE OF REPERFUSION VENTRICULAR ARRHYTHMIAS WITH THE DURATION OF EXPERIMENTAL CORONARY ARTERY LIGATION

C. William Balke, BA; Eleiser Kaplinsky, MD FACC; Eric L. Michelson, MD; and Leonard S. Dreifus, MD FACC Jefferson Medical College, Philadelphia, Pennsylvania

Malignant ventricular arrhythmias (VA) occur frequently when experimental acute coronary artery ligation (CAL) is interrupted by coronary reperfusion (R). The present study was designed to determine the duration of antecedent CAL rendering animals most susceptible to subsequent reperfusion VA ($\geq$ 5 ventricular ectopic beats/min (VE), ventricular tachycardia ($\geq$ triplets) (VT), or ventricular fibrillation (VF). For this purpose, the incidence of reperfusion VA was studied following the release of a one-stage proximal ligation of the left anterior coronary artery after 5, 10, 20, 30, or 60 min in 86 dogs:

Min of CAL	Total VA	VE or VT	VF
5', N=19 dogs	5/19 (26%)	3/19 (16%)	2/19 (10%)
10', N=19 dogs	9/19 (47%)	3/19 (16%)	6/19 (31%)
20', N=14 dogs	11/14 (79%)	0/14 (0%)	11/14 (79%)
30', N=16 dogs	16/16 (100%)	3/16 (19%)	13/16 (81%)
60', N=18 dogs	14/18 (78%)	10/18 (56%)	4/18 (22%)

Reperfusion VA occurred with increasing incidence as CAL periods were lengthened from 5 min to 30 min (5/19 (26%) vs 16/16 (100%), $p<0.001$) but, remarkably, reperfusion VA and especially reperfusion VF occurred less commonly when R was delayed from 30 min to 60 min after CAL (13/16 (81%) vs 4/18 (22%), $p <0.005$).
Conclusion: These data suggest that there is a distinct time course for the susceptibility to reperfusion VA and VF after experimental CAL. The highest risk for reperfusion VF corresponds to a time (20-30 min) when ischemic changes are most marked but infarction is minimal. These findings may explain the phenomenon of "spontaneous" VF in patients without demonstrable myocardial infarction.

COMPARATIVE EFFECTS OF VERAPAMIL AND NIFEDIPINE ON REACTIVE HYPEREMIA, AND VENTRICULAR ARRHYTHMIAS DURING CORONARY ARTERY REPERFUSION. Lair G.T. Ribeiro, MD; Thomas L. DeBauche, MD; Tedd A. Brandon, BS; Lawrence A. Reduto, MD, FACC; Peter R. Maroko, MD, FACC; Richard R. Miller, MD, FACC. Baylor College of Medicine, Houston, Texas and Deborah Heart & Lung Center, Browns Mills, New Jersey.

To examine effects of the calcium antagonists verapamil (Ver) and nifedipine(Nif) on coronary hemodynamics and ventricular arrhythmias during coronary reperfusion(CAR), 24 open chest dogs underwent proximal left anterior coronary artery occlusion(CAO). At 25 minutes(min) CAO was released. Regional myocardial blood flow(RMBF)(ml/min/100g) was determined by microspheres (^{85}Sr and ^{141}Ce,8-10 μ) 18 min post CAO and after 10 min of CAR. At 20 min post CAO, dogs were randomized to control(C) (n=8), Ver (n=8) (.2 mg/Kg in 5 min followed by .01 mg/Kg/min infusion) or Nif (n=8) (100 μg/Kg in 5 min followed by 3μ Kg/min infusion). In C, 6/8 animals had ventricular tachycardia(VT) (3) or ventricular fibrillation(VF)(3). With Ver, VT did not occur and 1/8 had VF ($p<.05$ vs C). In Nif 4/8 had VT (2) or VF (2) (p=ns vs C). Ten min after CAR transmural RMBF in ischemic myocardium increased 829% (24±5 to 223± 60) ($p<.01$) in C and to similar extent ($p>.05$ vs C) with Ver and Nif. RMBF in non-ischemic myocardium was increased by Nif, 99±11 to 189±42 ($p<.05$) and unchanged (p=ns) by Ver and in C. Endocardial and epicardial distribution in hyperemic and normal regions were unchanged by Ver or Nif (both $p>.05$ vs C). Coronary resistance in ischemic myocardium declined (80-90%), similarly (p=ns) in C, Ver and Nif groups. Thus, Verapamil decreases reperfusion ventricular arrhythmias without altering RMBF. Although both Ver and Nif are calcium antagonists, their membrane antiarrhythmic effects appear to differ in CAR-induced arrhythmias.

THE EFFECT OF A MOBILE CORONARY CARE UNIT ON MORTALITY IN ACUTE MYOCARDIAL INFARCTION. A RANDOMIZED STUDY. Stig Holmberg, MD; Bertil Wennerblom, MD; Dept. of Cardiology, Sahlgrenska Hospital, Göteborg, Sweden.

The aim of the study was to elucidate the effect of a mobile coronary care unit (MCCU) 1) on mortality in the prehospital phase of acute myocardial infarction (AMI), 2) on hospital mortality in AMI. -- Pilot study: Of 165 consecutive patients (pts) with AMI arriving alive at hospital 53% were transported by ambulance. The ambulance controller could correctly diagnose 55% of AMI pts requesting an ambulance. In only 21% of pts preliminarily classified by ambulance controller as AMI was this diagnosis confirmed. -- In the randomized study pts requesting an ambulance and suspected by ambulance controllers to have AMI were randomized to MCCU or standard ambulance transport (ST.AMB.) in proportions 60/40. The MCCU was hospital based and operated by two ambulance drivers and two CCU nurses. -- Results: 844 pts were included; of these 58 pts were found in cardiac arrest. Two of 38 in MCCU group were resuscitated and discharged from hospital alive. No pts in ST.AMB.group of 20 survived. Among 786 pts alive on arrival of ambulance 163 were diagnosed as AMI, 99 in MCCU group and 64 in ST.AMB. Median delay from start of symptoms to call for ambulance was ≤ 2 hours. -- Mortality: Two pts in MCCU group developed ventricular fibrillation during transport and were successfully resuscitated. Two pts in ST.AMB. group had cardiac arrest and could not be resuscitated.Hospital mortality for MCCU pts was 16% and for ST.AMB. 31% ($p<0.05$). 625 pts did not develop AMI. Of 360 pts in MCCU group there were 4 hospital deaths (1.1%) whereof one caused by cardiac disease. Of 265 pts in ST.AMB.group there were 8 deaths (3.0%), thereof 4 caused by cardiac disease. -- In conclusion a MCCU caused a modest reduction of prehospital mortality and a significant reduction of hospital mortality in AMI.

MYOCARDIAL CYCLIC ADENOSINE MONOPHOSPHATE AND HIGH ENERGY PHOSPHATES IN VENTRICULAR VULNERABILITY TO FIBRILLATION IN THE ISOLATED RAT HEART AFTER CORONARY ARTERY LIGATION Wilhelm F. Lubbe, MD,FACC, Cecile A. Muller, B.Sc.,Lionel H. Opie, MD, FACC. MRC Ischemic Heart Disease Research Unit, University of Cape Town, Cape Town, South Africa.

The role of cyclic adenosine monophosphate (cAMP), adenosine triphosphate (ATP) and phosphocreatine (PCr) in the mediation of changes in vulnerability to ventricular fibrillation (VF) in the first 15 min of myocardial ischemia was assessed in the isolated rat heart. Ventricular fibrillation threshold (VFT) fell from 8.6 ± 0.7 ma to 1.6 ± 0.2 ma (n = 25 hearts) by 15 min after coronary artery ligation. Ischemic tissue ATP and PCr fell to 1.7 ± 0.1 and 1.2 ± 0.1 μmol/g fresh weight (f.wt.) in comparison to 3.6 ± 0.1 and 3.9 ± 0.2 μmol/g f.wt. respectively in uninvolved myocardium. cAMP increased from 0.45 ± 0.01 in uninvolved myocardium to 0.60 ± 0.03 nmol/g f.wt. in ischemic myocardium. Atenolol, a β_1-adrenoceptor antagonist (70 to 700 μmol/l) failed to inhibit the fall in VFT, ATP and PCr or the increase in cAMP. Propranolol (d-, l- and dl-isomers, 8-24 μmol/l) inhibited the fall in VFT and increase in cAMP but not the fall in ATP and PCr. Sotalol failed to attenuate the fall in VFT. Lidocaine (7 to 21 μmol/l) inhibited the fall in VFT, but did not alter changes in ATP, PCr or cAMP. Amiodarone which inhibits adrenergic activity noncompetitively, prevented the fall in VFT and increase in ischemic myocardial cAMP but not the fall in ATP and PCr.

Alterations in vulnerability to VF with onset of regional ischemia in this model are linked to changes in cAMP and not ATP or PCr. Selective adrenergic antagonism suggests that mechanisms independent of the β_1-adrenoceptor are involved to increase ischemic tissue cAMP but are inhibited by amiodarone and d- and l-isomers of propranolol.

REDUCTION OF MYOCARDIAL INFARCTION MORTALITY BY PRUDENT PATIENT ACTIVATION OF MOBILE CORONARY CARE John M. Stang, M.D.; Richard P. Lewis, MD, FACC; Alonzo A. Alonzo, PhD; Martin D. Keller, MD, PhD; James V. Warren, MD, FACC; The Ohio State University College of Medicine, Columbus, Ohio.

The City of Columbus has eight years of experience with a citizen-activated Emergency Medical Services System (EMS) which employs autonomous paramedics (EMT-P) acting solely by protocol-direction without telemetry. During 1976-1977, 1,102 patients (pts) with apparent acute cardiac symptoms were studied with respect to pre- and intra- hospital course. From this comprehensive city-wide one-year infarct-suspect group, 544 pts with acute myocardial infarction (AMI) were found and comprise the focus of this report. AMI pts were divided into those who elected to use the EMS and those who did not (and reached the hospital by other personal or public transportation). Comparison of the two follows:

	Users	Non-Users	
Patient Decision Time	41 min	252 min	$p < .01$
Serious Complications*	45%	12%	$p < .01$
Overall Mortality	16.7%	1.4%	$p < .01$
Initial Ventricular Fibrillation (VF)	10.6%	0%	
Mortality Initial VF	45%	0%	

*VF, cardiac arrest, pulmonary edema, shock, severe bradycardia

EMS users were more ill and had quickly and correctly perceived their need for pre-hospital coronary care. Others with uncomplicated AMI chose not to activate the system despite 96% awareness of it. Hence, the effective use of EMS facillitated successful pre-hospital therapy of AMI with sudden death in over half and contributed to a city-wide overall mortality of AMI of 18%.

VENTRICULAR ARRHYTHMIAS AND VENTRICULAR FIBRILLATION IN ACUTE MYOCARDIAL INFARCTION.

Ronald W.F. Campbell, MRCP; Alan Murray, PhD, Desmond G. Julian, FRCP. Freeman Hospital, Newcastle upon Tyne, U.K.

The natural history of ventricular arrhythmias (VA) was studied in 1066 pts with AMI; therapy for VA was given only for VF and prolonged VT. Two groups, both admitted within the first 3 hrs of AMI, were investigated: 1) 17 pts who developed VF in the absence of shock, heart failure (primary VF) and who also had not received digoxin, diuretics or any antiarrhythmic drug (including B-blockers) in the previous 72 hrs, 2) 21 comparable pts without VF. Computer assisted analysis of continuous EKG recordings was performed by 3 independent observers. In both groups VA frequency varied with time from the onset of AMI. R-on-T VEBs ($QR'/QT \leq 0.85$) frequency was highest in the first 4 hrs. Single VEBs, multiform VEBs, VEB pairs and VT were most frequent in the 6-12 hrs when R-on-T VEBs were rare. The prevalence of R-on-T VEBs was >1/1000 mins EKG in 8 VF and 1 nonVF pt. A striking increase of R-on-T VEB frequency occurred in the 10 mins prior to VF and all 17 episodes of VF were R-on-T initiated. VT occurred in 4 of 17 VF pts in 19 episodes of which 2 (10.5%) were R-on-T initiated. By contrast VT occurred in 14 of 21 nonVF pts and R-on-T initiation occurred in only 2 of the 246 episodes (1.5%).
These results demonstrate: 1) an association of R-on-T VEBs and primary VF but the relationship cannot be readily appreciated by CCU monitoring, 2) important time relationships of VA in AMI, 3) different initiating mechanisms for VF and VT showing in this context that these are not closely related, 4) a similar incidence of VEBs (single, multiform), VEB pairs and VT in the VF and nonVF groups when compared at corresponding times from the onset of infarction.

DECREASED SHUNT FLOW IN ACUTE VENTRICULAR SEPTAL DEFECT USING 15-METHYL-PROSTAGLANDIN $F_2\alpha$ AS A PULMONARY CONSTRICTOR

Frank L. Mikell, MD; Peter F. Carlyle, BA; Patricia N. Eekhoff; Charles R. Jorgensen, MD, FACC; Jay N. Cohn, MD, FACC; Hennepin County Medical Center and the Univ. of MN, Mpls., MN.

An important determinant of left to right shunt flow (Qp/Qs) in ventricular septal defect (VSD) is the relationship between the pulmonary (Rp) and systemic (Rs) vascular resistance (Rp/Rs). Although agents which reduce Rs, thus increasing the ratio Rp/Rs, have been shown to decrease Qp/Qs, no information is available on the effect of pharmacologically increasing pulmonary resistance in order to increase Rp/Rs and reduce shunt flow. We investigated the possibility that augmentation of the pulmonary resistance with the pulmonary constrictor, 15-methyl prostaglandin $F_2\alpha$ (PG), either alone or in combination with the systemic vasodilator nitroprusside (NP), would increase Rp/Rs and reduce the magnitude of Qp/Qs in a canine model of acute VSD.

In 6 dogs with VSD, PG increased Rp from control values (374±50.8 to 1091±173.0 dyne-sec-cm^{-5}, mean±SEM, $p < .01$). The effect of PG on Rs was variable. In 4 dogs, Rs did not change while Rp increased. Thus, Rp/Rs increased from control (0.095 ±.01 to 0.260 ±.04, $p < .05$) and Qp/Qs decreased (2.28±0.26 to 1.56±0.17, $p < .01$) due to a fall in Qp. In 2 dogs, PG increased Rs and Rp/Rs decreased. Addition of NP to these 2 animals reduced Rs but did not change Rp. Thus, with nitroprusside, Rp/Rs increased and shunt flow decreased. At maximal drug response for the 6 dogs, Rp/Rs increased significantly (0.078±.01 to 0.258 ±.03, $p < .01$) and Qp/Qs fell from a control value of 3.04±0.51 to 1.67±0.1 ($p < .05$) due largely to a decrease in Qp.

In summary, PG increased Rp and reduced Qp/Qs when systemic resistance was not affected. If Rs increased, NP reduced Rs without affecting Rp. NP thus increased Rp/Rs and reduced Qp/Qs. These data indicate that pharmacologic manipulation of the pulmonary vascular resistance is useful in reducing shunt flow and may become a potential therapeutic maneuver in the management of acute VSD.

HOSPITAL RECURRENCE OF VENTRICULAR FIBRILLATION IN ACUTE ISCHAEMIC HEART DISEASE

Kathleen R. Logan, MB; Werner J. McIlwaine, MB; A.A. Jennifer Adgey, MD, FACC, Royal Victoria Hospital, Belfast, N. Ireland.

Two hundred and seventy consecutive patients who developed ventricular fibrillation (VF) outside or inside hospital were studied. Of the 141 with ischaemic heart disease who survived the initial arrest, 121 had an acute myocardial infarction (MI) and 20 an acute ischaemic episode without infarction (AIE). One hundred and five were male and 36 female (mean age 59). Primary VF was VF in the absence of cardiogenic shock or pump failure. VF was considered recurrent when it developed 30 or more minutes after the initial cardiac arrest.
In 41 (29%) of 141, VF recurred. VF recurred in 19 (20%) of the 94 patients with MI and primary VF, and in 12 (44%) of the 27 with secondary VF. In those with AIE, VF recurred in 8 (50%) of 16 with primary VF, and in 2 (50%) of 4 with secondary VF. Of the 41 patients with MI or AIE who had primary VF which occurred within 2 hours of the onset of symptoms, 6 (15%) had one further arrest. This arrest occurred 40 minutes to 6 days (average 2½ days) from the first arrest.
Recurrent VF was more likely in AIE, and in patients with MI who had had secondary VF ($P<0.05$). Age, sex, site of infarction, adequacy of initial resuscitation, site of initial cardiac arrest, onset of symptoms to intensive care, onset of initial cardiac arrest to attempted defibrillation and antiarrhythmic agents used or dosage of the agents given had no significant effect on recurrence in the 141 patients. Ninety-seven (69%) of 141 were discharged from hospital.

INTRA AORTIC BALLOON PUMP FOR SHOCK COMPLICATING INFARCTION. FACTORS INFLUENCING OUTCOME.

Rolf Michels, MD; Max Haalebos, MD; Marcel v/d Brand, MD; Paul G. Hugenholtz, MD, FACC; Thoraxcenter, Rotterdam, the Netherlands.

To predict outcome, age, delay of therapy (in 72 pts) and the findings at catheterization (in 35 pts) were related to survival of cardiac shock after acute myocardial infarction (CSMI) treated with the intra-aortic balloon pump (IABP). Of 41/72 pts (57%) surviving the acute stage, 11 died < 3 mo; 30/72 pts (42%) survived > 1 y, to date 26 are alive, and 19/26 (73%) lead active lives. Of the pts ≤ 60 y, 25/52 (48%) survived > 1 y, as compared to only 5/20 pts (25%) > 60 y. When IABP was instituted < 6 hrs, 26/31 pts (77%) survived > 1 y, compared to only 6/41 (15%) in whom IABP was delayed.
The combination of these factors, demonstrated a favourable course for pts ≤ 60 y with IABP delay < 6 hrs: 19/24 (79%) survived > 1 y. On the other hand all pts > 60 y with IABP delay ≥ 6 hrs died < 3 mo.
In the catheterized pts, no significant differences could be demonstrated for right sided pressures, cardiac index, isometric parameters, ejection fraction, and number of vessels diseased, for pts surviving > 1 y (25/35, 71%) and pts dying < 3 mo (10/35, 29%). These pts could be separated however by left ventricular end diastolic volume (99 ml/m^2, n=21, resp. 135 ml/m^2, n=6, $p < 0.002$) and end systolic volume (70 ml/m^2, n=18, resp. 103 ml/m^2, n=6, $p < 0.002$). Associated with this finding, dyskinesia and mitral incompetence occurred more often in pts dying < 3 mo, than in pts surviving > 1 y (7/10 resp. 3/35, and 5/10 resp. 1/35).
Conclusion : Age, IABP delay, left ventricular volumes and associated mechanical lesions are the major determinants of outcome in CSMI treated with IABP.

IDENTIFICATION OF LEFT VENTRICULAR THROMBI IN HUMANS USING INDIUM-111 LABELLED AUTOLOGOUS PLATELETS

Michael D. Ezekowitz, MRCP; Eileen O. Smith; E. William Allen, MD; Joseph Leonard, MD; Carl Smith, MD; Garo P. Basmadjian, PhD; Fletcher B. Taylor, MD, University of Oklahoma Health Sciences Center, Oklahoma City, Okla.

Left ventricular (LV) aneurysms following myocardial infarction are associated with a significant incidence of mural thrombi and systemic emboli. The purpose of this study was to determine whether Indium-111 labelled platelets could be used for in the identification of these thrombi. Six patients ranging in age from 43 to 77, all with contrast ventriculographic evidence for a LV aneurysm located in antero-apical portion of the LV were studied. Four of the 6 patients had persistent ST segment elevation and 2 had a double precordial pulsation on physical examination. The time from the last infarct to the time of the study varied from 2 months to 10 years. Clearcut clinical evidence for systemic emboli were found in 3 patients. Platelets were separated from whole blood by centrifugation. These platelets were labelled in normal saline at a pH of 6.5 using Indium-111 complexed to 8-hydroxyquinoline. Imaging was performed in the anterior, LAO and left lateral views on the day of the injection of the platelet suspension and at one or two day intervals for a maximum of 8 days. Three patients had positive studies. Two of these 3 patients required surgery and in both, thrombi were confirmed in the LV. In the only patient where clot:blood activity was determined, it was 800:1. Two of 3 patients with negative scans underwent surgery and did not have thrombi in the LV. It is concluded that myocardial imaging using Indium-111 labelled platelets promises to be an effective non-invasive method of identifying clot within the LV.

MULTIPLE GATED ACQUISITION THALLIUM SCINTIGRAMS WITH COMPUTER ENHANCEMENT: IMPROVED SENSITIVITY IN ASYMPTOMATIC MEN WITH ABNORMAL TREADMILL TESTS

Gregory S. Uhl, MD, James R. Hickman, Jr., MD, and Thomas D. Kay, BS, USAF School of Aerospace Medicine, Brooks Air Force Base, TX

In asymptomatic patients, treadmill tests (TM) have poor sensitivity (SENS), specificity (SPEC) and predictive value (PV) for coronary artery disease (CAD). Rest and stress Thallium (Tl) scintigrams may demonstrate an improved diagnostic accuracy, especially when computer enhanced (CE) multiple-gated acquisition (MUG) Tl scans are performed. One hundred asymptomatic men with abnormal TM had exercise and equilibrium MUG-Tl scans done in four views. These were then displayed in a rotating, gated movie. Both unprocessed scintigrams (US) and CE MUG-Tl were interpreted without knowledge of coronary angiography by three observers. CAD was defined as ≥50% lesion in any major vessel. Importantly, none of the CAD patients had a prior myocardial infarction, which can cause fixed perfusion defects which may be easier to detect than reversible ischemia. This eliminated the bias for an observer to "detect" reversible ischemia in a patient with a fixed defect since such a "positive" decision would be a "true positive" decision. Sixteen patients had CAD and all had abnormal CE MUG-Tl scans. The effect of CE vs US is shown below:

	CE	US
SENS%	100 (16/16)	75 (12/16)
SPEC%	89 (75/84)	89 (75/84)
PV%	64 (16/24)	60 (12/20)

Many false positive results would be expected in a population with only a 16% prevalence of CAD but only 9 were found. The use of computer enhancement in gated Tl scans results in improved SENS without loss of SPEC and facilitates accurate comparison of stress and redistribution Tl scans.

A COMBINED TREADMILL-SCINTISCAN SCORE TO PREDICT THE PRESENCE AND EXTENT OF CORONARY ARTERY DISEASE.

David M. McCarthy, MD, FACC, Robert R. Sciacca, EngScD, David K. Blood, MD, FACC, and Paul J. Cannon, MD, FACC. Columbia University College of Physicians & Surgeons, New York, NY

The ability to detect the presence and predict the extent (# vessels) of coronary artery disease (CAD) objectively from an exercise treadmill test (ETT) and thallium myocardial scintiscans was evaluated using discriminant function (DF) analysis. Exercise and redistribution scans in the 30° LAO view were characterized by their two-dimensional Fourier transforms. The analysis was performed in 174 patients(pts), including 110 with CAD (≥70% stenosis); 43 pts had single-vessel (1V) and 67 pts had multiple-vessel (2-3V) CAD.

Input to the analysis included age, sex, 17 variables from the ETT, and 36 Fourier frequency coefficients from each scan. Two linear DFs were constructed using 9 of the input variables, including: duration of exercise; peak double product (HR x BP); change in systolic BP during the last two stages of ETT; change in ST-segment slope with exercise; sex; and two coefficients from each scan.

The method detected the presence of CAD in 103 of 110 pts (94% sensitivity) and correctly classified 58 of 64 controls (91% specificity). Multiple-vessel disease was correctly predicted in 54 of 67 pts with 2-3V CAD (81% accuracy); another 11 pts with 2-3V CAD were predicted to have 1V CAD. In contrast, only 22 of 43 pts with 1V CAD (51%) were correctly classified; of the remaining 21 pts, 16 were predicted to have 2-3V CAD and 5 called controls.

The data demonstrate that numerical functions derived from ETT parameters and Fourier coefficients of thallium scans can be used to detect the presence of CAD with a high degree of accuracy. The predictive accuracy for the number of diseased vessels was 77% (134 of 174 pts classified correctly).

AN INTEGRATED FORMAT FOR MULTIPLE TESTING IN CORONARY ARTERY DISEASE

Howard Staniloff, MD, George Diamond, MD, Daniel Berman, MD, FACC, Michael Freeman, MD, Uri Elkayam, MD, Alan Waxman, MD, James Forrester, MD, FACC. Cedars-Sinai Medical Center, Los Angeles, Calif.

New imaging techniques have improved the noninvasive detection of coronary artery disease (CAD), but difficulty in interpretation is often caused by discordant test results. To investigate whether serial Bayesian analysis decreases this clinical uncertainty, we evaluated 18 pts with suspected CAD with stress ECG's, stress and redistribution thallium imaging (THAL), and exercise multiple gated equilibrium scintigraphy with Tc-99m-RBC's for ejection fraction (LVEF) and segmental wall motion (WM) abnormalities. The data were analyzed quantitatively using Bayes' Theorem: for each pt, a single post-test likelihood for CAD was calculated, based on a pretest estimate by age, sex and symptom (SYMP) and the sensitivity and specificity of each test. Post-test likelihood was then correlated with subsequent coronary angiography. There were 27 (30%) incorrect test and SYMP responses occurring in 13 of the 18 pts (SYMP 6, ECG 8, LVEF 7, WM 1, THAL 5). The mean pretest likelihood was 33.5±32.6% and the post-test likelihood was 0.5±0.5% in the 6 non-CAD pts and 98.6±2.3% in the 12 CAD pts. Therefore, serial Bayesian analysis of multiple imaging and nonimaging techniques allows accurate prediction of the probability of subsequent angiographic CAD in any individual and provides a meaningful basis for resolving conflicting test results.

^{201}TL IMAGING: A COMPARISON OF SINGLE PHOTON EMISSION COMPUTED TOMOGRAPHY AND PLANAR IMAGING EMPLOYING A STANDARD HEART PHANTOM.

James L. Ritchie, MD, FACC; Stig Larson, PhD; Anders Israelson, PhD; Jan I. Thorell, MD; Seattle Veterans Administration Hospital, Seattle, Wa., Karolinska Institute, Stockholm, and the University of Lund, Malmö, Sweden.

A heart phantom (U. of Iowa design) with a defect simulating a myocardial infarction was imaged by standard planar techniques and by a single photon emission computed tomographic technique (ECT). The latter used a large field of view camera on a circular gantry, which was computer driven to rotate about the phantom, collecting 64 images. These were reconstructed, using filtered back projection, into 32 1.2 cm slices and displayed in the transverse, frontal or saggital views. The phantom was suspended in a 30 cm diameter cylindrical lucite tank filled with water and ^{201}Tl. Heart (phantom) to tank activity was 2:1, mimicking that seen clinically. A 3 cm long transmural defect (24 cc) was filled with water and its midplane located 10 cm from the tank exterior. Myocardial walls (1 cm) contained ^{201}Tl; the blood pool had 5% of the wall activity. The minimum ratio of activity in the defect/normal wall fell to .54-.74 (rather than 0 as expected) in planar images, and was dependent on proximity of the defect to the face of the camera. ECT imaging showed minimal defect/normal ratios of .25-.42. The 3 cm defect was seen in only 4 of the 1.2 cm transverse slices. Apical and basal slices had entirely normal activity.

We conclude that ECT ^{201}Tl imaging, employing a commercially available gamma camera system, offers improved defect detection, localization, and quantitation.

CONTINUOUS MONITORING OF REGIONAL MYOCARDIAL RADIOTRACER KINETICS IN LABORATORY ANIMALS.

Marshall L. Jacobs, M.D., Robert D. Okada, M.D., H. William Strauss, M.D., Burt N. Fowler, M.D., John B. Newell, Dennis D. O'Keefe, M.D., Willard M. Daggett, M.D., FACC, Gerald M. Pohost, M.D., FACC. Massachusetts General Hospital, Boston, Mass.

Previous studies of Tl-201 kinetics in canine myocardium have employed the punch biopsy technique which is technically difficult and provides only a few data points. We have developed an implantable device for continuous measurement of regional myocardial radioisotope activity. The probe consists of a 2mm^3 Cadmium Telluride crystal surrounded by a lead foil and housed in a 4mm (O.D.) steel cylinder. Collimation is such that 75% of measured activity is within a cone of solid angle of 60°. Probe-measured activity in serial dilutions of Tl-201 vs. well-counter determined activity correlated well (r=0.996). The crystal was mounted on a modified arterial clamp and placed in the left ventricular cavity via an apical incision. Sensitivity to epicardial activity is approximately 70% of that to endocardial activity. In vivo validation was done in 10 dogs. After I.V. Tl-201, serial biopsies were obtained (n=49). Probe vs. biopsy measurements correlated well (r=.90). Use of 2 probes permits simultaneous monitoring of an ischemic region and a normal zone. The probe is situated within the cavity facing outward so ischemic zone activity can be accurately monitored without normal zone background. This new device allows accurate and continuous monitoring of transmural myocardial radioisotope activity, which has not been possible previously and will permit validation of new quantitative approaches to Tl-201 imaging as well as experimental studies to investigate Tl-201 kinetics. In addition, this probe will permit serial assessment of other radiotracer agents which localize in the myocardium.

PATTERNS OF DISTURBED MYOCARDIAL PERFUSION IN PATIENTS WITH CORONARY ARTERY DISEASE

Andrew Selwyn, MB, MRCP; Timothy Pratt, MSc; Kim Fox, MB, MRCP; Robert Steiner, MD, Postgraduate Medical School, London, U.K.

Fifty patients with angina pectoris (AP) were studied to determine the relationships between disturbances of regional myocardial perfusion (RMP) with stress, exercise tolerance and coronary artery stenosis. All patients underwent a maximum ECG exercise test, left ventricular and coronary angiocardiography and a continuous assessment of RMP using krypton -81m (half-life, 13 sec) with a standardized atrial pacing test. Resting RMP was 0.72 ± 0.13 ml/ml/min (50 patients). Eleven patients had no coronary artery disease (CAD), negative exercise test and uniform increases (101 ± 15%) in RMP with pacing. The remaining 39 patients all had significant CAD (≥70% stenosis), positive exercise tests and both increases (97 ± 17%) and decreases in RMP with pacing. Ten of the 39 patients achieved 30000-43000 Joules in positive exercise tests and RMP in an affected segment increased (18 ± 7%, P = <.001) perfusion for 7-10 min. of pacing and then decreased to 61 ± 17% below control. Twelve of the 39 patients achieved 26000-32000 Joules in the exercise tests and RMP in the affected segment remained unchanged for 5-9 min. of pacing and then decreased (79 ± 11%) during pacing. Finally 17 of 39 patients achieved 7000-22000 Joules in the exercise tests and RMP in the affected segment decreased immediately with atrial pacing to 81 ± 14% below control. Decreases in RMP were followed by ST segment depression (140 ± 17 sec) and AP (250 ± 21 sec) in all 39 patients. The 3 different patterns of disturbed RMP showed the pathophysiology that links chest pain, ST depression, exercise tolerance and coronary artery stenosis.

EFFECT OF CORONARY BLOOD FLOW AND SITE OF INJECTION ON ^{99m}Tc-PYP DETECTION OF EARLY CANINE MYOCARDIAL INFARCTS

Robert W. Parkey, MD, FACC; Padmakar V. Kulkarni, PhD; Samuel E. Lewis, MD; Gregory J. Dehmer, MD; L. Maximilian Buja, MD, FACC; Frederick J. Bonte, MD; James T. Willerson, MD, FACC, University of Texas Health Science Center, Dallas, TX.

Technetium-99m stannous pyrophosphate (^{99m}Tc-PYP) myocardial scintigraphy is capable of detecting acute myocardial infarcts (MI) within 24 to 96 hours after the event. To determine whether different means of administration or different physiological circumstances might allow ^{99m}Tc-PYP to detect experimental canine MI within 3 hours, we have studied 24 anesthetized dogs with proximal left anterior descending coronary artery (LAD) ligations for 3 hours. 13 had temporary (T) LAD occlusions (occl) and then reflow provided; ^{99m}Tc-PYP (PYP) was injected into the LADs (I.C.) (6 dogs) and intravenously (I.V.) (7 dogs) at time of reflow. 11 dogs had permanent LAD occls (P) followed by IC (5) or I.V. injections (6) 3 hours later. LV MI and non MI tissue were obtained for well counting 2 hours after PYP administration. T LAD occls with I.C. PYP injections resulted in central MI subendocardial (SE) concentrations of PYP of 88±20 (S.E.) while I.V. injections resulted in PYP concentrations of 40±8.7 ($p<0.05$) times normal LV tissue values. With P LAD occls I.C. produced PYP SE concentrations of 4±0.9 and I.V. of 2±0.5. In vivo scintigraphic visualization of MI was routinely possible only with I.C. and I.V. injections in the T LAD occl animals. The data demonstrate that very early MIs, within 3 hours, may be detected with PYP if reflow to the MI is excellent and/or if IC injection beyond a site of complete occl is provided. The more delayed development of an abnormal PYP scintigram with acute MI appears to be importantly related to lack of adequate flow to MI.

GLUCOSE METABOLISM OF REGIONAL MYOCARDIAL ISCHEMIA EVALUATED BY ^{18}FLUORO-2-DEOXYGLUCOSE AND POSITRON EMISSION COMPUTED TOMOGRAPHY. Heinrich Schelbert, M.D., Michael Phelps, Ph.D., Carl Selin, M.S., Edward Hoffman, Ph.D., David Kuhl, M.D.; UCLA School of Medicine, Los Angeles, CA.

Glycolysis is known to increase in acute myocardial ischemia. The possibility of demonstrating this metabolic alteration noninvasively by positron emission computed axial tomography (PCT) and the glucose analog ^{18}fluoro-2-deoxyglucose (FDG) was examined in 5 dogs. Ischemia was induced by stenosing the anterior descending coronary artery (LAD) and atrial pacing. O_2 and glucose consumption and lactic acid production in the LAD distribution were determined by arterial and coronary venous blood sampling and myocardial blood flow (MBF) by microspheres. Ischemia was induced twice in each dog: For assessment of a) MBF by N-13 ammonia and PCT and b) regional myocardial glucose uptake by PCT imaging of the myocardial FDG distribution. During pacing, MBF increased in normal myocardium by 27.5%, but fell in the LAD distribution from 83.2 to 62.7 ml/min/mg ($p<.03$). MVO_2 fell from 8.4 to 6.6 ml/min/100gm ($p<.01$). Glucose consumption increased from 1.97 to 7.64 mg/min/100gm ($p<.03$). Lactic acid production was variable but increased for the entire group (0.97 to 1.98 mg/min/100gm; NS). On the PCT images MBF in the LAD distribution decreased by 47.2% but FDG concentration by only 18.6% ($p<.01$) as compared to control segments. This "mismatch" was clearly visualized by PCT. Using invitro tissue counting, FDG concentrations in normal myocardium were related linearly to MBF. In segments with MBF's <60 ml/min/100gm the FDG/MBF ratio was 2.3 times above control ($p<.01$). Thus, a relative increase in glucose uptake occurs in acute myocardial ischemia that can be demonstrated noninvasively by PCT. We conclude that FDG and PCT may permit characterization of the changes in regional metabolism associated with acute myocardial ischemia.

QUANTITATION OF REGIONAL MYOCARDIAL BLOOD FLOW BY POSITRON EMISSION TOMOGRAPHY; Gerald Wisenberg, M.D., Heinrich Schelbert, M.D., Edward Hoffman, Ph.D., Henry Huang, D.Sc., Michael Phelps, Ph.D., Dave Skorton, M.D., John Child, M.D., UCLA School of Medicine, Los Angeles, CA.

This study was undertaken to demonstrate the ability of positron emission tomography (PCT) to accurately measure myocardial indicator concentrations and thus regional myocardial blood flow (RMBF). Gated PCT imaging was performed in 7 open chest dogs after left atrial injection of gamma-emitting and Ga-68 positron emitting microspheres. Two dogs were studied at control and 5 during circumflex ischemia or hyperemia (RMBF range .01 to 4.6ml/min/gm). RMBF determined in vivo from regions-of-interest on PCT images was compared to RMBF calculated in vitro after sacrifice by tissue counting and the arterial reference technique. According to phantom studies, count recovery with PCT is dependent on object size and thus on wall thickness (WT). Therefore, WT was measured a) postmortem and b) in vivo by echocardiography, 3 dogs having 2-D studies and 4 having M-mode. The echocardiographic diastolic measurements matched precisely the postmortem data. PCT measured RMBF corrected and uncorrected for WT effect correlated with in vitro measured RMBF by $y=.007+.99x$(SEE 0.12ml/min/gm), $r=.99$, and $y=.05+.60x$(SEE 0.14ml/min/gm), $r=.98$ ($n=84$), respectively. Count recovery for a given region increased in proportion to the systolic increase in WT, as measured by echocardiogram. We conclude that a) RMBF can be quantitated in vivo by PCT when corrections are made for WT effect; b) These corrections can be made accurately using echocardiographic WT measurements; and c) systolic wall thickening, as an index of regional function, can be estimated from the change in regional count recovery from diastole to systole.

LABELED METABOLIC SUBSTRATES FOR POSITIVE IMAGING IN ISCHEMIA

Roger M. Allan, MB: Andrew P. Selwyn, MRCP: Colin C.G. MacArthur, MRCP, Royal Postgraduate Medical School, London, UK.

Positron emission tomography allows non-invasive monitoring of the uptake and clearance by the heart of natural substrates labeled with carbon-11. To assess the value of labeled acetate (Ac) and palmitate (Pa) for such studies, the myocardial kinetics following bolus injections of (1-^{14}C)-substrates were investigated in the open-chest dog, with and without coronary artery (CA) occlusion. Aortic and coronary sinus blood samples and serial myocardial biopsies from ischemic (Is) and non-ischemic (NIs) muscle were collected. Ac extraction was 60.7 ± 3.3% (SEM). CA occlusion was produced 1.5 min after injection and at that time 3.7 ± 0.3% of the injected dose was in the myocardium. Efflux of activity from NIs muscle ($t_{½}$=4.1 min) was more rapid than from Is muscle ($t_{½}$=10.0 min) so that after 7 min of ischemia the ratio of activity Is:NIs exceeded 2.4. The ratio of activity in NIs muscle to that in arterial blood exceeded 2.8 at this time. Lung activity was always less than 30% of that in NIs myocardium. Ac concentrated in the liver and the liver:NI ratio was 1.5 at 6 min. Pa extraction was 37.4 ± 1.4% and initial efflux of activity from NIs was much slower ($t_{½}$=14 min) than for Ac.

We conclude that the greater extraction and different kinetics of Ac make it more suitable than Pa for assessing altered myocardial metabolism during ischemia using physiological tomography. The significant retention of labeled Ac in acutely ischemic myocardium provides a new approach to positive imaging of myocardial ischemia.

TOMOGRAPHIC QUANTIFICATION OF REGIONAL MYOCARDIAL METABOLISM IN VIVO

Rene Lerch, MD; Michel M. Ter-Pogossian, PhD; Burton E. Sobel, MD, FACC, Washington University, St. Louis, Mo.

We have recently quantified infarction in man with cyclotron-produced ^{11}C-palmitate and positron tomography. However, it has not yet been possible to quantify regional metabolism in vivo. In this study, 10 mCi of ^{11}C-palmitate were administered i.v. to 7 dogs at rest and after augmentation of cardiac work with i.v. atropine or paired pacing to determine whether regional metabolic rates remained homogeneous within each heart regardless of changed overall metabolism in response to physiological demand. A fast-scan tomograph (PETT V), developed to permit rapid acquisition of data, was employed to acquire ^{11}C-palmitate time-activity data from multiple, 1.5 cm^3 regions of myocardium from each heart. Curves were consistently bi-exponential and similar to those seen in isolated perfused hearts. In dogs at rest the metabolic rate of ^{11}C-palmitate initially incorporated into neutral lipids was first order from 5 to 15 min after injection (average $r = .99$) with an average rate constant (k_2) of .067 ± .005 (SE) min^{-1} that varied regionally by only 9.5 ± 1.6% ($n = 20$ regions from 7 dogs). After atropine, sufficient to double heart rate, or paired pacing regional metabolic rates increased but remained homogeneous within each heart varying by only 6.6 ± 1.4% and 10.4 ± 2.5%. Thus, regional metabolic rates remain homogeneous in the normal heart over a wide range of global metabolic demands in vivo. Accordingly, heterogeneity independent of global demands and detectable by positron tomography should permit sensitive localization of myocardium reversibly compromised by ischemia in patients under conditions of rest or stress.

AM
PEDIATRIC ECHOCARDIOGRAPHY
8:30-10:00

A NEW ULTRASOUND TECHNIQUE FOR ASSESSMENT OF FEMORAL VASCULAR ANATOMY BEFORE AND AFTER CARDIAC CATHETERIZATION (CC) IN CHILDREN AND INFANTS David J. Sahn, MD, FACC; Mark J. Friedman, MD; Lothar W. Lange, MD; Hugh D. Allen, MD, FACC; Stanley J. Goldberg, MD, FACC; Dept. of Peds., University of Arizona Health Sciences Center, Tucson, AZ

In this study, we applied a new electronically focused 9 MHz real-time ultrasound device with total examination depth of 4 cm and range gated pulsed Doppler capability to evaluate the anatomy of the femoral artery (FA) and femoral vein (FV) before and serially after percutaneous CC in 45 patients aged 6 wks-16 yrs. FA and FV size at the level of the inguinal ligament correlated poorly with age and with body surface area (all correlations $r<+0.45$). Nonetheless, individual imaging of FA size allowed location of vessels and selection of catheters 2mm less than the diameter of the FA, resulting in continued flow around the catheter during the procedure. Serial studies after CC revealed characteristic patterns for types of vascular damage. Needle holes with hematomata anterior or posterior to the FA (n=13) or vein (n=6) have been easily identified. A pattern of thickened FA walls with long segment reduction of lumen size has characterized spasm, which in association with continued distal pulsation and Doppler flow in 29 children, allowed prediction of full recovery. The resolution of FA spasm was serially imaged in 23. Late studies >6 months after CC in 14 have revealed no discrepancy in FA size or appearance between the catheterized and the control side. Images of torn endothelial flaps (n=4) and absence of distal pulsatile Doppler flow allowed early recognition of irreversible vascular damage requiring surgical revision, at which time the ultrasound observations were verified anatomically. This new ultrasound technique allows assessment of femoral vascular anatomy prior to CC and appears to aid definition of the short and long term effects of percutaneous femoral catheterization.

WIDE-ANGLE TWO-DIMENSIONAL ECHOCARDIOGRAPHIC ASSESSMENT OF FETAL CARDIAC ANATOMY James C. Huhta, MD; Donald J. Hagler, MD, FACC; Philip B. Bailey, MD; Charles R. Fish, MD, Mayo Clinic, Rochester, MN.

The reliability of two-dimensional echocardiographic (2DE) assessment of fetal cardiac anatomy was analyzed in 16 consecutive fetuses varying from 4-9 mo gestation. Whereas previous studies have used M-mode and 2DE linear-array imaging systems, this study investigated wide-angle phased-array 2DE for this purpose. 2DE fetal (intrauterine) examination was performed with 2.25- and 3.5-MHz transducers placed over the maternal abdominal wall. Scans obtained in 11 patients simulated parasternal long- and short-axis and apical four-chamber views, which allowed assessment of all cardiac chambers, valves, and great arteries. In 3 patients, only two scans were possible, and in the remaining 2 patients only one view could consistently be obtained (usually subxiphoid four-chamber and long-axis scans). In all patients the examination allowed detection of all four cardiac chambers and at least one semilunar valve. Mitral-semilunar valve continuity was detected in all. No abnormalities were discovered. With the occiput-posterior position, imaging quality was enhanced; breech positioning did not affect imaging quality. Fetal movement hampered imaging in some cases, most commonly before 7 mo gestation. 2DE can be used for complete imaging of intrauterine fetal cardiac anatomy during the last 2 trimesters of gestation in 70% of patients, and in the others, ventricular and atrioventricular valve anatomy can be defined.

WIDE-ANGLE TWO-DIMENSIONAL ECHOCARDIOGRAPHIC CRITERIA FOR VENTRICULAR MORPHOLOGY Donald J. Hagler, MD, FACC; Abdul J. Tajik, MD, FACC; James B. Seward, MD, FACC; Douglas D. Mair, MD, FACC; Donald G. Ritter, MD, FACC, Mayo Clinic, Rochester, MN.

Wide-angle two-dimensional echocardiography (2DE) was used to establish criteria for recognition of ventricular situs and ventricular morphology in 20 patients (age ½ to 58 yr) with atrioventricular (AV) discordance in comparison with 20 normal subjects (age 1 day to 60 yr). Ventricular morphology was characterized in all by (1) AV valve position relative to ventricular septum, (2) papillary muscle (PM) arrangement (two discrete vs. multiple and irregular), and (3) type of trabeculation (coarse vs. fine). Supportive but less reliable criteria were AV valve configuration (bi- vs. tri-leaflet), basic ventricular shape, and presence or absence of mitral-semilunar continuity to allow a long-axis scan of the left ventricular outflow tract. Left ventricle was recognized by an AV valve that was attached more superiorly and had a fish-mouth (bicommissural) appearance in diastole, presence of two discrete PM, fine trabecular pattern, mitral-semilunar continuity, and ellipsoid shape. Right ventricle was recognized by an AV valve that was attached more inferiorly and had a triangular (tricommissural) appearance in diastole, presence of multiple, irregular PM and coarse trabecular pattern, AV-semilunar valve discontinuity, and triangular ventricle shape. From these criteria, 2DE provided reliable noninvasive determination of ventricular situs and morphology.

TWO DIMENSIONAL ECHOCARDIOGRAPHIC FEATURES OF CORRECTED TRANSPOSITION Rodney A. Foale, MRCP; Lino Stefanini, MD, Anthony F. Rickards MRCP; Jane Somerville, MD, FACC, The National Heart Hospital and Cardiothoracic Institute, London, U.K.

The value of two dimensional echocardiography (2 D echo) in the diagnosis of corrected transposition (TG) defined as atrioventricular (AV) and ventriculo-arterial (VA) discordance with a left sided anterior aorta, has been examined in 10 patients with this diagnosis proven by angiocardiography, 6 patients undergoing subsequent surgery. 2 D echo criteria for atrial situs included the recognition of vena caval, hepatic and pulmonary venous return to atrial chambers. A right ventricular morphology of the systemic ventricle was diagnosed by the more caudal attachment of its associated AV ring to the interventricular septum (IVS), a 3 cusped AV valve and the diffuse ventricular insertion of chordae tendinae (CT). A left ventricle draining a right atrium was defined by a mitral AV valve morphology and by CT insertion to discrete papillary muscle groups. Scanning the ultrasonic plane superiorly identified infundibulum beneath systemic vessel, the pulmonary artery being defined as moving posteriorly and bifurcating. AV discordance was recognised in all patients studied, the most characteristic feature being reversal of the normal pattern of attachment of the tricuspid valve ring to the right of the IVS. VA discordance was diagnosed in 7 patients as scanning superiorly resulted in loss of echo definition of the great vessels in 3 patients.

Using a segmental approach with the criteria described the AV and VA connections of corrected TGA may be correctly diagnosed.

FACTORS AFFECTING REAL-TIME CROSS-SECTIONAL (2D) ECHOCARDIOGRAPHIC (ECHO) IMAGING OF VENTRICULAR SEPTAL DEFECTS (VSD)

Jesus M. Canale, MD, David J. Sahn, MD, FACC, Hugh D. Allen, MD, FACC, Stanley J. Goldberg, MD, FACC; Dept of Peds., Univ. of Az. Health Sciences Ctr., Tucson, Az.

Recent studies suggest good prospective accuracy for 2D echo imaging of VSDs. In this study we obtained 2D images with a dynamically focused phased array (3.5 MHz) scanner from 32 patients proven by cardiac cath to have isolated membranous VSD. All 32 had VSDs imaged on long axis, apex 4-chamber and subxiphoid echo views. The smallest VSD imaged was 2mm, the largest 23mm. The imaged size of VSDs differed markedly between end diastole (D) and end systole (S) by paired T test: For long axis (D=8.9±0.9(SE)mm, S=5.3±0.8 mm), apex 4-chamber (D=11.7±1.1mm, S=5.8±0.9mm), subxiphoid (D=8.5±1.0, S=4.8±0.9mm) (all $p<0.005$). VSD size also varied between views with no predictive relationship except between apex and subxiphoid 4-chamber views in D ($r= +0.70$, $p<0.001$). This agreed with qualitative direct observations of an ellipsoid or irregularly shaped VSD in 14 of 16 operated patients. VSD size on echo could be used to separate large (QP:QS>2.5:1) from small shunts in D and S only if the largest VSD size between all views was used, mean in D=13.6±1.0mm for large shunts vs. 7.7±1.0mm, for small, $p<0.005$, and in S=7.5±1.0mm for large vs. 4.1±0.7mm for small shunts, $p<0.01$. Review of 250 studies from patients proven not to have a VSD revealed 28 individual views with false + VSD. None of the false + VSDs were imaged consistently on all views. Additionally, a "T" artifact (broadening of septal edges around a VSD) has been found to be a reliable marker of true VSD imaging. In order to best achieve some quantification of VSD size and to avoid false +, it is necessary to use multiple views and to consider the marked changes in VSD size which occur between diastole and systole.

CROSS-SECTIONAL ECHOCARDIOGRAPHIC EVALUATION OF CORONARY ARTERY ABNORMALITIES IN CHILDREN

Randall L. Caldwell, MD, FACC; Arthur Weyman, MD, FACC; Roger A. Hurwitz, MD, FACC; Donald A. Girod, MD, FACC; Harvey Feigenbaum, MD, FACC, Indiana University Hospitals, Indianapolis, Indiana

Our purpose was to determine the ability of cross-sectional echocardiography (CSE) to record the proximal coronary arteries in children and to determine if congenital abnormalities of the coronary arteries would be demonstrated by CSE. To determine the ability of CSE to record the proximal coronary arteries, 66 children with normal coronary arteries demonstrated at catheterization and normally related great vessels were studied. The mean age was 5.8 years, with 13 (20%) being less than 1 year of age. The proximal left coronary artery (LCA) was recorded in 89% (59/66) and was 18% ± 4% of the aortic root diameter. The proximal right coronary artery (RCA) was recorded in 50% (33/66) and was 16% ± 3% of the aortic root diameter. Of the infants one year of age and under, the LCA was recorded in 85% (11/13); whereas, the RCA was recorded in only 31% (4/13).

During the past two years 10 patients were noted to have larger than expected proximal coronary artery dimensions. Of the seven having a large RCA, five had anomalous LCA arising from the pulmonary artery with a dilated and tortuous RCA. The other two having a dilated RCA had a RCA fistula. All three patients having a dilated LCA had a LCA fistula.

We have therefore demonstrated that the proximal coronary arteries can be recorded by CSE in the majority of children, and CSE may be helpful in evaluating for possible abnormalities of the coronary arteries.

ASSESSMENT OF VENTRICULAR FUNCTION IN INFANTS AND CHILDREN
10:30-12:00

EVALUATION OF LEFT VENTRICULAR FUNCTION DURING UPRIGHT EXERCISE USING CONTINUOUS ECHOCARDIOGRAPHIC MONITORING (CEM)

Brenda E. Armstrong, MD, Gerald A. Serwer, MD, Page A.W. Anderson, MD, FACC, Duke University, Durham, N.C.

Noninvasive evaluation of cardiovascular adjustments to upright submaximal (SE) and maximal exercise (ME) was investigated as a method for evaluation of cardiac function in children and adults. Change in echocardiographically defined parameters as a function of the degree of exercise performed was investigated in normal (N) and cardiomyopathic (C) patients (pts). Pts performed work on a treadmill until exhaustion. Heart rate (HR), blood pressure (BP) and left ventricular (LV) minor axis were continuously monitored with data being obtained every 30sec during exercise. LV end-diastolic dimension (LVEDD), LV end-systolic dimension (LVESD), and % fractional shortening (%FS) were measured. Data was analysed as a function of the % of total work performed. Group I(N)(n=11) ages 4-29yrs, was comprised of normal subjects. Group II(C)(n=4) ages 8-16 yrs, had a cardiomyopathy. In N: Endurance times (ET) were 10-23min. HR and systolic BP rose to peak levels at 60-80% of ME and remained constant. LVEDD initially decreased or remained unchanged and then gradually rose to above resting values by 70-80% of ME. LVESD progressively decreased to reach a constant value by 60-80% of ME. %FS gradually increased throughout exercise due to a decreasing LVESD at SE and due to increasing LVEDD at ME. In C: ET was 8-15min, LVEDD remained constant or rose slightly during SE and ME. LVESD paralleled changes in LVEDD and did not show a decrease as in N. Unlike N, %FS never increased and had fallen by ME. Thus, the major adjustment to exercise in C was increasing HR unlike N who showed an increase in both HR and %FS. CEM during SE and ME provides a description of how LV adaptation to exercise is modified in the presence of cardiac dysfunction.

Emax DURING EXERCISE IN CHILDREN WITH LEFT-SIDED CARDIAC DISEASE.

Bruce Alpert MD, Lee Benson MD, Peter Olley MB,FACC The Medical College of Georgia, Augusta, GA

Emax, the peak ratio of left ventricular (LV) systolic pressure (P) / systolic volume (V), is an index of contractility independent of both preload and afterload. Experimental animal and adult investigations have shown its potential usefulness. We studied 17 children during catheterization by a combined high-fidelity catheter and m-mode echo technique. The diagnoses were: LV pressure (P) load, aortic (A) stenosis (S), Group (Gr) Ia, n=5, and coarctation, Gr Ib, n=5; LV volume (V) overload from either A or mitral regurgitation (R), Gr II, n=3; V+P load, AS + AR, Gr III, n=3; congestive cardiomyopathy (CC), Gr IV, n=1. Emax, indexed for body surface area, was calculated at rest and during supine exercise (Ex) at 25% and 50% of maximal upright workload:

Group	Resting	25% Ex	50% Ex
Ia	2.69 ± 1.65	3.39 ± 1.39	-
Ib	3.53 ± 1.34	5.83 ± 3.72	6.60 ± 5.29
II	1.19 ± 0.70	1.09 ± 0.79	1.75 ± 1.49
III	3.70 ± 2.13	3.83	-
IV	1.01	1.21	1.27

Compared to the indexed adult normal value, approximately 1.9 ± 0.3, LV P and P+V load (Gr I + III) patients (pts) had normal or increased Emax values at rest, while V and CC pts (Gr II + IV) had decreased values. The P pts showed expected increases in Emax with exercise. The V and CC pts, however, did not show this increase. The V+P patients, whose resting values were above normal, also showed no increase with exericse, indicating poor contractile reserve. Emax in children seems to be a sensitive index of contractility during physiologic stress and can be used to assess LV functional reserve capacity.

EXERCISE CAPACITY AFTER VALVE REPLACEMENT IN CHILDREN AND ADOLESCENTS

Robert A. Mathews, M.D; Sang C. Park, M.D., FAAC; William H. Neches, M.D., FAAC; Frederick J. Fricker, M.D; Cora C. Lenox, M.D., FAAC; James R. Zuberbuhler, M.D., FAAC
Division of Pediatric Cardiology, University of Pittsburgh, School of Medicine, Pittsburgh, Pa.

Twenty pediatric patients who have undergone valve replacement (VR) were studied by bicycle exercise testing. The patients underwent VR from 8 to 17 yr. of age (mean, 13 yr). Ten had mechanical VR and 10 have undergone porcine xenograft VR. Nine patients had VR in the aortic position; 6 had mitral VR; 2 had pulmonary VR and 3 had their tricuspid valve replaced. All have promptly resumed normal activities after surgery and have been followed from 6 to 90 months (mean, 36 mo) after VR. At post-operative cardiac catheterization most had minimal gradeints across the replaced valve.

Exercise testing to maximal levels by bicycle ergometry revealed normal exercise tolerance with all patients achieving at least 75% of expected normal values.

Cardiac output during exercise determined by continuously measuring oxygen consumption was normal. No significant arrhythmias or ischemia was precipitated by exercise and blood pressure response was normal in all patients.

Our results indicate that most pediatric patients undergoing VR have a normal exercise response postoperatively. Stringent restrictions of physical activity in these patients may not be warranted.

CAN EJECTION FRACTION BE MEASURED NON-INVASIVELY IN CHILDREN AFTER VENTRICULAR SEPTAL PATCHING?

Roger A. Hurwitz, MD, FACC; Aslam Siddiqui, MD; Donald A. Girod, MD, FACC; Randall L. Caldwell, MD, FACC; Indiana University Hospitals; Indianapolis, Indiana

Ejection fraction (EF), currently considered a major indicator of ventricular performance, is most reliably measured at cardiac catheterization. Though non-invasive assessment of EF by M mode echocardiography correlates reasonably well with catheterization results, the accuracy of M mode echo measurement of ventricular dimensions following open-heart surgery is questionable. Radionuclide angiography (RA) has also been successful in determination of EF in adults. Therefore, this study was undertaken to compare the left ventricular EF obtained by 1) M mode echo; 2) quantitative RA; and 3) cardiac catheterization in 17 children following cardiac surgery in which the ventricular septum was patched. Mean EF by all methods ranged from 61-63%. However, M mode echo did not correlate with cardiac catheterization (r=.15). RA quantitation of EF had significantly better agreement with the hemodynamic results (r=.74). The radio-isotope method identified all 4 patients of the group (EF $<$ 50%) with significant cardiomegaly and clinical evidence of depressed ventricular function. Assuming cardiac catheterization determined EF to be the standard, this study suggests that M mode echo is not reliable in evaluating EF in children after open-heart surgery involving the ventricular septum. However, EF measured by RA has good correlation with EF determined by cardiac catheterization. Thus, it should be possible to non-invasively quantitate ventricular performance of children following cardiac surgery involving septal patching by measuring EF with quantitative radionuclide angiography.

SYSTEMIC VENTRICULAR FUNCTION IN PATIENTS WITH CONGENITAL HEART DISEASE REPAIRED DURING INFANCY.

Kenneth M. Borow, M.D.,; Laurence H. Green, M.D.; John F. Keane, M.D.; Aldo R. Castaneda, M.D., FACC; Michael D. Freed, M.D., FACC. Children's Hospital Medical Center and Peter Bent Brigham Hospital, Boston, Massachusetts.

Work-function (WF) curves relating systemic ventricular (SV) end diastolic pressure (EDP) to minute work index (MWI) were used to assess ventricular performance in 6 patients (pts) with tetralogy of Fallot (TOF), 9 with d-transposition of the great arteries (TGA) and 2 with ventricular septal defects (VSD). All pts underwent repair prior to 18 months of age and were found to have excellent anatomic results by catheterization when studied 12 to 47 months (mean=15) following repair. The TOF pts and non-operated controls have previously been shown to have similar WF curves. WF curves were generated by increasing afterload by methoxamine infusion and measuring EDP, mean SV systolic pressure and cardiac index (CI). Heart rate was kept constant. The slopes (m) of the WF curves were calculated for each pt's EDP vs MWI. A SV with a steep m (large increase in MWI for small increase in EDP) has superior function when compared with a SV with a less steep m.

	VSD	P	TOF	P	TGA
	Mean±SEM		Mean±SEM		Mean±SEM
HR	122 ± 2.0	NS	117 ± 7.0	NS	111 ± 8.0
EDP	6.5 ± 0.5	NS	6.8 ± 1.0	<.05	4.0 ± 0.4
CI	3.9 ± 0.4	NS	4.4 ± 0.2	<.02	3.5 ± 0.2
MWI	5.0 ± 0.9	NS	5.1 ± 0.2	<.001	3.7 ± 0.2
m	1.05 ± .05	NS	1.04 ± 0.12	<.02	0.65 ± .08

Despite normal SV function at rest in all pts, the m of the WF curves were depressed in pts with repaired TGA when compared to age matched pts after repair of TOF and VSD. This suggests that at early post-operative follow-up, an afterload stress can unmask SV dysfunction in TGA pts.

EVALUATION OF CARDIAC CHAMBER SIZE AND LEFT VENTRICULAR FUNCTION IN CHILDREN USING TWO DIMENSIONAL APEX ECHOCARDIOGRAPHY

Thomas G. DiSessa,MD; Jason H. Kirkman, MD; Ching C. Ti, MD; Arthur D. Hagan, MD, FACC; Stanley E. Kirkpatrick, MD, FACC; William F. Friedman, MD, FACC; UCLA Medical Center, Los Angeles, California

The ability of two dimensional (2-D) apex echocardiography to measure chamber size and left ventricular (LV) function was evaluated in 24 normal subjects and 22 children also studied by angiography. From the apical 4-chamber (4C) view the end diastolic area of the left (LVA) and right (RVA) ventricles and end systolic area of the left (LAA) and right (RAA) atria and left ventricle were planimetered; LV end diastolic and systolic volumes (LVEDV, LVESV) were calculated by the Dodge single plane area-length method LVEDV and LVESV were also calculated from the apical 2-chamber (2C) view areas. LV stroke volume (LVSV) and ejection fraction (LVEF) were compared to data obtained from single plane right anterior oblique angiograms. For 27 normals a linear relationship existed between LVA, RVA, LAA, RAA, and body surface area (r = 0.95, 0.92, 0.88, and 0.86 respectively). Compared to normals, RVA and RAA were $>$ 95% confidence limits in patients with atrial septal defects (n=3), tricuspid (n=1) and pulmonic (n=1) regurgitation; LVA and LAA were $>$ 95% confidence limits in patients with patent ductus arteriosus (n=4), ventricular septal defects (n=2), mitral regurgitation (n=2) and LV out flow tract obstruction (n=2). Four patients with endocardial cushion defects had enlargement of three or four chambers. The LVA/RVA and LAA/RAA ratios also allowed for prediction of chamber enlargement. LVEDV, LVSV, and LVEF echo 2C and 4C views correlated well with angio values (2C r = 0.96, 0.96, 0.70, 4C r = 0.94, 0.97, 0.76 respectively). Thus 2-D apex echocardiography is an accurate means of predicting chamber size and measuring LV function.

EXERCISE TESTING IN CORONARY DISEASE
2:00-3:30

RELATION OF TREADMILL EXERCISE RESULTS TO FLOW-LIMITATION AND PERFUSION-SIZE OF THE AFFECTED CORONARY ARTERY

Geun C. Jang, M.D., Sergio E. Schabelman, M.D., and Roy V. Jutzy, M.D., F.A.C.C., Loma Linda University Medical Center, Loma Linda, CA.

To assess if the results of treadmill exercise test has any relation to the size of myocardial segment perfused, additional to the flow-limitation of the obstructed coronary artery, we studied 23 consecutive patients (pts) who had treadmill test (TMT) and coronary arteriogram. Segmental perfusion area (SPA) associated with the diseased artery distal to the lesion was obtained from the coronary cine of each patient by a computer program developed and verified, based on a truncated-ellipsoidal LV model. SPA is expressed as % of total LV surface area. There were 19/23 males (83%). Positive TMTs with ≥1 mm ST depression were in 16/23 pts (70%). Cross-sectional stenosis of ≥75% of at least one vessel were in 19/23 pts (83%). With coronary stenosis ≥75%, TMT sensitivity is 100% if the coronary lesion distal to obstruction has SPA ≥40% and specificity is 100% if the lesion has SPA ≤29%. Conversely, SPA ≤29% has zero false positive results and SPA ≥40% has zero false negative results.

	Sensitivity	Specificity	False (+)	False (-)	Predictive Value	(p)
Stenosis (≥75%)	.79	.75	.25	.21	.94	<.05
(c) CPA (≥40%/≤29%)	1.00	1.00	.00	.00	1.00	<.001

These data suggest that the TMT result is a function of both the degree of flow-limitation and the size of perfusion-segment distal to the lesion. Thus, it may be indicating that the false negative results do not occur in coronary lesions with large SPA and the false positive results not in small SPA.

BODY SURFACE DISTRIBUTION OF ST DEPRESSION DURING EXERCISE TESTING IN PATIENTS WITH CORONARY ARTERY DISEASE

G.M. Vincent, MD, FACC; R.L. Lux, PhD; D. Davis, RCT; F. Yanowitz, MD, FACC; M. Merchant, MS; LDS Hospital and University of Utah, Salt Lake City, Utah

During exercise treadmill testing (ETT) ST depression is the usual endpoint to define ischemic heart disease (IHD). To determine the torso distribution of ST depression in IHD, we recorded 32 lead potential maps, and 12 lead ECGs, during ETT in 12 subjects with a known positive ETT and angiographically proven coronary artery disease, selected from 70 subjects who have undergone exercise mapping. The ST segment area in each lead was calculated by integrating the ECG over an 80 msec interval following the end of the QRS. The body surface ST distribution at 192 sites was estimated by transforming the 32 calculated ST areas using the limited lead map estimation technique of Lux et al. Four to 14 beats were averaged to reduce noise and baseline artifact. Baselines were defined between adjacent P-R segments.

Five of 12 patients had peak ST depression more inferior and/or lateral than V_{4-6} leads so that V_{4-6} did not sample the peak ST change. Also, the distribution null line between ST elevation and ST depression often occurred between V_3 and V_5 positions, with steep gradients, so that small changes in electrode location in V_{4-6} area might substantially modify whether ST depression, no shift, or ST elevation was recorded.

The results indicate that more extensive sampling during ETT is appropriate, particularly with electrodes placed inferior and lateral to V_{4-6} locations. This may increase accuracy of ETT by 1) detecting those patients with ST depression outside usual sampled areas or 2) more accurately reflecting significant ST depression where ST depression amplitude is low and sampling from V_{4-6} (in ST distribution periphery) yields negative or borderline results.

VARIABILITY OF TREADMILL EXERCISE TESTING RESULTS IN PATIENTS WITH ANGINA PECTORIS

Mark Moody, MD; Mark Starling, MD; Michael Crawford, MD, FACC; Bernard Levi, MD; Robert O'Rourke, MD, FACC, University of Texas Health Science Center and Veterans Administration Hospital, San Antonio, Texas.

As a prelude to evaluating the efficacy of new antianginal medications, we assessed the day one (D_1) to day 2 (D_2) and the same day control (C) to post-placebo (Pl) reproducibility of graded treadmill ECG exercise testing (ET) done under similar conditions in a randomized double-blind fashion. The 23 patients (pts) studied had documented coronary artery disease and stable angina pectoris (AP) with ischemic ST segment depression (ST↓) and AP on one or more prior ETs. The time in minutes (±1SD) to AP, ST↓ and maximal exercise (maxE) are compared below:

	Day 1	vs Day 2	(Same Day) Control	vs Placebo
AP	7.4±3.2	9.0±3.3*	8.0±3.2	9.2±3.5†
ST↓	7.8±3.9	9.6±3.6**	8.6±3.7	9.9±3.8†
maxE	9.7±3.7	11.0±4.1**	10.4±3.9	11.4±3.9**
	*p<.05	**p<.01	†p<.005	

Additionally, 22-30% of pts showed more than a 3 minute difference between D_1 and D_2 in time to AP, ST↓ or maxE. Likewise, 14-17% of pts showed more than a 3 minute difference between C and Pl in the same measures. In some cases, differences as high as 8 minutes were observed between D_1 and D_2 and 6 minutes between C and Pl with no detectable change in the pts condition. Also, heart rate-systolic blood pressure product (HRxSBP) at AP, ST↓ and maxE was not different on D_1 and D_2 or C vs Pl. We conclude that certain pts have considerable variability in the time to AP, ST↓ and maxE but not in HRxSBP. This variability in ET duration is greater between days than in sequential ETs on the same day and should be considered when evaluating new antianginal drugs by ET.

REPRODUCIBILITY OF SYMPTOMS, CARDIAC AND ELECTROCARDIOGRAPHIC RESPONSES DURING SYMPTOM-LIMITED EXERCISE IN PREOPERATIVE CORONARY PATIENTS.

Kenneth F. Hossack, MD; Robert A. Bruce, MD, FACC; Bert Green, MD; Laurent Belanger, MD; Fusako Kusumi, MS; University of Washington, Seattle, WA.

Reproducibility of symptoms, heart rate(HR), blood pressure(BP) and electrocardiographic responses during 2 exercise tests(ET) 1 hour apart are reported in 25 patients (21 males, 4 females) of 40 to 73 years of age. Prior to undergoing bypass surgery, direct Fick measurement of maximal cardiac output during upright exercise is made. BP during the first ET is measured with a sphygmomanometer and for this analysis mean pressure is estimated from systolic and diastolic readings. A Swan-Ganz catheter is placed in the pulmonary artery and a radial artery line inserted for pressure monitoring and blood sampling during the second ET. During both ET's, expired air is collected for measurement of maximal oxygen uptake($\dot{V}O_2$ max ml/min).

RESULTS:

	Non-invasively	Invasively	p*	r**
Rest HR	75±15	73±14	NS	.66
Max HR	114±17	113±19	NS	.95
Rest mean BP	87±12	105±13	<.0001	.53
Max mean BP	98±12	109±17	<.001	.60
Max PRPx10^{-2}	113±26	122±29	<.01	.86
$\dot{V}O_2$ max	1092±353	1125±384	NS	.95

Angina and ischemic ST depression occurred in 22 and 20 persons respectively during first ET and 21 each during second ET.

These results indicate that despite catheterization, symptoms, electrocardiographic changes, VO_2 max, HR rest and HR max are reproducible. The differences in BP largely relate to the different techniques in measurement however, the correlation between maximal pressure rate product is high(r=.86). *paired t-test, **correlation coefficient

PREDICTIVE ACCURACY OF POSITIVE EXERCISE ELECTROCARDIOGRAM: RELATION OF HEART RATE AT WHICH ISCHEMIC RESPONSE INITIALLY APPEARS TO PRESENCE OF CORONARY ARTERY DISEASE

Reginald Low, MD; Ezra A. Amsterdam, MD, FACC; Craig Lindsey, BS; Garrett Lee, M.D.; Najam Awan, MD, FACC; Anthony N. DeMaria, MD, FACC; Dean T. Mason, MD, FACC, University of California, Davis, California

We examined the relationship of the predictive accuracy (PA) of a positive exercise electrocardiogram (ExECG) to the heart rate (HR) at which ST↓ initially occurred. A positive ExECG was defined by ischemic ST depression (ST↓) for ≥80 msec in an ST segment that was normal at rest. The study group consisted of 118 symptomatic patients (pts) (99 males, 19 females, group mean age 55 yrs) evaluated for the presence of coronary artery disease (CAD). All pts had ExECG and coronary angiography. PA of the ExECG based on coronary angiography was defined as percent true positive (TP) ExECG divided by all positive ExECG. TP ExECG was defined as a positive ExECG associated with ≥70% stenosis of ≥1 CA; false positive (FP) ExEG = positive ExECG in the presence of normal coronary arteries (CA). CAD was present in 91 pts and 27 pts had normal CA. PA was inversely related to HR, expressed as percent of predicted maximum heart rate (PMHR), at which ST↓ initially appeared:

	% PMHR at Initial ST↓				
	65%	66-74%	75-84%	85-94%	95%
Predictive accuracy	91% (19/21)	88% (14/16)	86% (23/27)	67% (20/30)	63% (15/24)

There was no relation between number of diseased CA and HR at which ST↓ appeared. Occurrence of ST↓ in ExECG at <85% PMHR correlates highly with presence of CAD. By contrast, initial appearance of ST↓ at ≥85% PMHR is associated with a high proportion of false positive results.

QUANTIFICATION OF THE EXERCISE TEST THAT BEST MAXIMIZES THE PREDICTION OF SEVERE CORONARY DISEASE

Donald A. Weiner, MD; Carolyn H. McCabe, BS; Thomas J. Ryan, MD, FACC, Boston University Medical Center, Boston

Recent studies suggest abandonment of the "positive-negative" classification of exercise tests (ET) in favor of a more comprehensive quantitative analysis. To determine which combination of ET variables best maximizes the identification and prediction of the extent of coronary disease (CAD), we correlated 11 ET variables with the findings of coronary arteriography in 436 consecutive patients (pts). The pts were grouped as follows: group 1 (n=35) had ≥ 50% stenosis of the left main coronary artery (LMCA), group 2 (n=124) had either LMCA or ≥ 70% stenosis of three coronary vessels, and group 3 (n=312) were the remaining pts. The sensitivity (S) and predictive value (PV) of the following seven selected ET variables alone and in combination were:

		Group 1		Group 2	
		S	PV	S	PV
1.	≥ 2 mm ST↓	91%	20%	75%	59%
2.	Downsloping ST↓	83%	18%	78%	61%
3.	ST↓ beginning in stage I	89%	17%	80%	57%
4.	ST↓ lasting ≥ 6 minutes	77%	22%	69%	64%
5.	ST↓ involving ≥ 5 leads	86%	22%	65%	58%
6.	Exercise-induced angina	83%	15%	76%	48%
7.	Treadmill Time ≤ 6 minutes	86%	13%	72%	45%
	COMBINATION 1-3	77%	24%	57%	69%
	COMBINATION 1-5	74%	32%	49%	75%
	COMBINATION 1-7	57%	38%	36%	83%

Although the diagnosis of LMCA remains largely unpredictable by ET, the combination of ET variables 1-5 best maximizes both the sensitivity (49%) and the predictive value (74%) in patients with either left main or three-vessel coronary disease and thus delineates a "markedly-positive" exercise test.

ECHOCARDIOGRAPHIC EVALUATION OF LEFT VENTRICULAR SIZE AND FUNCTION
2:00-3:30

ACCURATE VOLUME DETERMINATION IN THE ISOLATED EJECTING CANINE HEART FROM A LIMITED NUMBER OF TWO-DIMENSIONAL ECHOCARDIOGRAPHIC CROSS-SECTIONS.

Leland W. Eaton, MD; W. Lowell Maughan, MD; James L. Weiss, MD, FACC, Johns Hopkins Univ. Baltimore, Md.

It has been shown that accurate measurement of left ventricular volume (LVV) is possible in the intact ejecting dog heart by reconstruction of serial two-dimensional echocardiographic (2D) cross-sectional images (XS) taken at 3 mm intervals through the long axis. However, volume reconstruction from such frequent 2D XS is impractical in intact animals or clinical situations. Therefore, we studied volume accuracy with fewer XS/heart. Cross-circulated paced dog hearts were suspended in a blood-filled tank designed to allow echo transducer movement in the vertical plane. Instantaneous LVV was measured every 50 ms with a volumetric chamber accurate to 0.5 ml/100 ml, connected to a balloon in the beating LV. For each heart these direct LVV (9.4-45 ml) were compared to simultaneous reconstructions of serial 2D XS taken at evenly-spaced intervals from apex to base. LV cavity area for each XS was planimetered with a light-pen system and summated for volume: LVV by 2D = Σ (XS area x L), where L = length between XS, and ranged from 3 to 57 mm to give LVV based on 1 to 19 XS/heart. In 59 separate LVV from 6 different ejecting hearts at various loads, we calculated the accuracy of 2D LVV for a decreasing number of XS/heart. By linear regression, we compared 2D LVV with directly measured LVV (r), and 2D LVV for fewer XS/heart with 2D LVV for XS at 3 mm intervals (15-19) (r'):

XS/heart	15-19	8-10	5-6	4	3	2	1*
r	.962	.956	.960	.926	.918	.883	.827
SEE (ml)	2.57	2.84	2.83	3.96	4.28	5.51	7.24
r'	-	.989	.982	.974	.946	.924	.864
SEE (ml)	-	1.43	1.89	2.38	3.50	4.52	6.54

all P values <.001 * mid LV level

Thus, provided XS localization is available, accurate LVV can be echocardiographically determined in the non-infarcted ejecting heart from as few as 3 to 4 XS without reliance on major geometric assumptions.

QUANTITATION OF HUMAN LEFT VENTRICULAR (LV) MASS AND VOLUME BY CROSS-SECTIONAL ECHOCARDIOGRAPHY: IN VITRO ANATOMIC VALIDATION

Joseph Helak, MD; Nathaniel Reichek, MD; Eugene Pearlman, MD; Karl Weber, MD, FACC; Guiseppe Pietra, MD; John A. Kastor, MD, FACC, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

The accuracy of digitized phased array cross-sectional echo (E) imaging for LV area(A),mass(M)and chamber volume (V) was determined in 88 formalin fixed short axis sections (S) of 8 human hearts (2 cardiomyopathy, 2 valvular disease, 2 coronary artery disease with infarction and/or aneurysm and 2 normal). E data were compared to S weight(SW) and photographic(P) SA, SM and SV. SM and SV were calculated using the formula V=A(S thickness). Total LVV and LVM were determined for each heart by Simpson's rule and as (A at high papillary muscle level)x(LV length). SMp correlated well with SW(r=.97). Mean interobserver variation for SAe was small (8.8%) and correlation excellent (r=.96, slope=1.04). SAe, SMe and SVe correlated well with SAp, SMp and SVp (r=.95, .91 and .97) and with actual SW (r=.90, n=31). Simpson's rule LVVe was highly accurate (Vp=1.06Ve+7 ml, r=.99, n=8). LVMe correlated well with LVMp (r=.94, n=8) and with LVW (r=.99, n=4). The area-length method gave excellent estimates of LVV (Vp=.58 Ve+17 ml, n=8, r=.98, range 12-183 ml) and LVW(=.58LVMe+66g, n=4, r=.96) and good estimates of LVMp (=.52LVMe+105g, n=8, r=.85). Ve was consistently more accurate than Me suggesting that endocardial boundry identification is more reliable than epicardial boundry identification. We conclude that, in vitro, short axis imaging by E is accurate and permits reliable estimation of LVV and LVM by either Simpson's rule or area-length methods in normal and abnormal ventricles. The area-length method is sufficiently simple to be readily applicable in vivo.

BIPLANE APEX ECHOCARDIOGRAPHY VERSUS BIPLANE CINEANGIOGRAPHY IN THE ASSESSMENT OF LEFT VENTRICULAR VOLUME AND FUNCTION: VALIDATION BY DIRECT MEASUREMENTS

William Bommer, MD, FACC; Tam Chun; Oi Ling Kwan, BS; Alexander Neumann, BS; Dean T. Mason, MD, FACC; Anthony N. DeMaria, MD, FACC, University of California, Davis, CA.

No data are available comparing the accuracy of cineangiography (Cine) and 2-dimensional echocardiography(2DE) against direct measurements in the evaluation of left ventricular (LV) volume and function. Therefore, we obtained measurements of volume in 18 human LV casts and 2 contracting heart models by 2DE, cine, and water displacement; while LV shortening was assessed by 2DE, cine, and motion photography in the contracting heart models. Estimates of volume and function by 2DE and cine were also compared in 20 pts. Comparable biplane 2DE and angulated cine and optical images were outlined and volumes were calculated using Simpson's Rule. Actual LV cast volumes correlated closely with those values obtained by both 2DE and cine (r=.97). Comparisons between actual measurements and 2DE and cine estimates for the models and patients were made by computing the following correlation coefficients:

LV-models	LV Volume	Stroke Volume	Ejection Fraction	Segmental Shortening
2DE vs actual	.97	.98	.99	.96
cine vs actual	.97	.97	.99	.97
2DE vs cine	.97	.96	.98	.96
LV-patients				
2DE vs cine	.80	.80	.84	.70

Thus, in LV casts and contracting models, biplane apical 2DE predicts LV volume and function with comparable accuracy to LV cine. The reduced correlation between biplane apical 2DE and cine in patients may be related to measurement errors referrable to either method.

THREE-DIMENSIONAL DISPLAY AND VOLUME DETERMINATION OF THE LEFT VENTRICLE BY TWO-DIMENSIONAL ECHOCARDIOGRAPHY

Keiko Ueda,MD; Keiichi Kuwaki, MD; Kiyoshi Inoue, MD; Tokyo Metropolitan Police Hospital, Tokyo, Japan

Using a new tomogram image processor (Sumitomo Electronic Ind., Model TP-300) and a 72° wide angle phased array (Toshiba, Model SSH-11A) two-dimensional echocardiogram (2DE), we examined whether serial 2DE images of the left ventricle (LV) would allow three-dimensional reconstruction and accurate volume determination in 20 patients undergoing routine LV single-plane angiography. Transapical 2DE echo window covers the whole LV area from the apex to the base. For this reason, serial trans-apical 2DE images were taken at a 5° angle interval from anterior through inferoposterior LV area using a new 2DE transducer holding device. Whole LV area by this method was usually covered by serial 8-10 images. LV cavity and muscle area of each image were planimetered with a light-pen system and summed for volume. Angiographic LV volume calculation was made by an area-length method. In 20 patints, systolic and diastolic volume determinations by the angiographic method were compared with the volume obtained from image processor.
Extremely good correlation (r=0.92, p<0.01) among the two method was obtained.
Accurate cross-sectional reconstruction and volume determinations were obtained by this method.
And these suggest stedy state LV volume can be determined non-invasively from multiple cross-sectional image.

A PRACTICAL TWO-DIMENSIONAL ECHOCARDIOGRAPHIC MODEL TO ASSESS VOLUME IN THE ISCHEMIC LEFT VENTRICLE

Pascal Gueret, MD; HL Wyatt, PhD; Samuel Meerbaum, PhD, FACC; Eliot Corday, MD, FACC, Cedars-Sinai Medical Center, Los Angeles, Calif.

Most techniques currently available for left ventricular volume (LVV) quantification do not adequately account for regional myocardial dyssynergy (DYS). Previous in vitro studies show that 2-dimensional echocardiography (2DE) may account for LV-asymmetry when short-axis areas (A) are utilized for reconstruction. The present in vivo study was designed to test 2DE short-axis models for LVV versus single plane cineangiography before and after proximal left anterior descending intracoronary balloon occlusion (O). In 11 closed chest dogs, LVV at end-diastole (EDV) and at end-systole (ESV) were quantified and ejection fraction (EF) calculated in control and during regional ischemia. Simpson's reconstruction using A from 5 LV short-axis levels and LV length (L) showed good LVV correlations before and after O (r from .89 to .92). A simplified formula (LVV=5/6 AL) utilized A from either the mitral valve level area (MV-A) proximal to O or the mid-papillary level area (MP-A) distal to O; correlation coefficients for EDV, ESV and EF were (*=nonsignificant):

	MV-A			MP-A		
	EDV	ESV	EF	EDV	ESV	EF
CONTROL	.97	.95	.81	.81	.89	.84
LAD-O	.90	.56*	.60*	.82	.87	.92

In control, good results were observed using either MV-A or MP-A. With pronounced systolic DYS due to O, results were poor for ESV and EF using MV-A, but were satisfactory using MP-A (p<.001). EDV correlated well in O as well as in control. CONCLUSION: In dogs with ischemic myocardium, LVV in vivo may be satisfactorily assessed by 2DE using either multiple short-axis section analysis or a clinically applicable simplifed formula, 5/6 AL if the section-A is from the zone of LV asymmetry.

SELECTION CRITERIA FOR ECHOCARDIOGRAPHIC ASSESSMENT OF LEFT VENTRICULAR PRESSURE AND PEAK GRADIENT IN PATIENTS WITH VALVULAR AORTIC STENOSIS

Jason Kirkman, MD; Arthur D. Hagan, MD; Thomas G. DiSessa, MD; Ching Ti, MD; Linda M. Samtoy, MD; William F. Friedman, MD; Walter V.R. Vieweg, MD; UCSD Medical Center, San Diego, California

M-mode echocardiography was employed to estimate the left ventricular peak systolic pressure (LVPSP) and the left ventricular-aortic valve peak pressure gradient in 47 patients being evaluated for aortic stenosis prior to cardiac catheterization. A wall thickness to cavity dimension ratio: LVPSP = 225 X systolic posterior wall thickness ÷ end-systolic dimension, was employed. The aortic valve pressure gradient was determined by subtracting the cuff systolic blood pressure from the calculated left ventricular peak systolic pressure. All measurements were obtained at the level of the chordae; 10 of 47 echocardiograms were technically unsatisfactory. In 27 selected adult patients (22-89 yrs) left ventricular peak systolic pressure and aortic valve pressure gradient correlated poorly with catheterization (cath) data (r = 0.49 and 0.64 respectively). When 10 patients with significant left ventricular dilatation, wall motion abnormalities, poor left ventricular performance, or systemic hypertension were excluded from analysis, correlation of left ventricular peak systolic pressure and aortic valve pressure gradient with cath data improved markedly (r = 0.78 and 0.92 respectively). All 10 pediatric patients (age 7-10 yrs) had excellent correlation of left ventricular peak systolic pressure and aortic valve pressure gradient with cath data (r = 0.95 and 0.91 respectively). Echocardiography is a reliable method to estimate severity of aortic stenosis in children but in only selected adults.

AFTERPOTENTIALS AS A CAUSE OF LONG QT SYNDROME?- ELECTROPHYSIOLOGICAL STUDIES OF A CASE.
Ralph Lazzara, MD, FACC; Ronald R. Hope, MD, FACC; Charles C. Freeman, MD; Eliot Schechter, MD, FACC; University of Oklahoma Health Sciences Center, Oklahoma City, OK

A young woman with long QT interval (up to 600 msec) presented with ventricular tachyarrhythmias, and syncope. The QT was shortened and the arrhythmias suppressed by propanolol. Left stellate ganglion block further shortened the QT. Bipolar electrograms (1 centimeter apart) were recorded from various sites at the endocardial surfaces of both ventricles. At some sites, distinct slow potential waves were detected coincident with or just after the terminal portion of the T wave of the surface ECG and just after the "T" wave of the endocardial electrogram. The amplitudes of these extra potentials (EP) were greatest (up to 2mV) at the basal posterior portions of the ventricles. The EP occupied the interval 450-600 msec from the onset of the QRS. The QT interval on the ECG was 450 msec during this study. Epinephrine infusion (0.02 µg/kg/min) induced ventricular ectopic beats arising from the EP. The findings are compatible with the hypothesis that abnormally large afterpotentials generated by ventricular myocardial cells are enhanced by beta-adrenergic stimulation to reach threshold for excitation and produce automatic firing. The abnormal T waves reflect contributions from the afterpotentials as well as repolarization potentials.

TERMINAL T IN EXERCISE ELECTROCARDIOGRAMS
Jacqueline O'Donnell, MD; D. Eugene Lovelace, BS; James V. Faris, MD, FACC; Paul L. McHenry, MD, FACC; Suzanne B. Knoebel, MD, FACC, Krannert Institute of Cardiology, Indiana University School of Medicine, Indianapolis, IN

The T wave of the ECG is sensitive to regional changes in ventricular repolarization. In particular, apex to end of T (aT-eT) reflects a composite phase 3 of uncancelled action potentials and has been shown to be rate independent in resting ECGs. This study was undertaken to determine if aT-eT and/or aT-eT as a percent of QT (aT-eT/QT) is rate independent with exercise (EX) and if coronary artery disease (CAD) patients (PTS) demonstrate differences in aT-eT or aT-eT/QT from normal subjects (N). Treadmill EX tests were performed on 50 N and 50 CAD PTS. A two-lead ECG was continuously recorded, the last 25 beats of each EX stage computer averaged and plotted as a single QRS-T on a scale of 2 msec/mm. Measurements of aT-eT and QT were made according to the method of Lepeschkin and Surawicz.

There was no significant change in aT-eT or aT-eT/QT with heart rate (HR) in N except at HRs ≥155. N and CAD PTS with similar HR at maximal EX were compared:

	#PTS	HR		aT-eT (msec)		aT-eT/QT%	
N	25	147.8	NS	70.39	p<0.001	25.14	p<0.001
CAD	25	141.6		52.30		18.48	

Conclusion: aT-eT and aT-eT/QT are rate independent at HRs from 80-160 and differ in N and CAD PTS when compared at similar HR. The measurement may represent an additional criterion for normal and abnormal EX ECGs. Shortening of aT-eT may result from K+ release from ischemic areas affecting slope of phase 3 through electrotonus.

SYSTOLIC (ST) CURRENT FLOW ACROSS INFARCT BOUNDARIES
Gary J. Anderson, MD., FACC, Joseph Reiser, Ph.D., William B. Gough, Ph.D., William Likoff Cardiovascular Institute, Hahnemann Medical College & Hospital, Philadelphia, PA.

The purpose of this study was to characterize ST segment current flow in anesthetized animals (n=9) subjected to acute coronary ligation. After visual identification of the infarct border zone (BZ), plunge Ag/AgCl electrodes were implanted in the normal zone (NZ), BZ, and frankly infarcted zone (IZ). Intramyocardial and surface electrograms were recorded and current was measured by placing a 100Ω resistor across the input of a differential amplifier. Current flow (direction of + charge) was then mapped for each electrode pair within the matrix of electrodes. Following control recordings, the left anterior descending coronary artery was ligated in the middle 1/3. Within 15 sec following acute occlusion ST current developed and flowed from the NZ→BZ→IZ. The highest current values were recorded between NZ and BZ electrode pairs (5-7µ amp) and rarely exceed 5µ amp between BZ and IZ. When both electrode pairs were located in NZ or IZ no significant current was recorded. Current flow maps revealed the early development (< 5min) of both ST current sources and sinks. However, most current sources showed substantial variation in current output (range 1 to 7µ amps) during the 3-4 hour observation period, and in 1 experiment a current sink became a current source. From these data we conclude: 1) ST segment current flows from NZ→BZ→IZ, 2) little or no ST current flows within the IZ, 3) ST current sources and sinks developed early following an acute coronary occlusion and generated up to 7µ amp current, significantly greater than TQ current (reported elsewhere), and 4) the differences in current flow across the ischemic boundary suggests marked variation in electrophysiological response to ischemia and/or preferential low resistance current pathways in ischemic boundaries.

TOTAL BODY SURFACE POTENTIAL MAPPING DURING EXERCISE: QRS CHANGES IN NORMAL YOUNG ADULTS
Walter T. Miller, III, PhD; Madison S. Spach, MD, FACC; Robert B. Warren, PhD, Duke University, Durham, N.C.

Reductions in the magnitudes of the R waves in left precordial leads recorded from normal subjects during exercise have often been reported, but the electrophysiologic mechanisms underlying the observed changes in ECG waveform shape are only partially understood. In order to gain insight into such ECG changes, we examined in detail total body surface potential distributions recorded from 20 normal young adult subjects (25-35 years old) during multistage maximal exercise procedures on a bicycle ergometer. Using a previously reported system for obtaining total body surface potential distributions from measurements at 24 locations, high quality maps were obtained during exercise without requiring waveform averaging or special modes of exercise. To study R wave changes, serial maps recorded at each millisecond during QRS (before exercise and at intervals during and after exercise) were examined. Reductions in the magnitude of the R wave in the standard lead V5 during exercise were accompanied in our data by changes in the body surface potential distributions in early QRS and by increases in QRS duration (0-10 msec), indicating that the changes in R wave magnitude were related to changes in the sequence of activation in the ventricles during exercise. The map pattern changes in early QRS during exercise strongly suggested a delay in the initial activation of the anterior left ventricle relative to the onset of activation in the right ventricle and septum. The results indicate the importance of analyses of total body surface potential distributions in obtaining an improved physiological understanding of ECG changes during exercise.

MYOCARDIAL INFARCTS IN THE LATERAL THIRD OF THE LEFT VENTRICLE: SIZE AND ECG RECOGNITION.
RM Ward, RE Ideker, GS Wagner, DR Alonso, SP Bishop, CM Bloor, JT Fallon, GJ Gottlieb, DB Hackel, HR Phillips, KA Reimer, SF Roark, WJ Rogers, WK Ruth, RM Savage, RH Selvester, Duke Hosp., Durham, NC, U. Ala. Med. Ctr., Birmingham, Ala., UCSD Sch. of Med., La Jolla, CA, Mass. Gen. Hosp., Boston, MA, Cornell Med. Ctr., New York, NY, Rancho Los Amigos Hosp, Downey, CA.
Although ECG signs of anterior and inferior myocardial infarcts (MI's) are well established, ECG criteria for lateral MI's remain unsettled. This quantitative postmortem study of 63 hearts with single MI's anywhere within the left ventricle (LV) was performed to evaluate the ability of the ECG to detect lateral MI's and to compare their size to that of MI's in other locations. Each heart was cut transversely into 5-7 slices. The MI was traced from circumferential histologic sections of these slices and the percent of LV infarction determined by computerized planimetry. Sixteen MI's were predominantly in the lateral third of the LV, 28 in the anteroseptal third, and 19 in the posteroseptal third. Lateral MI's were smaller (mean 9% of LV, range 1-34%) than anteroseptal (mean 21%, range 1-57%) or posteroseptal MI's (mean 16%, range 4-41%). Four lateral MI's were not detected by ECG and averaged 2% of the LV (range 1-3%). The 12 lateral MI's detected by ECG averaged 11% of the LV (range 2-34%). The ECG's of these 12 MI's exhibited one or more of the following signs:R in VI $\geq$ .04 sec (6 cases), R in V2 $\geq$ .05 sec (4 cases), Q in aVL $\geq$ .03 sec (5 cases), Q in I $\geq$ .30 sec (1 case), Q in V6 $\geq$ .30 sec (1 case), or Q in aVF $\geq$ .03 sec (2 cases). Thus, when >3% of the LV, lateral MI's are detected by ECG but the signs are multiple and diverse suggesting true posterior, high lateral, apical, or inferior location. Lateral MI's are probably more common than diagnosed clinically; when small they can go undetected, and when larger they can result in QRS changes which have been previously considered to indicate other locations.

CLINICAL SIGNIFICANCE OF THE ECG INTERVAL PROLONGATION ACCOMPANYING EFFECTIVE ENCAINIDE THERAPY.
Dan M. Roden, MD; Stots B. Reele, MD; John A. Oates, MD; Raymond L. Woosley, MD, PhD; Vanderbilt University, Nashville, TN.

Encainide (E), a new, highly effective antiarrhythmic agent, is known to markedly prolong H-V conduction time in man. The clinical significance of the resulting changes in the surface ECG was evaluated in 10 patients (pts) whose chronic high frequency ventricular arrhythmias (VA) were completely abolished during a dose-ranging trial of E. ECG intervals were measured daily using the Frank orthogonal lead system. PR and QRS durations prolonged in a step-wise fashion as dosage of E was increased. Smaller changes (largely attributable to QRS prolongation) were seen in rate-corrected QT: ($\bar{X}\pm SE$)

	Placebo	50%+VA	VA Abolition
PR (msec)	150±6	180±9**	221±13** (+47.3%)
QRS	93±4	105±6*	136±10** (+46.2%)
QT_C	405±7	416±7†	452±10** (+11.6%)

**P<.001 compared to placebo *P<.01 †P>.05

Cardiac performance was evaluated during effective E therapy by treadmill testing (TMT) and radionuclide ventriculography. VA control persisted, exercise tolerance and BP response during TMT were unchanged compared to placebo, and ejection fraction (.57±.02, $\bar{X}\pm SE$) and global contractility were normal. Monitoring for ≥5 days on effective regimens did not detect 2° or 3° block in any of these pts. Supra-effective dosages produced transient asymptomatic RBBB in 2 other pts receiving E on an emergency basis; outpatient treatment with lower dosages successfully controlled their VA. ECG interval prolongation due to other antiarrhythmic agents has been interpreted as a sign of drug toxicity. However, effective E therapy produced marked interval changes without adverse effects. These ECG changes may thus provide useful indicators of compliance and of the drug's pharmacologic actions.

EVIDENCE SUPPORTING A DIRECT CHOLINERGIC EFFECT ON VENTRICULAR MUSCLE REFRACTORY PERIOD IN MAN
Eric N. Prystowsky, MD; Robert L. Rinkenberger, MD; Warren M. Jackman, MD; James J. Heger, MD; Douglas P. Zipes, MD, FACC, Krannert Institute of Cardiology, Indiana University School of Medicine, Indianapolis, IN

Although evidence exists supporting the anatomic presence of the parasympathetic nervous system (PNS) in human ventricle, little is known about the possible electrophysiologic effects of cholinergic activity. To assess the effect of the PNS on ventricular refractoriness, electrophysiologic studies were performed on seven patients in a control state and repeated in the presence of autonomic blockade using propranolol (P) (0.15 mg/kg i.v.) and atropine (A) (0.03 mg/kg i.v.) plus P. In each patient the ventricular pacing cycle length was the same for all refractory period determinations using the extrastimulus technique.
Control effective refractory period (N=7; 243 ±18 msec; mean ±SD) significantly shortened after A plus P administration (216 ±21 msec, p<.001). The effective refractory period after P alone (N=5; 252 ±13 msec) was not changed from control (250 ±15 msec, p>.05). The control functional refractory period (N=7; 260 ±25 msec) significantly shortened after A plus P administration (236 ±18 msec, p<.001). The functional refractory period during P alone (N=5; 273 ±18 msec) did not change from control (271 ±18 msec, p>.05). In all patients spontaneous sinus cycle length decreased significantly from control (879 ±111 msec) in the presence of A plus P (599 ±66 msec, respectively, p<.001).
These data demonstrate that cholinergic blockade, independent of β-receptor blockade, shortens ventricular muscle refractoriness, suggesting that tonic vagal influences prolong ventricular refractoriness in man.

CELLULAR ELECTROPHARMACOLOGY IN EXPERIMENTAL ISCHEMIC LESIONS: COMPARISON IN ACUTE AND HEALED ISCHEMIC INJURY.
RJ Myerburg, MD, FACC; H Gelband, MD, FACC; K Epstein; MS Gaide, PhD; RJ Sung, MD, FACC; A Castellanos, MD, FACC; AL Bassett, PhD, University of Miami School of Medicine, Miami, Florida

We have previously reported the effects of 2 ischemia models on action potential duration at 90% repolarization (APD) and local refractory periods (RP) of ventricular muscle (VM) cells on the endocardial surface of isolated cat hearts. In acute ischemic injury (AMI) studied 1-2 hours after acute myocardial infarction, APD's and RP's are shorter than normal (N) controls; in healed ischemic injury (HMI) studied 2-4 months after acute infarction, APD's and RP's are prolonged. When these preparations are exposed to procainamide (PA) (40 µg/ml for 60 min.), the AMI cells were more responsive to the APD lengthening effects compared to the HMI cells. Histologically, the AMI areas showed predominantly acute cellular injury, with loss of cytoplasmic striation, acidophilia, focal hemorrhage, and interstitial edema. The HMI areas had dense collagen deposition and nuclear pleomorphism, but no acidophilia or loss of striation. To determine whether scarring in HMI hearts might cause poor access of PA to endocardial cells, similar preparations were exposed to either PA or tetrodotoxin (TTX) (1-2 µg/ml). The effect of TTX was the same in the HMI areas and in N cells, suggesting that poor perfusion due to scarring was not the reason for the lesser response of HMI cells to PA. We conclude that the dissimilar effect of PA on acutely ischemic tissue and healed tissue 2 to 4 months after ischemia is due to different cellular characteristics in the 2 preparations, rather than to poor perfusion of cells in the HMI hearts. Cells surviving acute ischemic injury and subsequent healing processes respond differently to PA than do N or AMI cells.

KINETICS OF ANTIARRHYTHMIC EFFECTS OF BRETYLIUM: CORRELATION WITH MYOCARDIAL DRUG CONCENTRATIONS. Jeffrey L. Anderson, M.D.; Eugene Patterson; Marilyn Conlon; Stanislaw Pasyk, M.D.; Benedict R. Lucchesi, PhD,M.D., University of Michigan, Ann Arbor, Michigan.

In order to study the relative importance of myocardial (C_m) vs serum (C_s) drug concentrations in predicting antiarrhythmic effects of bretylium tosylate (BT), kinetic studies were performed in 27 dogs after bolus injection of saline, bretylium 6mg/kg (BT-6) or 2mg/kg (BT-2). Parallel determinations of drug concentrations (C_m,C_s) and antiarrhythmic effects (ventricular effective refractory period [ERP], repetetive ventricular response [RVR], and ventricular fibrillation threshold [VFT]) were made without and with 2 min of coronary ischemia (I). C_s fell rapidly after IV BT, whereas C_m rose gradually, peaking at 1.5-6hrs. C_m:C_s rose progressively (1.2±.3 [SEM] at 30 min, 6.4±1.0 at 12 hr; [n=7,BT-6]). ERP,RVR and VFT followed C_m rather than C_s, with peak effects (increases) at 3 hrs. These kinetic results were similar with or without I and for both doses of BT. In contrast, parameters for saline controls did not vary with time. Selected results ± SEM (msec) for BT-2 (n=6) are representative:

	t (h) 0	.03	.5
ERP	154±1	-	157±3
RVR	1.2±0.2	2.8±1.1	2.5±0.8
VFT	3.6±.5	7.5±2.5	10.3±2.7*
	t (h) 1.5	3	12
ERP	167±3**	175±6**	163±3
RVR	4.0±1.1*	5.4±1.9*	4.3±1.0*
VFT	15.4±3.4**	23.5±5.4**	15.8±2.1**

* $p \leq .05$, ** $p \leq .01$ vs 0 value

These kinetic studies quantitate the prolonged antifibrillatory effect of BT, with its delayed maximum, and emphasize the importance of C_m in determining this behavior.

REPERFUSION ARRHYTHMIAS: DIFFERENTIAL EFFECT OF LIDOCAINE ON REENTRY AND ENHANCED AUTOMATICITY

Glenn Kabell, PhD; Benjamin J. Scherlag, PhD, FACC; Ronald R. Hope, MD, FACC; Ralph Lazzara, MD, FACC, Veterans Adm and University Hospitals, University of Oklahoma, Oklahoma City, Oklahoma

We studied the effects of reperfusion (R) in 31 dogs following a 30-45 min period of left anterior descending coronary artery (LAD) occlusion using ECG and composite electrogram recordings. One-stage R in 14 of 16 dogs produced ventricular arrhythmias (VA) which degenerated into ventricular fibrillation (VF) within 60 sec. The onset of VA was associated with continuous electrical activity (CEA) in epicardial and intramural electrograms recorded from the reperfused zone (RZ). Vagal slowing during R (72±8/min) did not prevent VF (8 of 8 dogs) and escape beats were often followed by one or more coupled ectopic beats associated with CEA. Rapid atrial pacing (270/min) also did not prevent the appearance of CEA-related VA and VF (4 of 4 dogs) nor did 4 mg/kg lidocaine (10 of 11 dogs). In 4 untreated dogs resuscitated by DC cardioversion (<40 Watt-sec) VA were observed in the absence of CEA in local electrograms. In all cases VA were reversibly suppressed by reocclusion of the LAD suggesting these VA did not result from DC shock. In another group of 15 dogs R was performed in 2 stages resulting in no VF but in 8 of 15 dogs VA were observed beginning 2-3 min after R and lasting 20-30 min. Atrial pacing suppressed VA and idioventricular rate averaged 164±10/min vs 55±10/min pre-R control. The earliest site of activation indicated automatic foci in the subendocardium of the RZ. Lidocaine (2-4 mg/kg rapidly (< 90 sec) restored normal sinus rhythm and suppressed automaticity (72±11/min) as did LAD reocclusion (52±6/min). We conclude that both reentry and enhanced automaticity play a role in VA due to R. Lidocaine suppresses automatic but not reentrant VA.

EFFECTS OF ETHMOZINE AND LIDOCAINE ON VENTRICULAR FIBRILLATION AND DEFIBRILLATION IN ANESTHETIZED DOGS. Susan Fox, Bruce Hoffman, Michael Rosen MD, FACC, Brian Hoffman MD, Columbia Univ., College of Physicians & Surgeons, NY, NY

Lidocaine (L) and ethmozine (E) are both effective in suppressing ventricular arrhythmias. We induced single and multiple ventricular premature beats (VPB) and fibrillation electrically in 9 mongrel dogs 1 to 6 weeks following surgical placement of electrodes on the ventricles and studied E and L effects on the VPB and ventricular fibrillation and defibrillation thresholds. The effects of the drugs on threshold (mamps) were as follows: (*P<.05)

	Single VPB		Multiple VPB		V. Fib.		V. Defib.	
	Cont.	Drug	Cont.	Drug	Cont.	Drug	Cont.	Drug
L								
M	6.3	+5.4*	10.4	+7.7*	14.9	+15.7*	82.4	+36.6
SD	2.6	5.6	3.7	5.9	3.2	6.3	20.4	67.1
E								
M	7.6	+4.8*	12.5	+3.7*	18.7	+ 2.1	90.0	+21.7
SD	3.2	3.8	4.4	2.4	7.4	2.4	27.7	47.7

L and E significantly increased the threshold for inducing single and multiple VPB's. L significantly increased the ventricular fibrillation threshold; E did not. With respect to defibrillation threshold, neither drug affected this to a statistically significant degree. However, for L, 4 dogs showed no change in defibrillation threshold, another 4 could not be fibrillated (and hence, defibrillation threshold could not be tested); and only in one dog was an increase in defibrillation threshold seen. In comparison, with E, defibrillation threshold increased in 4 dogs and decreased in two. Another 2 dogs could not be defibrillated after E. We concluded that both L and E are effective drugs when used for the suppression of VPB's. L had more of an antifibrillatory effect than E and - whereas L did not alter defibrillation threshold - this appeared to increase with E.

TEMPORAL DISPERSION OF REFRACTORINESS: LACK OF CORRELATION WITH ANTIARRHYTHMIC EFFICACY IN A MODEL OF CHRONIC INFARCTION

Joseph F. Spear, PhD, FACC; Eric L. Michelson, MD; E.Neil Moore, DVM, PhD, FACC; University of Pennsylvania and Lankenau Hospital, Philadelphia, Pennsylvania

A chronic infarction model has been developed using occlusion of the mid or distal left coronary artery modified by a reperfusion stage. Three to 30 days after surgery either sustained ventricular tachycardia (VT, 3 dogs) and/or fibrillation (VF, 3 dogs) was initiated using routine methods of programmed electrical stimulation. Strength interval curves were constructed using unipolar cathodal stimulation via plunge electrodes during ventricular pacing at a cycle length of 300 msec. Measurements were made at 26 normal and/or infarcted sites distributed over the left ventricle in these 6 dogs. The temporal dispersion of both effective (ERP) and relative refractory periods (RRP) was determined before and after infusion of 15-30 mg/kg procainamide (PA) and correlated with its effect on the inducibility of VT and VF 20-30 min after infusion.

Dispersion of:	ERP (msec)	RRP (msec)
Pre PA	40.5 ± 41	54.6 ± 37
(mean ± SD)	(p=NS)	(p=NS)
Post PA	43.3 ± 38	55.1 ± 39

While mean dispersion of ERP and RRP were unchanged after PA, PA did prevent reinitiation of VF in 3/3 dogs, and had salutory effects on VT in 3/3 dogs (↑ cycle length, episodes nonsustained). We conclude that (1) dispersion of refractoriness characterizes chronic infarction, (2) the antiarrhythmic effects of PA cannot be explained simply by its effects on dispersion of refractoriness, and (3) measurements of dispersion of refractoriness have limitations in the study of arrhythmogenesis.

IMPORTANCE OF LEFT VENTRICULAR FILLING IN DIFFERENTIATING CONSTRICTIVE PERICARDITIS VS. RESTRICTIVE CARDIOMYOPATHY.
Rene A. Langou, MD, FACC; Theodore I. Tyberg, MD; Allan Y.N. Goodyer, MD, FACC. Yale University School of Medicine, New Haven, CT.

Left ventricular filling (VF) was evaluated by left ventriculograms (LVgram) in patients (pts) with 1) constrictive pericarditis (CP), 2) restrictive cardiomyopathy (RC), and 3) normals (NM). CP (7 pts) was established by characteristic right and left heart hemodynamics and surgical pathology. Four pts had calcific CP and 3 had non-calcific pathology. RC (4 pts) was established by right and left heart hemodynamics and postmortem pathology. All 4 pts had amyloid heart. NM (7 pts) had normal hemodynamics, LVgram, and coronary arteriography.

LVgram silhouettes were digitized and left ventricular volumes (LVV) were calculated by computer at 16 msec. intervals. Curves of LVV and VF rate were constructed for each pt and also for each group. Points along these curves were statistically analyzed using unpaired Student "t" test. CP pts had a sudden and premature plateau of the diastolic LVV curve representing 85±4% of VF. Furthermore, VF rate was faster than NM during the first 50% of diastole. RC pts had no plateau of the diastolic LVV curves and their VF rate was slower than NM during the first 50% of diastole. Statistical analysis of VF rate in CP, RC and NM pts showed significant differences during the first half of diastole; CP had 85±4%, RC had 55±4% and NM had 66±5% of their VF completed at 50% of diastole ($p<0.05$).

Thus, this study showed a significantly different profile of diastolic LVV and VF rate curves during the first half of diastole in CP and RC pts, suggesting their importance in differentiating CP and RC at cardiac catheterization.

AMYLOID HEART DISEASE: A SIMULATOR OF CORONARY, (MYOCARDIAL INFARCTION, SUDDEN DEATH), PERICARDIAL, (CONSTRICTION AND/OR EFFUSION), VALVULAR (FLOPPY ATRIOVENTRICULAR VALVES) AND MYOCARDIAL (HYPERTROPHIC CARDIOMYOPATHY) HEART DISEASES - AN ANALYSIS OF 42 NECROPSY PATIENTS WITH GROSSLY-VISIBLE CARDIAC AMYLOID
Bruce F. Waller, MD, Renu Virmani, MD, William C. Roberts, MD, FACC, National Heart, Lung, and Blood Institute, Bethesda, Maryland

Cardiac involvement by amyloid (A) is well-known but cardiac A simulating other heart diseases is not. We studied at necropsy 42 patients (pts) (aged 21-89 yrs [avg=60], 29 men) with cardiac A which produced in each symptoms of cardiac dysfunction (CD): congestive heart failure in 38 (90%), chest pain in 10 (24%) and sudden death in 3 (7%). Some type of ECG abnormality was present in all 42 pts including low voltage, myocardial infarcts (MI) patterns, conduction and rhythm disturbances, and axis deviation. Although all had increased heart weighs (370-780 gm [avg = 570], none by ECG had evidence of ventricular hypertrophy. Although CD was diagnosed clinically in all 42 pts, cardiac A was diagnosed in only 19 (45%). The cardiac conditions diagnosed in the other 23 pts (55%) were: coronary heart disease, in 14 (33%), only 1 of whom had > 75% x-sectional area coronary narrowing; pericardial (P) heart disease in 5 (12%), 3 of whom had large P effusions; and hypertrophic cardiomyopathy (HC) (by echocardiogram) in 4 (10%), all of whom had thicker ventricular septa from A than left ventricular (LV) free walls (ASH). Ten pts (24%) had LV transmural myocardial A deposits which looked like transmural healed MI. Six (14%) pts had floppy atrio-ventricular valves, each of which had A deposits in the leaflets. Thus, pts with grossly-visible cardiac A had CD which simulates coronary, pericardial, valvular, and/or myocardial heart disease.

DIABETIC NEUROPATHY OF THE HEART AND ARTERIES
John A. Mantle, MD, FACC; Eugene M. Strand, BA; Thomas N. James, MD, FACC; William J. Rogers, MD, FACC; Richard O. Russell, Jr., MD, FACC; and Charles E. Rackley, MD, FACC; University of Alabama Medical Center, Birmingham, Alabama.

Autonomic neural regulation of the sinus node (SN) and systemic arteries was investigated in 16 diabetic (D) ischemic heart disease (IHD) patients (pts) and compared to 30 IHD pts without D and 5 normals. Neural regulation of the SN was examined by the beat by beat changes to respiration (sinus arrhythmia), valsalva (40 mmHg) and intravenous atropine (0.8-2 mg). Regulation of the arterial bed was studied by monitoring the abdominal aortic pressure during the valsalva. The duration of D ranged from 0 to 21 yrs. Nine D pts were insulin dependent, 2 were juvenile onset. Complications included retinopathy (5 pts), peripheral neuropathy (5 pts) and renal insufficiency (1 pt). Normal sinus arrhythmia was absent in 14 of 16 (88%) D pts. Twelve of the 16 (75%) D pts had an abnormally blunted reflex slowing with increase in arterial pressure. Fifteen of 16 D pts, however, had an increase in heart rate with atropine indicating some vagal influence was still present. Six D pts had a normal arterial pressure response to the valsalva. Seven D pts had an abnormal progressive fall in diastolic pressure during strain and no overshoot after release. The arterial response could not be assessed in the other 3 D pts because of heart failure. There was a direct correlation between loss of cardiovascular neural regulation and the severity of the D.

Summary: In adult diabetic pts with IHD: 1) cardiovascular neuropathy is prevalent, 2) both vagal and sympathetic defects occur as early complications, 3) important adaptive cardiovascular reflex control of heart rate and blood pressure may be absent.

IDENTIFICATION OF SUBCLINICAL CARDIAC ABNORMALITY 5-15 YRS. AFTER THERAPEUTIC MEDIASTINAL IRRADIATION
John S. Gottdiener, MD; Michael J. Katin, MD; Jeffrey S. Borer, MD, FACC; Stephen L. Bacharach, PhD; Michael V. Green, MS; Lewis C. Lipson, MD; NHLBI, Bethesda Md.

Therapeutic irradiation of the mediastinum has been associated with pericardial, myocardial, and coronary arterial injury shortly after therapy. In order to assess the late effects of anterior irradiation, 28 pts. without prior cardiac disease or exposure to cardiotoxic chemotherapy, were prospectively recalled for evaluation 5-15 yrs. after radiation therapy for Hodgkins disease. Median age at evaluation was 34 yrs; range 25-29 yrs. ECG gated $Tc^{99}M$ radionuclide left ventricular cineangiography (15 pts) at rest and with exercise, and M-mode echocardiography (28pts) were performed. Although radionuclide ejection fraction (EF) at rest was depressed in only 2/15 (13%) radiation pts, the average for this group (0.52± 0.03 SEM) was below normal (0.57±0.01, $p<0.05$). With exercise, EF was below normal in 5/15 (33%) pts. Average EF with exercise (0.58±0.04) was below normal (0.71±0.02, $p<0.05$). Regional wall motion abnormality, at rest or with exercise, was present in only one pt, a 33 yr old woman with abnormal coronary arteriograms who did not have "risk factors" for atherosclerosis. Pericardial effusion on echocardiogram was present in 8/28 (29%) pts. Asymptomatic restrictive cardiomyopathy was documented at cardiac catheterization in 2 pts. Hence, asymptomatic pericardial effusion, restrictive cardiomyopathy, and systolic left ventricular dysfunction, are evident many years after therapeutic mediastinal irradiation. Left ventricular functional reserve may be decreased despite normal EF at rest. Life-long cardiologic follow-up is indicated for all pts following therapeutic mediastinal irradiation.

HEAVY MEDIASTINAL IRRADIATION CAUSING SEVERE CORONARY NARROWING IN PATIENTS 15 TO 33 YEARS OF AGE: A POORLY APPRECIATED CAUSE OF CORONARY HEART DISEASE IN YOUNG PEOPLE:
Frank C. Brosius III, MD, Bruce F. Waller, MD, William C. Roberts, MD, FACC, National Heart, Lung, and Blood Institute Bethesda, Maryland

Pericardial heart disease after mediastinal irradiation (I) is well-known; however, radiation effects upon the coronary arteries (CA), endocardium (valvular and mural) and myocardium is not. We studied 15 patients (pts) who had I (3600-8000 rads [avg = 6500]) for Hodgkin's disease (12 pts), metastatic carcinoid (2 pts), or reticulum cell sarcoma (1 pt) 12-120 months (avg = 56) before death. The study pts were compared to 5 control subjects (CS) who had no I. Of the 15 pts, 3 had had congestive heart failure; 2 mitral regurgitation, and 1, sudden coronary death. None clinically had had angina pectoris, myocardial infarction, or valvular heart disease. At necropsy, 30 major CA (left main [LM], left anterior descending [LAD], left circumflex [LC], right [R])(8 pts) were studied: of them, 12 (40%) had > 75% x-sectional area (XSA) narrowing by atherosclerotic plaque (A) (CS = 0). The CA from 5 pts were sectioned in 5-mm segments (total = 293) and examined histologically: 14 (5%) were narrowed 76-100% in XSA (CS = 0); 42 (14%) 51-75%, (CS = 0); and 237 (81%) 0-50% (CS = 100%). Only 1 of the 15 study pts had transmural myocardial necrosis or scar, and this pt had the LAD, LC, and R CA narrowed > 75% in XSA by A. Of 15 pts, 11 had ventricular mural endocardial thickening. Of 60 cardiac valves examined, 24 (40%) were thickened by fibrous tissue: 12/15 mitral, 5/15 tricuspid, 5/15 aortic, and 2/15 pulmonic. Thus, heavy I accelerates coronary A, produces fibrous thickening of the mural and valvular endocardium and the pericardium but spares the myocardium.

CARDIAC FUNCTION
2:00-3:30

IMPORTANCE OF PRE-OPERATIVE WALL STRESS IN PREDICTING REGRESSION OF LEFT VENTRICULAR DILATATION IN CHRONIC AORTIC INSUFFICIENCY.
Andrew G. Kumpuris, MD; Miguel A. Quinones, MD, FACC; Donna J. Kanon, BMa; Jean G. Nelson, RDMS; Richard R. Miller, MD, FACC, Baylor College of Medicine and The Methodist Hospital, Houston, Texas.

To develop predictors of post-operative (op) regression of left ventricular (LV) dilatation in pure aortic insufficiency (AI), 57 patients (pts) with AI[43 chronic (C), 14 acute (A)] and normal coronaries were studied with pre- and post-op echograms. Normal post-op LV diastolic dimensions (Dd≤5.8 cm) were seen in 27 C-AI (Group A) and all A-AI, versus increased post-op Dd(>5.8 cm) in 16 C-AI (Group B). Significant ($p<0.001$) differences were noted between Groups A and B in pre-op Dd(6.6 vs 7.9 cm), LV end systolic (ES) dimension (Ds) (4.3 vs 6.1 cm), shortening fraction (SF)(0.34 vs 0.22), end-diastolic radius-thickness ratio (RTR)(2.8 vs 3.7),mean(m) RTR(1.9 vs 2.8),mean wall stress (MWS)(252 vs 374 mm Hg) and ES stress (S)(169 vs 288 mm Hg). Pre-op MWS (301 mm Hg) was higher ($p<0.05$) in A-AI than in Group A but other indices were similar (P=NS). Predictive values (PV%) for post-op Dd≤5.8 cm in C-AI:

	Dd≤7.2	Ds≤5	SF≤.28	RTR≤3.2	mRTR≤2.5	MWS≤300	ESS≤235
PV%	82	92	80	92	93	90	88

PV% for post-op Dd>5.8 cm in C-AI:

	Dd>7.2	Ds>5	SF>.28	RTR>3.2	mRTR>2.5	MWS>300	ESS>235
PV%	67	76	56	72	93	86	100

In Group A, post-op Ds, MWS and ESS decreased significantly ($p<0.001$) from pre-op values. In Group B, post-op Ds remained unchanged while MWS & ESS decreased slightly ($p<0.05$). Thus, in C-AI, ESS, MWS, mRTR & Ds are the best predictors of post-op regression of LV dilatation and superior to SF implying that in C-AI (in contrast to A-AI) maintenance of a near normal end-systolic stress-fiber length relation through appropriate hypertrophy is essential in preventing irreversible cardiac decompensation.

PULSUS ALTERNANS DETERMINED BY BIVENTRICULAR SIMULTANEOUS ECHOCARDIOGRAPHIC SYSTOLIC TIME INTERVALS
Yoshiyuki Hada, MD; Ernest Craige, MD, FACC, University of North Carolina, Chapel Hill, N.C.

Pulsus alternans (PA) is generally detected by alterations in the systemic circulation. It may, however, also occur in the pulmonary circulation. In order to determine concordant or discordant PA we obtained simultaneous bilateral STIs from echograms of both semilunar valves in 32 patients (age 47.3 ±5.5) with various serious heart diseases excluding semilunar valve stenosis. Results:

Left PA	Right PA	Bilateral PA	No PA
5	1	4	22

PA, when present, was induced by ventricular premature beats (VPBs) and persisted for 3-15 beats. Ventricular function as determined by PEP/LVET was not significantly different in patients with (0.65 ± 0.13) or without (0.56 ± 0.19) left PA. However, RPEP/RVET was higher in those with right PA (0.52 ± 0.04) vs. those without right PA (0.40 ± 0.09; $p < 0.01$).
In a retrospective study of 100 cases of congestive cardiomyopathy (age 46.4 ±14.8) persistent left sided PA was found in 10 patients and VPB induced PA in 7 of 31 with VPBs recorded. There was no significant difference in PEP/LVET among patients with persistent PA, VPB induced PA or without PA (0.71 ± 0.12, 0.68 ± 0.14, 0.69 ± 0.14, respectively), although all the echocardiograms revealed severe LV dysfunction.
Conclusions: (1) Symmetrical or asymmetrical PA can easily be detected by simultaneous dual echocardiography. (2) Right PA is not rare. (3) VPB-induced PA is common in patients with heart failure, but (4) the incidence of persistent PA in cardiomyopathy is only 10%.

PARADOXICAL RISE IN LEFT VENTRICULAR FILLING PRESSURE WITH POSITIVE END EXPIRATORY PRESSURE VENTILATION: A REVERSED BERNHEIM EFFECT.
John R. Darsee, MD, J. Ronald Mikolich, MD, Paul F. Walter, MD, Robert C. Schlant, MD, FACC. Emory University School of Medicine, Atlanta, Georgia
Controversy exists whether positive end expiratory pressure (PEEP) ventilation lowers cardiac output by reducing left ventricular (LV) preload, increasing LV afterload, by influencing contractility, or by combination effects. Accordingly, 12 anesthetized mongrel dogs were studied both closed and open chest during 0,5,10,15 and 20 cm H_2O PEEP with high-fidelity measurements of LV systolic pressure, LV end-diastolic pressure (LVEDP), and dP/dt, cuff or catheter aortic flow probe, and sonomicrometry of LV dimensions. The right atrium was connected to a reservoir for rapid changes in right ventricular (RV) EDP measured with a high-fidelity catheter. With chest closed, changes were greatest during 20 cm H_2O PEEP: LVEDP rose from 4.1±1.2 to 8.2±2.4 mmHg as LV systolic fell from 124±8 to 98±4 mmHg, with no change in heart rate, a ↓ in stroke volume from 28±3 to 15±3 ml, ↑ in LVED dimension from 30.2±2 to 27.4±1.4 mm, ↓ in maximum negative dP/dt from -1800±120 to -790±80 mmHg/sec, and ↓ in peak wall tension from 110±8 to 64±6 g/cm^2, while RVEDP rose from 3.9±0.8 to 10.5±2.1 mmHg (for all changes $p<.01$). With lung and pleural factors eliminated in open chest dogs during 20 cm H_2O PEEP, LVEDP rise was less (to 6.9± 0.8 mmHg) than with chest closed. With a sudden drop in RVEDP (using the reservoir) to pre-PEEP values for 2 beats (which would not affect LV filling volume for ≥ 5 beats), LVEDP fell to < 2 mmHg in all dogs. We conclude 1) a paradoxical ↑ in LVEDP with ↓ LVED dimension (↓ LV compliance) during PEEP is caused primarily by elevated RVEDP transferred across the septum; and 2) with RV factors transiently removed, PEEP is associated with ↓ LVEDP and ↓ LV wall motion.

ATRIAL HYPEREMIA AND ISCHEMIA DURING ACUTE MITRAL REGURGITATION

Kirit Gosalia, MD, David Sewell, MD, John Oxendine, BA, William Neill, MD, VA Medical Center and Tufts University School of Medicine, Boston, Massachusetts

Coronary blood flow (CBF) presumably is regulated by metabolic requirements for myocardial work. We determined the effects of acute increase in left atrial (LA) pressure (P) due to mitral regurgitation (MR) on regulation of CBF to the left and right atrial (RA) myocardium. Experiments were done in 13 open chest dogs. Graded degrees of MR (mild 7 dogs, moderate 5 dogs, severe 7 dogs) were created by severing chordae tendinae through a left ventricular apical myotomy. CBF distribution was determined by the microsphere method.

	LAP	RAP	LA CBF		RA CBF	
	mmHg	mmHg	ml/min.g	% total	ml/min.g	% total
Control	8	4	0.47	3.3	0.27	2.2
Mild MR	12*	4	0.55*	3.4	0.36*	2.4*
Mod. MR	20*	4	0.75*	4.5*	0.43*	2.8*
Sev. MR	32*	5	0.30*	1.9*	0.42	3.4*

* Different from control, $p < 0.06$

Mild or moderate MR increased LAP. The LA CBF increased, and the LA received a larger percent of the total cardiac CBF. These results imply that augmented LA pressure work caused coronary vasodilation in the LA myocardium. RA CBF also increased during MR despite constant RAP, suggesting some interdependence between regulations of right and left atrial perfusion. Severe MR with very high LAP significantly decreased LA CBF but not RA CBF. We speculate that intramyocardial compression from high LA wall tension may have impeded LA perfusion during severe MR. LA ischemia from this mechanism could contribute to atrial arrhythmias in patients with mitral valve disease or left ventricular failure.

CORONARY CRITICAL CLOSING PRESSURE DURING CONTROL AND MAXIMAL VASODILATION

Joseph A. Gascho, MD: Stanley L. Herr; Melvin L. Marcus, MD, FACC, Univ of Iowa and VA Hosps., Iowa City, Iowa.

There is little information about critical closing pressure (CCP) in the coronary arteries. Bellamy (Circ Res 43:92, 1978) estimated by extrapolation that the diastolic CCP was 45 mmHg during control conditions, and decreased to 20 mmHg with adenosine. To further evaluate this problem, we studied pressure-flow curves in 5 chloralose anesthetized open chest dogs. We perfused the circumflex (CX) coronary artery via the femoral artery by a servo-controlled pump. This allowed us to maintain any desired pressure; flow was measured with an electromagnetic flow meter.

We studied pressure-flow curves during control conditions, and during maximal coronary vasodilation with intracoronary (IC) and intravenous (IV) adenosine. The doses of adenosine used ablated the reactive hyperemic response to coronary occlusion. CCP was determined by extrapolating the CX coronary flows at CX coronary pressures of 19±9 ($\bar{X}$±SD) to 36±4 mmHg. In this pressure range, there was an excellent linear relation between pressure and flow (mean correlation coefficient of the 15 measurements was .95±.07), and the difference between extrapolated CCP and lowest pressure measured was only 5±5 mmHg.

RESULTS:	HR (beats/min)	AoP (mmHg)	CCP (mmHg)
Control	140±13	124±13/89±11	11±9
IC Adenosine	146±12	128±15/89±8	14±9
IV Adenosine	101±21*	*97±14/50±11*	14±9

*P<.05 vs. IC adenosine, control

CONCLUSIONS:

(1) During control conditions, the CCP averaged for the entire cardiac cycle is lower than previously noted. (2) IC adenosine, without systemic hemodynamic effects, or IV adenosine, with significant systemic hemodynamic effects, does not alter CCP.

CAN INTRACARDIAC VOLUME CHANGES ADEQUATELY EXPLAIN R-WAVE VARIATIONS ASSOCIATED WITH ACUTE CORONARY ISCHEMIA?

Daniel David, MD, Joel Morganroth, MD, FACC, Chin C. Chen, MD, Masahito Naito, MD, Val Marcy, Eric L. Michelson, MD, Leonard S. Dreifus, MD, FACC, Lankenau Hospital, Jefferson Medical College, Philadelphia, PA

Previous human studies have attributed the increase in R-wave amplitude during coronary ischemia to an increase in left ventricular (LV) volume (the Brody effect). To test this hypothesis, R-wave voltages (R) in leads X, Y, Z, II and V6 were compared to M-mode and cross sectional echocardiographically determined LV end diastolic volume (LVEDV) and end diastolic diameter (LVEDD) in 11 open-chested dogs. The left anterior descending and circumflex coronary arteries were occluded temporarily and data collected during the hyperacute ischemic period (HIP) (1 min. after ligation (L)), during the peak ischemic period (PIP) (4-5 mins. after L), and 5 minutes after reperfusion (REP). Results are shown as percent of change from control ± SE.

	HIP	PIP	REP
LVEDV	+27 ± 4.8	+44 ± 3.6	+4 ± 0.9
LVEDD	+15 ± 1.8	+21 ± 2.4	+2 ± 0.6
R in X	-13 ± 5.1	+13 ± 6.0	-0.1 ± 3.3
R in Y	-14 ± 2.7	+12 ± 4.2	+0.4 ± 0.9
R in Z	- 4 ± 6.3	- 8 ± 8.7	-2 ± 0.9
R in II	-13 ± 5.1	+13 ± 2.4	-3 ± 1.8
R in V6	-14 ± 2.7	+17 ± 6.0	+3 ± 1.8

Accompanied by a progressive increase in LVEDV and LVEDD during HIP and PIP, R-wave amplitude decreases in HIP and subsequently increases in PIP and returns to control in REP. Thus, the Brody effect does not account for the initial R-wave changes during hyperacute ischemic period. Mechanisms other than the Brody effect must be considered to explain the change in R-wave amplitude during acute coronary ischemia.

SELECTIVE VULNERABILITY OF THE PAPILLARY MUSCLES TO SEQUENTIAL BLOOD FLOW CHANGES INDUCED BY ISOPROTERENOL.

Franklin C. Clayton, MS; Galen M. Pieper, MS; Gordon L. Todd, PhD and Robert S. Eliot, MD, FACC, University of Nebraska Medical Center, Omaha, NE.

The sequential changes in regional myocardial blood flow (MBF) following infusion of isoproterenol (ISP) were investigated with 15μ radiotracer microspheres in open-chested, anesthetized dogs. They were continuously infused for one hour with a necrogenic dose of ISP (2.5 μg/kg/min) and MBF determined prior to and after 5, 15, 30 and 57 min of infusion. Measurements of MBF were made in four circumferential regions (anterior, lateral, posterior and septal) for each of three levels (apex, mid and base). Each tissue block was further divided into endocardial (ENDO), midmyocardial (MID) and epicardial (EPI) thirds. In general, flow increased to a plateau by 15 min for all areas with the left ventricular free wall ENDO receiving only approximately ½ as much flow as the EPI (Control ENDO=1.20±0.05, EPI=0.91±0.04; ISP 15 min ENDO=2.67±0.16, EPI=4.18±0.27 ml/min/gm). In contrast, the anterior and posterior papillary muscle MBF did not significantly increase throughout the infusion period. There were only limited cases of heterogeneity in MBF in circumferential regions or apex to base levels. Therefore, isoproterenol stressed hearts exhibited a marked transmural gradient in MBF with a selective vulnerability of the inner layers. While ENDO blood flow may be marginally adequate, the ISP-induced MBF redistribution is even more accentuated in the papillary muscles which can seriously affect normal cardiac function.

CORONARY ARTERY DISEASE: THERAPIES
8:30-10:15

IMPROVED MYOCARDIAL PERFUSION AND FUNCTION FOLLOWING PERCUTANEOUS TRANSLUMINAL CORONARY ANGIOPLASTY (PTCA)
Kenneth M. Kent, MD, FACC; Robert O. Bonow, MD; Douglas R. Rosing, MD; Lewis C. Lipson, MD; Stephen L. Bacharach, PhD; Michael V. Green, MS; Stephen E. Epstein, MD, FACC, NIH, Bethesda, Md.

PTCA reduces the degree of coronary arterial stenoses and improves exercise capacity in selected patients (pts) with coronary artery disease. The purpose of this study was to determine whether the improvement in the angiographic appearance of the coronary arteries would reduce exercise-induced abnormalities in myocardial perfusion and function. Six consecutive pts with one (5 pts) or 2 (1 pt) coronary arterial stenoses (>75% diameter reduction) had perfusion (Tl^{201}) and gated blood pool (Tc^{99m}) scans at rest and during exercise before and 10 to 21 days following PTCA. Before PTCA, off medication, all pts had normal left ventricular (LV) blood pool and perfusion scans at rest. During exercise, all pts developed angina, 5 of 6 pts developed LV wall motion abnormalities (ventricular tachycardia terminated exercise in the 6th pt), LV ejection fraction either remained unchanged or fell, and 3 of 6 developed perfusion abnormalities. PTCA reduced the average stenosis from 83±4% to 43±4% (p<0.01). The average gradient across the stenoses was reduced from 63±4 to 28±6 mmHg (p<.01). Following PTCA, none of the pts developed angina during exercise. LV function and perfusion were unchanged at rest, but during exercise none of the 6 pts developed LV wall motion abnormalities, and ejection fraction during exercise increased in each of the pts from the rest value and was greater than the pre PTCA value during exercise (mean 53±3% pre PTCA to 63±2% post PTCA, p<.05). The exercise-induced perfusion abnormalities present in 3 pts before PTCA were absent after PTCA. Thus, these results demonstrate that the angiographic improvement obtained with PTCA leads to augmentation of functionally important coronary blood flow during exercise.

MECHANISM OF THE BENEFICIAL EFFECT OF INTRA-AORTIC BALLOON PUMPING IN PATIENTS WITH REFRACTORY ANGINA.
James L. Whittle, MD, Robert L. Feldman, MD, Carl J. Pepine, MD, FACC, Wilmer W. Nichols, Ph.D., FACC, John Selby, MD, FACC, Thomas Kelly, MD, C. Richard Conti, MD, FACC, University of Florida, Gainesville, Florida.

Beneficial effects from intra-aortic balloon pumping(IABP) in patients(pts) with coronary disease(CAD) may result from reduced left ventricular(LV) $\dot{V}O_2$ requirements and/or improved $\dot{V}O_2$ delivery($\dot{V}O_2$). Accordingly, we studied regional LV flow(F) and $\dot{V}O_2$ during and 5 min after IABP in 7 pts with severe angina persisting on propranolol and nitrates. IABP promptly eliminated evidence for ischemic (isch), ie. angina and ECG changes, in each pt. Total, anterior (supplied by anterior descending) and posterior (supplied by circumflex and right CA's) LVF and $\dot{V}O_2$ were assessed by coronary sinus(CS) and great cardiac vein(GCV) sampling. LV regions were considered isch if ST shifts were observed in either anterior or inferior ECG leads during angina before IABP. Of 14 regions studied, 9 were isch and supplied by CA's with ≥ 90% narrowing. Five, considered non-ischemic, were supplied by CA's with lesser narrowing.
Heart rate and mean aortic pressure were not significantly changed by IABP. CSF was greater during IABP(127±9,mean ± SEM) than off IABP(113±10 ml/min,p<0.05). Isch region F increased during IABP compared to off IABP(60±8 vs 50±8 ml/min,p<0.01). Non-isch region F was unchanged(67±15 ml/min,p=NS). Total LV$\dot{V}O_2$ was similar during and off IABP (12.2±0.6 vs 11.4±1.0 ml/min, p=NS). However, isch region LV$\dot{V}O_2$ was higher during IABP(4.8±0.7 vs 3.7±0.7 ml/min, p<0.01). Non-isch region LV$\dot{V}O_2$ was higher during IABP(4.8 ±0.7 vs 3.7±0.7 ml/min,p<0.01). Non-isch region LV$\dot{V}O_2$ was similar (7.4±0.4 vs 7.7±1.2 ml/min,p=NS). The data suggest that in certain pts IABP selectively increases O_2 delivery to isch LV regions.

COMPARISON OF TWICE DAILY AND FOUR TIMES DAILY THERAPY WITH PROPRANOLOL IN ANGINA PECTORIS.
Udho Thadani, MRCP, FRCP(C), John O. Parker, FRCP(C), FACC, Queen's University, Kingston, Ontario.
The efficacy of propranolol when used twice daily and four times daily was compared in 25 patients with stable angina pectoris. The patients were on a maintenance daily dose of propranolol (160 to 320 mg) for at least 3 months before entering the study and the same dose was prescribed during the definitive study. The study was double blind and cross over in design and each dose schedule was prescribed for a two month period. For a given patient, the total daily dose of propranolol was kept constant throughout the study. No adverse effects occurred when patients were switched between treatment schedules. The average number of anginal attacks experienced were 6±6 and 7±8 per month (mean±1SD) with twice daily therapy and 6±5 and 6±6 per month with four times daily therapy. Exercise times to angina 6 and 8 hours after a previous dose of propranolol during twice daily therapy were; month 1 356±138 and 358±147 sec; month 2 375±137 and 385±148 sec; and these values were similar to those obtained at 2 and 4 hours after the previous dose during four times daily therapy; month 1 350±143 and 351±157 sec; month 2 375±142 and 366±137 sec. The values for ST segment depression and rate pressure product at the onset of angina during twice daily therapy were similar to the corresponding values during four times daily therapy. The results show that propranolol given twice daily is as effective as when given four times daily in the treatment of angina pectoris.

DOSE RESPONSE AND DURATION OF ACTION OF ORAL ISOSORBIDE DINITRATE DURING SUSTAINED THERAPY IN ANGINA PECTORIS.
Udho Thadani, MRCP, FRCP(C), Andrew Darke, Ph.D., Ho-Leung Fung, Ph.D, and John O. Parker, FRCP(C), FACC. Queen's University, Kingston, Ontario.
Dose response relationships during sustained therapy with isosorbide dinitrate (ISDN) in angina pectoris (AP) are not known. Twelve patients (pts) with exertional AP were studied. After therapy with placebo (PL) for 2 weeks, the effects of PL on heart rate (HR), systolic blood pressure (SBP) and treadmill walking time (WT) to AP were measured for 8 hours (h). ISDN 15 mg four times daily was then prescribed for 7 days and the dose doubled at weekly intervals to a maximum of 120 mg four times daily. Before each dose increment, the effects of the previous dose were evaluated over an 8h period. Plasma ISDN concentrations were also measured. At rest SBP decreased at 1,2, and 4h after each dose of ISDN in comparison to PL values (P<0.01). The mean values for WT to AP in seconds are shown.

	0h	1h	2h	4h	6h	8h
PL	375	402	400	368	382	406
ISDN 15 mg	366	460*	450*	370	380	392
ISDN 30 mg	381	457*	456*	394	404	409
ISDN 60 mg	389	480*	469*	389	429	414
ISDN 120 mg	381	473*	452*	382	413	407

* = P<0.05 in comparison to PL. Angina occurred at the same product of HR x SBP before and after ISDN. A significant improvement in exercise tolerance after any given dose of ISDN was demonstrated at 1 and 2 hours, but a dose response relationship did not exist. The short duration of effects of ISDN on exercise tolerance during sustained therapy differ from the prolonged salutary effects reported with acute ISDN therapy.

EFFECTS OF DOBUTAMINE ON MYOCARDIAL OXYGEN CONSUMPTION AND LEFT VENTRICULAR FUNCTION IN PATIENTS WITH CHRONIC HEART FAILURE DUE TO ISCHEMIC HEART DISEASE

Kanu Chatterjee, MB, FRCP, FACC; Ruby Bendersky, MD; Thomas A. Ports, MD; Bruce H. Brundage, MD, FACC; Anne Holly, BS; William W. Parmley, MD, FACC, University of California, San Francisco, Ca.

To evaluate the effects of the inotrope, dobutamine, (DB), on myocardial oxygen consumption (MVO_2),changes in coronary sinus flow (CSF), MVO_2 (CSF x A-VO_2), rate/pressure (RP) product (peak systolic arterial pressure x heart rate), and transmyocardial lactate extraction (LEX) were studied in 6 patients (PTS) with chronic heart failure during infusion of DB at a rate of 1, 2.5, 5.0 and 10.0 μg/kg/min. Changes in cardiac output (CO), right atrial and pulmonary capillary wedge pressure (PCW) were also determined.

DB (μg/kg/min)	CO (L/min)	RP (mmHg/min/10^{-3})	MVO_2 (ml/min)	PCW (mmHg)
0	3.9±1.2	11.6±4.6	14.6±7.2	28±3.8
2.5	4.6±1.5	12.5±3.8	18.0±9.5	29±4.3
5	5.7±2.5	14.4±4.0	19.7±8.7	28±3.7
10	6.6±3.0	17.9±4.5	20.4±5.5	27±5.2

Increased CO with unchanged PCW suggests improved LV function. But, MVO_2 and RP increased concurrently, LEX remained unchanged in 5 PTS and changed to lactate production in 1 PT. These findings suggest improved cardiac performance with DB is associated with increased MVO_2, probably related to increased myocardial O_2 demand.

PROGRESSION AND REGRESSION OF CORONARY ARTERY DISEASE IN POST-INFARCTION PATIENTS UNDER AGE 40

Peter Stürzenhofecker, MD; Helmut Gohlke, MD; Lothar Görnandt, MD; Wilhelm Haakshorst, MD; Helmut Roskamm, MD, FACC, Rehabilitationszentrum, Bad Krozingen, Germany

This study was undertaken to delineate the angiographic progression (progr.) or regression (regr.) of coronary artery disease (CAD) in young patients (pts) after myocardial infarction (MI). 500 pts under age 40 with a history of MI underwent a first coronary angiogram. 193 pts who had their first angiogram more than 3 years before were asked - irrespective of symptoms - to have a repeat study done: 34 pts did not respond, 27 refused, 13 had died, 5 were excluded for medical reasons. 114 had a repeat study an average of 3.8 years after the first. Progr. or regr. of CAD was assumed if there was a difference of two grades based on the AHA classification of stenoses.

RESULTS:	total	Progr.	no change	Regr.
pts	114/100%	31/27%	64/56%	19/17%
continued nicotine use		21/67%	- * - 22/26%	
vessel: LAD	114/100%	12/10%	85/75%	17/15% *
ACX	114/100%	18/16%	96/84%	0/0 % *
RCA	114/100%	20/17%	90/79%	4/4 % *
				(* = $p < 0.05$)

CONCLUSION:
The majority of pts showed no change of their coronary morphology. Progr. was equally frequent in all three vessels. Regr. was only seen in pts with unilocular disease, occurred predominantly in the LAD, and was not seen in the ACX. Pts with progr. of stenoses continued to smoke more often.

IMPROVED CARDIAC FUNCTION DURING CORONARY PERFUSION WITH LOW OXY-HEMOGLOBIN AFFINITY HUMAN RED BLOOD CELLS

Carl S. Apstein, MD, FACC, Richard Dennis, MD, John J. Vecchione, MD, Jonathan Frazer, BS, and C. Robert Valeri, MD, Cardiac Muscle and Naval Blood Research Laboratories, Boston University School of Medicine, Boston, Ma.

With coronary artery disease (CAD) O_2 delivery may be adequate at rest, but inability to dilate may limit O_2 delivery in response to stress. We modelled this situation in isolated, isovolumic (balloon-in-LV), rabbit hearts (37° C) where CA flow was held constant during rest and isoproterenol (Iso) stress; we tested the ability of low oxy-hemoglobin (Hb) affinity human RBC to increase O_2 delivery with fixed CA flow. High affinity (HAF) RBC resulted from standard blood bank storage conditions. Low affinity (LAF) RBC were made by incubation with pyruvate, inosine, phosphate and adenine to increase the 2,3 diphosphoglycerate (2,3-DPG) level to 200% of normal. The p50 for the LAF RBC was 34.4 ± 0.5 vs. 18.2 ± 0.3 mm Hg for the HAF RBC ($P < 0.001$). Except for the differing O_2-Hb affinity, the preparations had the same perfusate composition, arterial Hb and O_2 contents, LV volume and CA flow rate. Six-ten alternating 15 min runs of HAF and LAF RBC were compared in 7 hearts. In unstressed hearts, compared to HAF, LAF RBC increased myocardial O_2 consumption (MVO_2) by 47% ($P < 0.01$), but did not consistently affect contractile function. However, during Iso stress, compared to HAF, LAF RBC increased myocardial O_2 consumption by 36% ($P < 0.005$) and LV developed (systolic-diastolic) pressure by 13% ($P < 0.001$). Thus, during stress, with fixed CA flow, LAF RBC can enhance myocardial O_2 delivery and improve contractile function. Conclusion: Since standard blood storage produces HAF RBC, LAF RBC should be considered in patients with CAD when extensive RBC replacement is necessary, such as during cardiac surgery, or after trauma and hemorrhage.

MECHANISMS FOR THE DISAPPEARANCE OF Tl-201 DEFECTS AT REST OVER TIME.

Robert D. Okada, M.D., Jeffrey A. Leppo, M.D., H. William Strauss, M.D., Willard M. Daggett, M.D., FACC, Charles A. Boucher, M.D., FACC, Marshall L. Jacobs, M.D., John B. Newell, Gerald M. Pohost, M.D., FACC. Massachusetts General Hospital, Boston, Massachusetts.

The disappearance of defects on rest Tl-201 scans may be due to accumulation of Tl by ischemic (I) zones or the release of Tl from normal (N) zones. This study was performed to define the contribution of each in mild-moderate I and severe I. Miniature radiation detectors were implanted in the left ventricle in 8 open-chested dogs allowing continuous monitoring of regional Tl activity. A balloon constrictor was used to create a fixed reduction in coronary blood flow by reducing distal left anterior descending pressure to 30-40mmHg while aortic pressure was maintained at 100mmHg. After 45 min of partial occlusion, 1mCi of Tl was injected I.V. and counts (cts) were recorded continuously for 4 hrs in the I and N zones. Microsphere determined regional blood flow did not change significantly during each study.

In all 8 dogs, Tl cts in the N zone peaked within 10 min then fell mono-exponentially at a mean rate of -7.9±4.1 (SD)%/hr. In 4 dogs with mild to moderate I (I flow=45 to 80% of N), Tl cts in the I zone peaked at a mean of 175±50 min then decreased. In 4 dogs with severe I (I flow <30% of N), Tl cts peaked within 10 min, then decreased. The ratios of Tl cts I/N and % change in Tl cts/hr (mean±SD, *=p<.05) were:

	Minutes ƃ Tl	Mild-Mod I	Severe I
Ratio Tl cts I/N	10	.57±.17 *	.21±.09 *
	240	.85±.20 *	.30±.12 *
% change Tl cts/hr	10-120	8.2±3.6	-5.6±2.2 *
	120+240	-0.9±3.6	-4.9±.07 *

We conclude that rest Tl defects due to mild to moderate I resolve by release of Tl from N zones and accumulation of Tl by I zones, whereas defects due to severe I resolve very slowly solely by washout from the N zones.

THE EFFECT OF TRANSIENT ISCHEMIA WITH REPERFUSION ON THALLIUM CLEARANCE FROM THE MYOCARDIUM

Henry Gewirtz, M.D., Ali Maksad, M.D., Albert S. Most,MD, FACC, Michael J. Sullivan, and Douglas Shearer, PhD. Rhode Island Hospital and Brown University, Providence,RI

Serial imaging with thallium (Tl) is often used to differentiate ischemic from infarcted myocardium. The following study was done to determine if transient ischemia following Tl administration could alter the appearance of the scan by influencing clearance of Tl from the heart. Eight dogs were given ^{103}Ru labeled microspheres (MS) via the left atrium and 4 min later Tl was given IV. Blood draining myocardium in the distribution of the left anterior descending (LAD) coronary artery was obtained from a catheter in the great cardiac vein and Tl activity and potassium concentration measured in it. One hour after Tl was given the LAD was occluded for 10 min and then reperfused for 20 min. ^{46}Sc labeled MS were given 5 min after occlusion. After 20 min of reperfusion the dog was sacrificed and the heart counted for Tl and MS activity. Regional blood flow (% control-mean±SEM) 5 min after occlusion decreased in the LAD zone (33±2,P< .01) but was unchanged in the circumflex zone (111±10, P=ns). During LAD occlusion potassium efflux (mEq/min x 10^{-4}) increased markedly (-71.5±1.04, P<.01 vs control (.34±2.4) from myocardium distal to the occlusion. In contrast Tl efflux (μCi/min x 10^{-2}) was similar to control (-0.7±0.4) both during occlusion (-1.1±0.3, P=ns) and in the 1st min of reperfusion (-0.8±0.5, P=ns). Postmortem Tl activity (LAD:circumflex zone) in the study dogs (1.01±.05) was similar to 5 non-occluded controls (1.04±0.5,P=ns). We conclude: 1) Tl unlike potassium does not leak from ischemic myocardium 2) transient ischemia with reperfusion does not alter the rate of Tl clearance from the myocardium 3) clinically, ischemia occurring after Tl administration may not be associated with a new or enlarged defect on serial scans.

INCREASED SENSITIVITY OF KINETIC VS. STATIC Tl-201 IMAGING IN DETECTING ACUTE ALTERATIONS IN MYOCARDIAL PERFUSION

Michael R. Jones, MD; Robert M. Beihn, MS;John D.Slack,MD; Michael Vannier, MD; Susan R.Yonts,RT; Henry G.Hanley,MD; Katherine A. Fowler, BS; Charles O.Lewis, MS; VA and Univ. of Kentucky Medical Centers, Lexington, Kentucky.

Since redistribution of Thallium-201 may limit the sensitivity of myocardial perfusion scintigraphy in detecting transient myocardial perfusion abnormalities, a new technique to analyze the minute to minute deposition kinetics of Tl-201 was developed. This technique computes separate rate constants (K) for Tl-201 myocardial deposition during each of two minutes following the Tl-201 injection. The K values are derived for each pixel of a 64x64 computer matrix by exponential least squares analysis.

This kinetic method was compared with static imaging in 10 dogs chronically instrumented with circumflex (cx)flow probes and occluders, LV pressure transducers, and ultrasonic segment length crystals. Each animal underwent a control study with atrial pacing (HR=180) and later studies with pacing and graded cx occlusions reducing flow from 10-64%. Tl-201 was injected after flow was stable in each study. K values for myocardial deposition in the cx area were determined for each of the next two minutes. Pacing was stopped and the occlusion released after the first minute. Conventional static images were collected from 0.5 to 30 minutes. Results: K values for Tl-201 accumulation in the cx distribution were reduced during partial occlusion (-15.75*±8.7 to -70.31*±19.34,mean±SEM,P<.05, N=16) in 15/16 studies and increased on release of the occlusion (to 43.13*±13.30,P<.001) in 16/16 studies. Only 1 of 16 studies produced an abnormal static image. Conclusion: Kinetic Tl-201 imaging is more sensitive than the static technique in detecting acute alterations in myocardial perfusion. It may be clinically useful in detecting rapidly reversible perfusion defects.

THE RELATIONSHIP OF CORONARY FLOW TO Tl-201 REDISTRIBUTION

Jeffrey A. Leppo, M.D., Robert D. Okada, M.D., J.L. Guerrero, H. William Strauss, M.D., Gerald M. Pohost, M.D. FACC. Massachusetts General Hospital, Boston, Mass.

Clinically, the appearance of new or enlarging defects on redistribution Tl-201 (Tl) myocardial scans have been attributed to changes in coronary flow subsequent to the initial injection. To determine the impact of a delayed increase in coronary flow on normal Tl redistribution over a 2 hr period studies were performed in 6 open-chested anesthetized dogs. Mean coronary flow was monitored with electromagnetic flow probes on the left anterior descending (LAD) and left circumflex (LCX) arteries and aortic pressure was held constant with a flow reservoir and pump. Sc-46 microspheres were injected into the left atrium and Tl injected intravenously at time zero. Ten min later, 4 dogs received a continuous adenosine infusion into the proximal LCX for 110 min while in 2 other animals no adenosine was given. A second radioactive microsphere (Sn-113) injection was performed and all dogs were sacrificed at 120 min. Both LAD and LCX myocardial regions were each divided into 30 full thickness 1 gram sections for gamma well determination of isotopic activities. The initial and final microsphere determined flows (Q) and Tl content in the LCX and LAD are presented as mean ratios ± S.D.

Group	Initial LCX/LAD Q	Tl LCX/LAD	Final LCX/LAD Q
Adenosine	1.05±.09	0.99±0.10	2.08±0.78
Control	0.99±0.06	0.97±0.01	0.99±0.04

Despite a nearly two fold increase in flow to the LCX region by 110 minutes (p<.02), Tl content was identical in the LCX and the normal flow zone (LAD region). The control studies demonstrate a stable relationship between LCX and LAD regional blood flow and Tl content over a 2 hr study period. These data suggest that Tl redistribution during the first 2 hrs after its initial injection is independent of subsequent changes in blood flow.

QUANTITATION OF TL-201 MYOCARDIAL DISTRIBUTION AND WASHOUT: NORMAL STANDARDS FOR GRADED EXERCISE STUDIES

Denny D. Watson, Ph.D; Norman P. Campbell, MD; Bruce C. Berger, MD; George A. Beller, MD, FACC, University of VA, Charlottesville, VA.

A computer technique has been used to determine the relative initial uptake and washout rates of thallium-201 (^{201}Tl) in patients undergoing stress perfusion imaging. Images were taken consecutively for 10 min in the anterior and 45° LAO projection starting at 10 min, 1 hr, and 2 hrs after injection. A modified bilinear interpolative method was used to estimate background and determine net residual myocardial counts. Peak residual counts in selected myocardial regions from the initial images were used to determine the initial relative distribution of ^{201}Tl. Time activity curves were constructed from the sequential images and linear regression analysis allowed determination of the myocardial ^{201}Tl washout rate. In 25 patients, including 16 with normal coronary angiograms and ventriculograms and 9 asymptomatic and clinically normal subjects, the mean ratios (±SD) of activity between various regions of myocardium were: Inferior(I)/Anterolateral(AL)=0.86 ± 0.12; Anteroseptal(AS)/Posterolateral(PL)=1.00 ± 0.15; Inferoapical(IA)/AS or PL=0.89 ± 0.12; Right Ventricle/AS or PL=0.30 ± 0.13. The mean washout T½ (hrs) from these regions was: I=3.98 ± 1.3; AL=3.85 ± 1.3; AS=4.17 ± 1.3; PL=4.07 ± 1.6; IA=4.17 ± 2.2. Numerical standards based upon these normal values and ranges were applied to studies of 140 patients of which 110 had angiographic evidence of coronary artery disease and yielded a sensitivity and specificity of 91% and 90% respectively. Thus, this method provides a simple and reproducible method of quantitation and useful reference standards for the objective evaluation of ^{201}Tl images.

COMPUTER ANALYSIS OF THALLIUM-201 MYOCARDIAL PERFUSION SCINTIGRAPHY: CIRCUMFERENTIAL MAPPING

Gregory S. Uhl, MD and Thomas D. Kay, BS, USAF School of Aerospace Medicine, Brooks Air Force Base, TX.

Thallium-201 (Tl) scintigraphy enjoys widespread use to evaluate regional myocardial perfusion. The interpretation of Tl images remains subjective and qualitative despite the availability of computers for data acquisition and processing. A new computer technique for analysis of Tl scans uses a circumferential map of the Tl image for objective comparison of stress and reperfusion scans. Complete cardiac cycle gated Tl images were obtained in 4 standard views on 102 patients. The computer algorithm automatically performs background subtraction (never >25%), filtering, enhancement and normalization and displays beating heart images in differential color graphics that show areas of maximum to minimum Tl perfusion. The operator selects discrete areas of the cardiac cycle and myocardium to be mapped. Hard copy graphics and digital data display circumferential profiles at 5 degree radials comparing wall thickness, total Tl uptake, Tl uptake per unit area, and % reperfusion or washout for both Tl images. Normal limits ± 2 SD were determined from 77 cath proven normal patients (age 42 ± 6) by averaging the maps with images aligned at the apex. Maps from 17 men with coronary artery disease without myocardial infarction (MI) and 8 patients with previous MI were compared to the normals and all found to differ significantly from the normal limits. The defects were scored quantitatively and agreed with subjective visual interpretations though the maps eliminated interobserver differences. In conclusion, this method of computer assisted analysis allows the comparison of stress and reperfusion Tl images to a normal circumferential map and is applicable to any projection and either right or left heart myocardium.

^{201}TL IMAGING IN PATIENTS WITH MYOCARDIAL INFARCTION: A COMPARISON OF PLANAR AND SEVEN-PINHOLE TOMOGRAPHIC IMAGES.

James L. Ritchie, MD, FACC; James H. Caldwell, MD; David L. Williams, PhD; Glen W. Hamilton, MD; Seattle Veterans Administration Hospital, Seattle, Wa.

Thirty-six stable patients (pts.) with proven remote myocardial infarction (MI) and 14 pts. without MI had imaging at rest with ^{201}Tl. Each pt. had 7-pinhole (7P) tomographic imaging with a large field of view gamma camera and then 4-view, standard planar imaging followed by a repeat 7P tomogram. This study aimed to: 1) compare sensitivity and specificity of the 2 techniques in detecting MI (in an idealized setting with no redistribution); 2) compare inter-observer variability in interpretation; and 3) determine whether the tomographic technique was reproducible. Studies were interpreted by 3 blinded observers using both Polaroid and computer displayed images.

Sensitivity for the 7P studies was 86.1% (31/36) and 69.4% (25/36)(P=.10) for planar images. Specificity for 7P was 71.4% (10/14) vs. 100% (14/14)(P=.2) for planar images. There was 10% inter-observer disagreement in planar image interpretation (i.e. not all 3 observers agreed as to normal or abnormal) vs. 28% disagreement (P=0.02) in 7P studies. In 46/48 pts. (96%) the repeat 7P image in the same pt. was identical. In 2 pts. the two were different, i.e. one normal and the second abnormal (in 2 pts. a second 7P was not done). Minor differences in pt. positioning may have contributed.

We conclude that: 1) sensitivity and specificity for 7P tomography and planar imaging do not differ significantly; 2) inter-observer agreement was less for 7P studies; and 3) 7P studies were occasionally not reproducible, even under ideal circumstances.

PROBLEMS WITH THE DEFINITION OF A NORMAL TOMOGRAPHIC THALLIUM-201 PERFUSION SCINTIGRAM

Steve Collins, Ph.D; James C. Ehrhardt, Ph.D; Raymundo T. Go, MD; Dan Francisco, MD; Melvin L. Marcus, MD, FACC, University of Iowa, Iowa City, Ia.

Quantitative interpretation of tomographic thallium-201 (Tl^{201}) perfusion scintigrams requires a precise definition of normal. Previous approaches have used normal curves (mean-2 standard deviations (SD)) obtained from patients (pts) with coronary obstructions <55%. Use of this simple statistical approach and the inclusion of pts with moderate coronary artery disease (CAD) is suspect. We studied 28 pts without significant CAD - <55% obstruction by arteriography. 17 pts had minor (<30%) or no lesions while 11 had moderate CAD (8 with 30-55% single vessel obstruction, 3 with systolic compression). Maximal coronary vasodilation was induced with dipyridamole (0.15 mg/kg/min i.v. x 4 min) prior to Tl^{201} injection. Seven pinhole scintigrams were obtained and analyzed using an approach similar to the CIRCLE program. Normal curves (mean-2SD) were derived from 27 of the tomograms (1 obvious false positive excluded). 13 of 28 pts (46%) had positive tomograms (exceeded mean-2SD at one or more points (x̄±1SD=16±14 points)). We also compared the tomograms from the 11 moderate CAD pts to the range observed in 16 pts with minor or no lesions (same false positive excluded). Using this modified criterion, 5 of 11 pts with moderate CAD had perfusion defects - exceeded the range at one or more points (x̄=36±25 points). Moreover, the location of these defects was concordant (5 of 5) with the anatomic distribution of the lesions. We conclude that, in defining normal, a simple statistical approach (mean-2SD) results in a high false positive rate because of the non-Gaussian data distribution and that pts with moderate CAD should probably be excluded because about 45% have detectable perfusion abnormalities.

THALLIUM-201 STRESS MYOCARDIAL SCINTIGRAPHY: COMPARISON OF MULTIPLE PINHOLE TOMOGRAPHY WITH PLANAR IMAGING IN THE ASSESSMENT OF PATIENTS UNDERGOING CORONARY ARTERIOGRAPHY

Daniel Berman, MD, FACC, Howard Staniloff, MD, Michael Freeman, MD, Ernest Garcia, PhD, Nancy Pantaleo, RN, Jamshid Maddahi, MD, Alan Waxman, MD, James Forrester, MD, FACC, H.J.C. Swan, MD, FACC. Cedars-Sinai Medical Center, Los Angeles, Calif.

To investigate the diagnostic potential of multiple pinhole tomography (TOMO) for Tl-201 stress myocardial scintigraphy, TOMO and standard planar imaging (PLANAR) were performed on 33 pts undergoing coronary arteriography. 23 pts had significant coronary artery disease (CAD) (>50% stenosis) and 10 had normal coronary arteriograms. Of the 23 CAD pts, 13 had disease in the anterior (ANT) and posterior (POST) coronary circulations, and 10 had either ANT or POST CAD. Following single injection of Tl-201 at peak exercise, all pts had PLANAR and TOMO studies, with random variation of study sequence. PLANAR was performed with ½" crystal mobile camera, and TOMO with large field camera and 7 pinhole collimator. Images were inspected independently by 2 experienced observers, with disagreements solved by consensus. Satisfactory images were obtained by both techniques in all 33 pts. TOMO was positive in 21/23 CAD pts, and PLANAR positive in 20/23. TOMO and PLANAR were negative in 9/10 pts with no CAD. Regarding extent of CAD, TOMO correctly identified 9/13 pts with both ANT and POST CAD, and incorrectly predicted ANT and POST in only 2/10 with single region CAD. PLANAR correctly identified 6/13 pts with both ANT and POST CAD, and incorrectly predicted 2 region CAD in only 1/10 with CAD in a single region. These preliminary results suggest that TOMO and PLANAR Tl-201 techniques have similar accuracy in the detection of CAD, and that TOMO may be slightly more accurate in the assessment of extent of CAD.

COMPARISON OF PLANAR AND TOMOGRAPHIC THALLIUM-201 SCINTIGRAMS FOLLOWING CORONARY VASODILATATION WITH DIPYRIDAMOLE

Dan Francisco, MD; Raymundo Go, MD; Steve Collins, Ph.D; James Ehrhardt, Ph.D; Melvin Marcus, MD, FACC, University of Iowa, Iowa City, Ia.

The sensitivity and specificity of quantitative myocardial tomographic perfusion imaging was compared to planar thallium-201 (Tl^{201}) images in 43 patients (pts) with coronary artery disease (CAD) defined as 70% obstruction or > in one or more vessels by arteriography (26-3VSD, 9-2VSD and 6-1VSD) and 17 pts with insignificant CAD (<30% obstruction in any vessel). Pts with coronary obstructions between 30-70% or systolic compression were excluded because they probably represented a "gray zone". Coronary dilation was induced by dipyridamole (0.15 mg/kg/min i.v. x 4 min) which was well tolerated by all pts. The tomograms (7 pinhole collimator) were analyzed with an approach similar to the CIRCLE program. The tomograms of CAD pts were considered abnormal if they exceeded the normal range based on 16 normal pts (one obvious false positive excluded) at one or more points. Results:

	Tomographic Tl^{201}		Planar Tl^{201}	
Sensitivity	39/43	91%	35/43	81%
Specificify	16/17	94%	11/17	65%

Of the 18 pts with normal resting ventriculograms, the planar and tomographic images were positive in 61% and 78% respectively. In CAD pts with abnormal ventricles, the planar and tomographic images were positive in 96% and 100%, respectively. In the 5 pts with CAD who also had left main obstruction, 5 of 5 tomograms were positive whereas 4 of 5 planar images were positive. Conclusion: Tomographic Tl^{201} perfusion scintigrams following coronary vasodilatation with dipyridamole are apparently more sensitive and specific in the detection of CAD than planar images, particularly in pts with normal ventricular function at rest.

THALLIUM-201 SCINTIGRAPHIC EVIDENCE OF ISCHEMIA IN PATIENTS WITH MYOCARDIAL BRIDGES

Masood Ahmad, MD; Steven L. Merry, MD; Helmut Haibach, MD, Veterans Administration and University Hospitals, Columbia, Mo.

The role of myocardial bridges in producing ischemia is not clear. We studied 7 male patients (age range 45-63 years) with chest pain syndromes and cineangiographically documented systolic coronary artery narrowing due to myocardial bridges. All patients had >50% systolic coronary artery narrowing in the proximal left anterior descending vessel. None of the patients had evidence of significant atherosclerotic coronary disease, resting left ventricular wall motion abnormality, and/or mitral valve prolapse. Myocardial perfusion was evaluated at rest and during exercise by performing Thallium-201 myocardial scintigraphy. None of the patients had electrocardiographic evidence of ischemia during or after exercise. Three patients with ≤75% systolic coronary artery narrowing had a normal resting and exercise Thallium-201 scintigram. In 3 of 4 patients with >75% systolic coronary artery narrowing, exercise induced perfusion deficits were observed in the distribution of the vessel. One of these 3 patients also developed chest pain on exercise. We conclude that a >75% systolic coronary artery narrowing may impair myocardial perfusion during exercise. In comparison to exercise electrocardiography, Thallium-201 myocardial imaging appears to be more sensitive in detecting an abnormal response in these patients.

DETECTION OF MULTIVESSEL DISEASE BY EXERCISE THALLIUM-201 SCINTIGRAPHY.

George A. Beller, MD, FACC; Denny D. Watson, PhD; Bruce C. Berger, MD; Randolph P. Martin, MD; George J. Taylor, MD.; University of Virginia, Charlottesville, Va.

The goal of this study was to determine the accuracy of quantitative ^{201}TL exercise scintigraphy for predicting multivessel disease (VD) in 91 consecutive patients (pts) referred for angiography. All pts received 1.5 mCi of ^{201}TL at peak exercise. Images were obtained serially over 2½ hrs. Abnormal regional ^{201}TL uptake was ascertained by quantitative criteria applied to multiple scan segments (segs) corresponding to the vascular supply of the 3 major coronary arteries. Abnormal myocardial segs were defined as 1) ≥ 25% persistent reduction in ^{201}TL uptake; 2) An initial defect with redistribution and 3) Abnormal ^{201}TL washout. A coronary stenosis of ≥ 50% was considered significant. Of 20 pts with angiographically normal coronary arteries, 2 were predicted to have 1VD (false positives). Of 18 pts with 1VD, 12 had abnormalities appropriate to the single diseased vessel and 5 were predicted to have 2VD. All five 2VD readings were in the distribution of circumflex (Cx) and right coronary artery (RCA) segs, when only one of these vessels was diseased. The remaining pt had a normal scan. Of 20 pts with 2VD, 12 had abnormal segs confined to the 2 diseased vessels. 5 had anbormal segs confined to 1 vessel, and one had a normal scan. Of 25 pts with 3VD, 10 had abnormal scan segs in the distribution of all 3 vessels, 12 had abnormal segs appropriate to 2 diseased vessels and 1 had a single abnormal vascular seg. Two pts with 3VD had normal scans. Thus, in 45 pts with 2 or 3VD, 36 demonstrated abnormal ^{201}TL uptake and/or washout in at least 2 vascular segs, yielding an 80% sensitivity for 2 or 3VD prediction. The lower specificity of 67% appears related to the inability to separate Cx and RCA vascular segs.

REVERSIBILITY OF ADRIAMYCIN INDUCED REDUCTION IN MYOCARDIAL THALLIUM-201 UPTAKE BY INTRAVENOUS DIGOXIN

David Forst, MD; Sherman Sorensen, MD; Robert O'Rourke, MD, FACC; Tuhin Chaudhuri, MD, University of Texas Health Science Center and Veterans Administration Hospital, San Antonio, Texas.

The anthracycline antibiotic Adriamycin (AD) is a highly effective antineoplastic agent which may produce acute and chronic cardiac toxicity. Observations that AD is a glycoside with cardiac effects that simulate and may be altered by Digoxin (D) suggest a mechanism of action involving the Na-K pump. To test this hypothesis, we quantitated myocardial uptake of the potassium analog, Thallium-201 (TL), by whole heart imaging and sectioned heart well-counting (r=.95). New Zealand rabbits were given IV TL (.12mCi/kg) without AD (control) and 5 min (AD-5), 24 hrs (AD-24) and 48 hrs (AD-48) after IV AD (3mg/kg). TL uptake was quantitated as counts/sec/mCi/gm heart tissue. Mean (±SEM) normalized counts were:

	N	Counts	P
Control	9	120±4	
AD5	9	91±3	.001
AD24	5	77±5	.001
AD48	5	112±9	NS

Another group of rabbits received IV digoxin (D-24) or IV digoxin (0.29 mg/kg) followed 1 hour later by IV AD (D-24AD) with TL uptake measured 24 hours later. Mean (±SEM) normalized counts and digoxin levels were:

	N	Counts	P	Serum Digoxin (ng/ml)			
				1 hr PD		24 hr PD	
Control	9	120±4					
D24AD	5	123±10	NS	2.7±.15	NS	1.0±.08	NS
D24	4	129±7	NS	2.8±.20		0.9±.09	

Thus, 1) Adriamycin causes an acute reversible depression in myocardial TL uptake that is prevented by pretreatment with digoxin. 2) Adriamycin may affect the myocardial Na-K pump.

MYOCARDIAL INFARCTION: CLINICAL STUDIES
8:30-10:00

SERIAL EVALUATION FOR LEFT VENTRICULAR THROMBUS DURING ACUTE TRANSMURAL MYOCARDIAL INFARCTION USING TWO-DIMENSIONAL ECHOCARDIOGRAPHY (2DE)

Richard W. Asinger, MD; Frank L. Mikell, MD; Gary Francis, MD, FACC; K. Joseph Elsperger, CCPT; Morrison Hodges, MD, FACC; Bim Sharma, MD. Hennepin County Medical Center and the University of Minnesota, Minneapolis, Minnesota.

We prospectively performed 2DE on 16 consecutive patients with acute transmural myocardial infarction (AMI). Serial 2DEs were performed on all but 4 (2-inadequate imaging and 2-withdrawal from study). The remaining 12 had serial 2DE exams (3 - 16; mean = 8) during their acute hospitalization (11-37 days). None had had a previous myocardial infarction and all survived hospitalization.

Four of the 12 pts had inferior myocardial infarction; none had apical wall abnormalities or evidence for left ventricular thrombus (LVT). In contrast, all 8 pts with anterior AMI had apical wall abnormalities (5 dyskinesis, 2 akinesis, and 1 hypokinesis). Three of these 8 developed left ventricular masses typical for LVT during hospitalization. LVT were first noted on the 6th, 7th, and 10th days post AMI. None of these patients had clinical evidence for embolic phenomena prior to detection by 2DE or during hospitalization. All pts with LVT were on prophylactic low dose subcutaneous heparin during the initial portions of their hospitalization (3 to 8 days). All three pts with evidence for LVT had dyskinetic apical segments early in the course of AMI which persisted during hospitalization.

We conclude: 1) LVT develop early in the course of AMI and can be detected with 2DE prior to embolic phenomena. 2)Initial prophylactic low dose subcutaneous heparin during AMI may not be effective in prevention of subsequent LVT. 3) LVT appear to occur in the setting of apical wall abnormalities, specifically dyskinesis, as detected by 2DE. Thus, identification of high risk pts for LVT formation and potential embolization appears feasible. This possibility deserves further study since more aggressive anticoagulation may prevent LVT and embolic complications in selected pts with AMI.

RELIEF OF CHEST PAIN AND REDUCTION OF Q-WAVE EVOLUTION IN ACUTE MYOCARDIAL INFARCTION BY LARGE DOSE SUBLINGUAL NITROGLYCERIN

Young I. Kim, MD, FACC; John F. Williams, Jr., MD, FACC, University of Texas Medical Branch, Galveston, Texas

Prolonged chest pain in the early hours of acute myocardial infarction (AMI) may be an indicator of ongoing injury. Of 28 patients with severe chest pain and ST elevation due to AMI, 13 received sublingual nitroglycerin (NTG) and 15 i.v. morphine (MS). In NTG group, increasing doses of NTG were given at 3-15 minute (min) intervals until pain was relieved while maintaining systolic blood pressure above 100 mm Hg. The severity of pain was scored from 4+ at admission to 0 for complete relief. NTG produced partial relief in 17 ± 5 min and complete relief of pain in 127 ± 65 min. To achieve the latter, 23.7 ± 10.6 mg of NTG was required. MS produced complete relief in 134 ± 79 min (NTG vs MS, p = NS) requiring 15 ± 7 mg. From 86 sites of initial ST elevation on the standard ECG's, Q-waves developed in 62 (72%) and 66 (77%) at 24 and 48 hours respectively in those receiving MS. In contrast, Q-waves developed in 21 (28%) and 22 (29%) respectively of 76 sites of ST elevation in those receiving NTG (MS vs NTG, $p < 0.001$). Location of AMI and number of initial ST elevation sites per patient were comparable in the 2 groups. There was no in-hospital mortality. Thus, large and frequent doses of NTG can be safely employed to treat chest pain and limit ECG Q-wave evolution in the hyperacute phase of AMI.

CORONARY OBSTRUCTION IN ANTERIOR MYOCARDIAL INFARCTION: THROMBUS OR SPASM?

Herman K. Gold, MD, FACC; Robert C. Leinbach, MD, FACC, Massachusetts General Hospital, Boston, MA

Therapy for acute injury during anterior myocardial infarction(AMI)is most effective when the left anterior descending coronary artery(LAD)is not completely occluded. We have therefore undertaken acute coronary angiography (angio)during early treatment in an attempt to identify the degree of occlusion and to determine its reversibility. There were 20 patients(pts)who underwent angio 4.4±.5 (SE)hours after onset of AMI. Prior to angio all received intravenous nitroglycerin(NTG)with monitoring of arterial pressure, heart rate, and the precordial ECG lead showing maximal ST segment elevation(STE). The administration of NTG produced a slight reduction in STE from .62±.07 to .48±.06 mV(23%, p<.01). Arterial pressure fell from 143± 5/85±3 to 129±4/82±2 mmHg with no change in heart rate. Angio showed complete LAD occlusion in 11 pts(55%). The mechanism of occlusion was shown to be thrombus in 8/11. Thrombus was defined as a persistent intracoronary convex filling defect. Thrombus was also seen in 3/9 pts with incomplete LAD occlusion. Intracoronary NTG(200 µgm)was administered to 14 pts, 7 with complete and 7 with incomplete LAD occlusion. No case showed a change in stenosis or a release of occlusion. Successful wire guide penetration of complete LAD occlusion was performed in 5 cases with partial restoration of flow. In conclusion: 1)pts with AMI seldom show marked resolution of STE with NTG suggesting no major change in coronary obstruction or release of coronary spasm; 2)intracoronary NTG does not appear to augment the effect of systemic NTG or to restore LAD flow; 3)a majority of cases studied within 4 hours show angiographically definable coronary thrombus; and 4)restoration of LAD flow in these cases may require catheter or surgical intervention.

CONTRACTION OF THE ACUTELY INJURED LEFT VENTRICULAR ZONE AFTER ACUTE MYOCARDIAL INFARCTION IN MAN: COMPARATIVE EFFECTS OF NITROGLYCERIN AND NITROPRUSSIDE AS A FUNCTION OF TIME

Kodangudi B. Ramanathan, MD; Monty M. Bodenheimer, MD, FACC; Vidya S. Banka, MD, FACC; Richard H. Helfant, MD, FACC, Presbyterian-Univ. of PA Med Ctr, Philadelphia, PA.

The relative effects of nitroglycerin (TNG) and nitroprusside (NPS) on coronary flow and contraction of an acute infarct area have not been systematically studied in man. Accordingly, in 18 patients with an acute transmural (new Q waves) myocardial infarct, response of the injured zone to either TNG or NPS was evaluated. Serial first pass radionuclide angiograms were performed using technetium in the right anterior oblique projection (hemiaxial quantitative method) in each patient within 24 hours, 5-7 days and 4-6 weeks (wks) after onset of chest pain. Blood pressure was similar after both drugs. TNG (sublingual 0.4-0.8 mg) improved ischemic zone hemiaxis shortening from 11±2% to 25±6% ($p < 0.05$); NPS (20-200 µg/min IV) improved the ischemic zone similarly from 14± 4% to 29±7% ($p < 0.005$) in the 24 hour study. In the 5-7 day study, TNG improved ischemic zone from 10±4% to 19± 5% ($p < 0.05$) and NPS similarly from 15±3 to 29±4% ($p < 0.001$). After 4-6 wks, however, both TNG and NPS had no significant effect on dysfunction of these areas. Hemiaxis shortening was 12±4% before and 10±4% after TNG and and 15±4% before and 16±5% after NPS. Improvement in non-ischemic zone hemiaxis shortening was similar after both NPS and TNG. Similar changes were also seen in ejection fraction, end-diastolic volume and cardiac output after both agents (in all 3 time periods following infarct). In summary, TNG and NPS improve ischemic zone contraction similarly early after acute myocardial infarction. Four to 6 wks after acute infarction, the ischemic zone is unresponsive to either agent.

PRESERVATION OF ISCHEMIC MYOCARDIUM WITH GLUCOSE-INSULIN-POTASSIUM IN PATIENTS WITH ISOLATED LEFT ANTERIOR DESCENDING STENOSIS

John A. Mantle, MD, FACC; William J. Rogers, MD, FACC; Russell C. Reeves, MD; Richard O. Russell, Jr., MD, FACC; Peter R. Bream, MD and Charles E. Rackley, MD, FACC, University of Alabama Medical Center, Birmingham, Alabama.

The effects of glucose-insulin-potassium (GIK) on the extent of myocardial infarction (MI) were examined in 30 consecutive patients with isolated left anterior descending (LAD) stenosis (90-100%) who presented within 12 hrs of the onset of their first MI. The GIK solution (300 gm glucose, 50 units insulin and 80 meq KCl per liter) was infused at 1.5 ml/kg/hr for the initial 48 hrs in 10 patients. Coronary angiography and quantitative biplane left ventriculography were performed an average of 3 weeks post MI. The extent of the MI was determined by calculating the ejection fraction (EF) and percent abnormal contracting segment (%ACS). Control patients with proximal LAD stenosis before the first septal perforator (10 pts) EF=.33±.03 and %ACS=32±9; with mid stenosis (7 pts) EF=.47±.02 and %ACS=19±2; and with distal stenosis (2 pts) EF=.62±.03 and %ACS=10±2 ($p<.05$). Five of the 9 GIK pts with proximal or mid LAD stenosis had an EF>.55 or an %ACS<10% vs none of the control pts ($p<.05$). Collateral filling of the LAD did not account for this significant reduction in the expected MI size. Summary: These data from pts with an isolated LAD stenosis indicate that: 1) the extent of MI is directly related to the location of the stenosis; 2) this subgroup provides a useful clinical model to evaluate interventions to preserve ischemic myocardium and 3) an acute metabolic intervention with GIK can significantly reduce the extent of MI scar and preserve left ventricular function.

PROTECTION OF ISCHEMIC MYOCARDIUM WITH INTRAVENOUS PINDOLOL IN ACUTE MYOCARDIAL INFARCTION

Juhani Heikkilä, MD; Markku S. Nieminen, MD, Cardiovascular Laboratory, University of Helsinki, Helsinki, Finland.

The mechanical performance of the ischemic and noninfarcted myocardial segments was recorded in patients with acute myocardial infarction by multidirectional echocardiographic method. It identified the abnormally contracting left ventricular segments quantitatively with excellent reliability in left ventricular cineangiographic and pathologic anatomic comparisons (r=0.88).
In 22 patients the effect of 0.2 mg pindolol intravenously was studied an average of 15 hours from the onset of symptoms. The small intravenous dose of pindolol was hemodynamically safe in patients with uncomplicated acute infarction or even in those with moderate heart failure. Left ventricular filling pressure and stroke volume by Swan-Ganz thermodilution did not change, nor did any ventricular dilatation take place.
The ST segments improved by 30% ($p<0.0005$) in 15 minutes. The systolic wall motion amplitudes of the ischemic myocardial segments improved by 26% of the normal ($p<0.0005$). The performance of the uninvolved segments was not depressed. Consequently, the total left ventricular performance was markedly improved by pindolol (18%, $p<0.0005$). The mechanism was probably reduction of the rate pressure product(-14%, $p<0.005$). Chest pain was relieved. Methylprednisone (2.0g) failed to reduce the signs of ongoing ischemia in 10 other patients, in contrast to subsequent beta blockade.
Our technique gave direct documentation of the reversible regional abnormalities of the left ventricular dynamics in ischemia. Beta blockade by pindolol considerably relieved the clinical, electrocardiographic and myocardial mechanical signs of ischemia in patients with acute myocardial infarction.

MYOCARDIAL INFARCTION: INFARCT SIZE
10:30-12:15

DELETERIOUS INFLUENCE OF HYPOMETABOLISM ON EVOLVING MYOCARDIAL INFARCTION IN CONSCIOUS DOGS

Ronald P. Karlsberg, MD, FACC; Wilbert S. Aronow, MD, FACC, University of California, Irvine, and Veterans Administration Medical Center, Long Beach

Hypometabolism may benefit ischemic myocardium by reducing myocardial oxygen demand. However, severe hypometabolism, such as occurs with hypothyroidism, may be deleterious both by impairing metabolic pathways and causing unfavorable hemodynamic changes. To evaluate the influence of severe hypometabolism on evolving infarction, 10 dogs were injected with 20 mCi of ^{131}I, which after 45 days, reduced ^{125}I-T4 68% (control 0.024±.01 µg/ml), $p<.001$. These dogs and 20 euthyroid controls were instrumented with left anterior descending coronary artery snares, left ventricular pressure microtransducers, aortic electromagnetic flowmeters, and arterial catheters. After recovery from surgery, coronary artery occlusion was produced in the conscious state, and 24 hours later, infarct size was determined by myocardial creatine kinase (CK) depletion. Hemodynamics prior to occlusion were (mean±SEM):

	CONTROLS	HYPOTHYROID	%CHANGE
Cardiac output (L/min)	2.1±.06	1.4±.07*	-33
Blood pressure (mmHg)	98±4	81±2*	-17
dp/dt (mmHg/sec)	1930±80	2060±45	+7
LVEDP (mmHg)	5±1	5±2	0
Heart rate (beats/min)	119±9	110±3	-8

(*=$p<.001$). Hemodynamic deterioration after coronary occlusion was the same in both groups. CK in non-infarcted myocardium was similar, but infarct size was 36% larger in hypothyroid dogs (30±2%) than in controls (22±3%), $p<.05$. Thus, despite the potential benefit resulting from minor reduction in afterload and cardiac output, severe hypometabolism, induced by hypothyroidism, is not beneficial to evolving infarction and is associated with infarct extension.

INFARCT SIZE MANIPULATION BY ALTERATION OF HEMATOCRIT

Manfred Hofmann, MD, Mechthild Hofmann, Wolfgang Schaper, MD, PhD, Kerckhoff-Institut, Bad Nauheim, West Germany

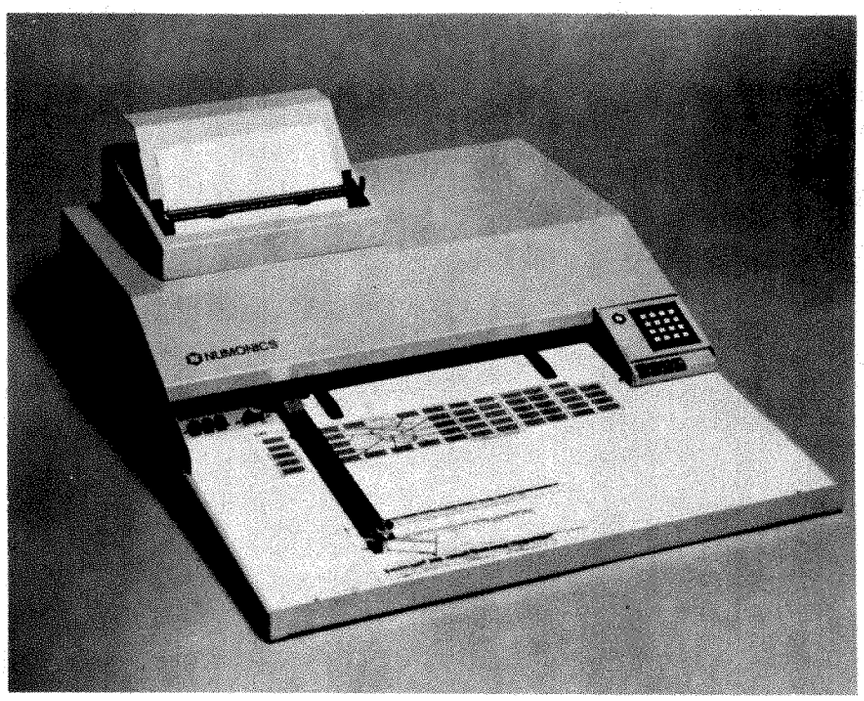
The aim of the study was to prove whether variations of hematocrit (HC) would lead to altered collateral blood flow (CBF) with consecutive altered infarct size (IS) after experimental coronary artery occlusion.
In each of 10 mongrel dogs a medium sized marginal branch and an equal sized diagonal branch were prepared. LVP, dP/dt, AoP, and HR were recorded continuously. In 3-min intervals $M\dot{V}O_2$ of the heart was calculated according to Bretschneider's equation. HC, Hb, and blood gases were evaluated every 15 min. Coronary and CBF were determined with tracer microspheres. One coronary artery was ligated over 90 min (control artery). Thirty min after reflow 1000 ml blood were slowly withdrawn. The erythrocytes were reinfused in 6 dogs, while 4 got the plasma together with 500 ml of an organic buffer followed by the occlusion of the 2nd artery (test artery) over 90 min. After 90 min of reperfusion of the 2nd artery the hearts were removed. The perfusion area of each occluded artery together with a normally perfused rim was cut into 6 slices and incubated in p-NBT. IS was expressed as ratio of necrosis (non-stained area) to perfusion area of the occluded artery (obtained from a p.m. angiogram).

	HC		IS		normal flow endocardial layer (ml/min.100g)		CBF endocardial layer (ml/min.100g)	
Control	41	x	.26	o	63	x	5.6	x
Dilution	25	x	.15	+	127	ns	22.0	x
Concentration	59		.32	ns	58		3.7	

o: $p<0.05$; +: $p<0.01$; x: $p<0.001$

Thus, hemodilution leads to improved flow conditions resulting in smaller IS, and vice versa.

The Numonics 1239 Cardiological Image Analyzer:



The heart of your graphics analysis process.

Numonics offers a computer-based graphics analyzer designed specifically for cardiology to augment qualitative analyses with hard numbers. Economic, convenient, consistant and accurate, the Numonics 1239 is completely self-contained, field upgradable and programmed for four standard cursor keyboards that quantify M-mode Echocardiography, Systolic Time Intervals, Ventricular Volumes from cineangiography or real-time ultrasongraphy, and Cath Lab Pressure Data including valve gradient, flow and resistance calculations. Then prints them all in chart-ready format, along with patient data and space for qualitative remarks. If your're interested in seeing just how much work the 1239 can take off your hands, write for further information.

NUMONICS

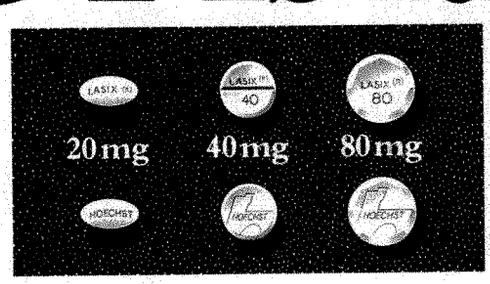
Just what the doctor ordered.

Or is it?



We're asking every physician who prescribes Lasix® (furosemide) tablets to show patients how to identify them. If it doesn't say Hoechst it isn't Lasix. Make sure your patient checks for the name "Hoechst" on the tablet.

For over 12 years, Lasix® tablets, manufactured in the U.S. exclusively by Hoechst-Roussel Pharmaceuticals Inc., have been prescribed for millions of patients. It is today one of the most widely prescribed drugs in the world and, clearly, one of the most respected. In fact, it can be characterized as the *diuretic most likely to succeed in all degrees of cardiac edema.*

Furosemide is a unique agent, potent in an unusually wide range of dosage strengths. *But it is also inherently insoluble.* And that's why the manufacture and quality control of this agent are but two of several critical factors in its effectiveness. For it has been shown that drug solubility can alter absorption and thus can seriously affect bioavailability.

And it was apparently this type of problem that prompted the FDA to alert patients that certain unlawfully marketed substitute versions of furosemide "may be ineffective and therefore harmful to patients who need the drug."[1]

Lasix® tablets, on the other hand, have a record of safety and efficacy that is exemplary — a record firmly established in almost 6,000 published papers. Since its introduction, 7.8 billion Lasix® tablets have been manufactured — without a product recall by the Government for any reason. Moreover, stability studies demonstrate that Lasix® tablets remain unimpaired in potency over a five-year period.†

All this is made possible by the thoroughness, experience, integrity and worldwide resources of the Lasix® innovator, Hoechst, the name behind the great clinical success of the product.

So to be sure of consistent performance, tablet after tablet, specify Lasix® and tell patients to double-check that the furosemide they recei is dispensed as Lasix®...available in a wide selection of dosage forms and strengths, including the only oral solution form of the drug.

Lasix®— one less variable in the treatment of cardiac edema.

(furosemide)

Because there's no substitute for quality

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide). Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Because animal reproductive studies have shown that furosemide may cause fetal abnormalities, the drug is contraindicated in women of childbearing potential. Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use.

It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

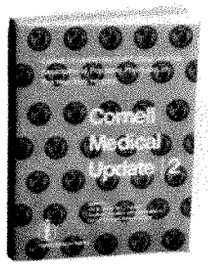
Now in book form...the latest Update Your Medicine lectures.

CORNELL MEDICAL UPDATE/2



Edited by LILA A. WALLIS, MD, FACP

Helps you keep up with the new advances in your specialty in the comfort of your home or office.

Just published with all new material—specialties expanded.

The series CORNELL MEDICAL UPDATE breaks all medical book tradition with its workbook format that gives practicing physicians a quick overview of the latest advances in their speciality. It transcribes into book form the Update Your Medicine lectures sponsored by New York Hospital-Cornell Medical. These lectures are well-known for helping physicians prepare for Recertification despite the demands of a heavy practice.

The new approach of the first volume was so well-received that it went through three printings in less than two years. Now the just published CORNELL MEDICAL UPDATE/2 takes up where the first volume left off. It has been specially designed for the practicing physician who has difficulty keeping up with the growing literature of the field. Each chapter transcribes one of the lectures and covers a specific speciality in-depth from basic physiologic and chemical principles to its clinical applications.

Lila A. Wallis, MD, FACP, the series editor, has eliminated all the filler material a *continuing* education does not need. You won't find historical reviews or a rehash of material you've known since medical school. You will find the practical, life-saving knowledge a dynamic practice depends on. Because the lectures have been edited for easy reading and laid out for quick comprehension, you'll be able to incorporate all the material into your own professional technique.

Earn 25 Credits Towards AMA Physician's Recognition Award. CORNELL MEDICAL UPDATE/2 has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit are included with every copy.

Yorke Medical Books, 666 5th Ave., P.O. Box 876, N.Y., N.Y. 10019

Please send me a copy of CORNELL MEDICAL UPDATE/2 at $38.00. I may use the book for 30 days and if not completely satisfied, return it for full credit or refund.

cardiocare

Medtronic... leading the way to man's heart.

Medtronic...a name synonymous with technological advancement in heart care through the years. A name that means superb craftsmanship and superior reliability in applied biomedical engineering today. A name that stands for commitment to excellence in cardiac screening, diagnosis, treatment and rehabilitation.

Medtronic helps you help the heart patient with a broad spectrum of outstanding products and services. Medical Data Systems, a division of Medtronic, specializes in software programs for nuclear cardiology. Cardiocare, another division, provides monitoring and arrhythmia detection services. Kastec Corporation produces prosthetic heart valves.

With the broadest selection of pacing leads, an entire family of accessories, and now, the introduction of the remarkable new Spectrax pacers and programmers, Medtronic continues leading the way to man's heart.

Medtronic®

beta-one receptors is all that counts in lowering blood pressure...
block beta-two receptors to the same extent?"
metoprolol tartrate
blocks beta-one receptors with relative selectivity.
Other available beta blockers do not.
For brief summary of prescribing information please see the following page.

Lopressor®
metoprolol tartrate

Geigy

the only relatively selective beta blocker for hypertension

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

667292 (8/79) C79-22

1980. A NEW ERA OPENS IN CRITICAL CARE.

The new CRITIKON

The company totally committed to critical care.

To create the new Critikon, Johnson & Johnson consolidated these established critical care names and product lines into one company:

- **The complete product lines of Jelco Laboratories and Applied Medical Research.**
- **Blood/gas monitors from Critikon Division, McNeil Laboratories.**
- **I.V. infusion pumps and Lanz™ tracheal tubes from Extracorporeal Medical Specialties.**

This concentration on critical care medicine has some special benefits for you and your patients.

For instance, our sales force is now unified and expanded. Each representative now covers a smaller area, has more time to devote to your critical care needs, and is closer than before when you need quick service.

By combining our research teams, we can expand our R & D programs, develop new and better products, and improve cost effectiveness.

And we promise you this—we will service what we sell. If Critikon medical electronic equipment should need servicing, we will handle it on the spot or at one of our new regional service centers.

Bigger can mean better. And stronger. Better products and a stronger service capability for all of your needs. Critikon—our commitment is to critical care.

Write or call for more information: Critikon, Inc., P.O. Box 22800, Tampa, FL 33622. 800-526-3928 (In New Jersey: 201-524-2555.)

REDUCTION OF ACUTE MYOCARDIAL ISCHEMIA IN ISOLATED RABBIT HEART BY HYALURONIDASE

Michael B. Simson, M.D., Wesley R. Harden, M.D., Clyde H. Barlow, Ph.D., Bruce Slagle, and Alden H. Harken, M.D., FACC, University of Pennsylvania, Philadelphia, PA.

The effects of Hyaluronidase (H) on acute myocardial ischemia was studied in isolated nonworking rabbit hearts. H was begun five minutes after coronary artery ligation at 4 units/ml perfusate. Coronary flow and myocardial oxygen consumption were determined. After 40 minutes, the hearts were perfused with fluorescein or rhodamine to indicate areas of myocardial perfusion, and quick frozen. The epicardial surface was removed. NADH fluorescence photography was used to detect areas of myocardial ischemia. In 13 H treated hearts, coronary flow increased to 138 ± 10% (mean ± SE) of the post-ligation control. In 10 untreated hearts, coronary flow decreased to 79 ± 9%. Myocardial oxygen consumption decreased to 63 ± 7% of control in the H treated hearts, but was unchanged (103 ± 11%) in untreated hearts. There was no difference between treated and untreated hearts in the amount of non-perfused myocardium, or control myocardial oxygen consumption, coronary flow or coronary venous PO_2. In H treated hearts, 55 ± 6% of the non-perfused myocardium was ischemic (NADH fluorescent) and the ischemic areas had a patchy distribution. In the untreated hearts 89 ± 2% of the non-perfused area was ischemic and ischemic areas were uniform. The distance between perfused and ischemic tissue was 861 ± 76 u in the H treated and 356 ± 19 u in the untreated hearts. No significant collateral flow was seen within the non-perfused areas in both groups. Conclusion: Hyaluronidase increases coronary flow, and decreases myocardial oxygen consumption during acute ischemia. In H treated hearts, significant amounts of myocardium remain normoxic within the non-perfused areas.

THE EFFECTS OF NIFEDIPINE ON ISCHEMIC MYOCARDIUM: PRESERVATION OF CONTRACTION DURING PARTIAL CORONARY OCCLUSION

Shigehiko Hattori, MD; William W. Weintraub, MD; Jai B. Agarwal, MD; Monty M. Bodenheimer, MD, FACC; Vidya S. Banka, MD, FACC; Richard H. Helfant, MD, FACC, Presbyterian-University of Pennsylvania Med. Ctr., Phila., Pa.

Although nifedipine (a calcium antagonist) has been used in the management of patients with angina pectoris, its effects on regional myocardial contraction are unknown. To study its effects on the myocardium, partial coronary occlusion (50% flow reduction) was produced on the left anterior descending coronary artery in 9 open-chested dogs. Pairs of ultrasonic crystals were implanted subendocardially in the nonischemic zone (NZ) and ischemic zone (IZ) to measure end-diastolic length (EDL) and % systolic shortening (%ΔL). Thirty minutes after partial occlusion (PO) nifedipine 5μg/kg/min was infused intravenously. During PO, %ΔL in IZ decreased from 26.3±1.1 to 3.4±1.3 ($p<0.001$). With administration of nifedipine, %ΔL increased from 3.4±1.3 to 13.1±2 ($p<0.001$). NZ %ΔL was unaffected by PO and nifedipine. End-diastolic length (EDL) increased from 10.0 to 10.9±0.8 mm ($p<0.05$) after PO. Nifedipine decreased EDL to 9.9±1.03 mm ($p<0.05$). NZ EDL did not change significantly after PO or nifedipine. Heart rate increased from 147.2±20.4 to 149.8±20.1 after PO and decreased to 142.6±14.5 after nifedipine (p-NS). LV systolic pressure decreased from 115±20.8 to 106.7±15.2 after PO and to 103±3.6 mmHg ($p>0.05$) after nifedipine. LVEDP increased from 3.8±0.5 to 4.4±1.1 after PO and decreased to 3.5±0.9 mmHg ($p>0.05$) after nifedipine. In summary, nifedipine in doses which have no significant hemodynamic effects improves contraction in the ischemic zone without affecting the nonischemic zone.

AUTORADIOGRAPHY WITH ^{99}Tc LABELED ALBUMIN MICROSPHERES, A NEW METHOD FOR DELINEATION OF ISCHEMIC TISSUE AT RISK OF INFARCTION: DEMONSTRATION OF THE PROTECTIVE EFFECT OF VERAPAMIL

Laurence W.V. DeBoer, MD, H. William Strauss, MD, Robert A. Kloner, MD, PhD, Robert E. Rude, MD, Richard F. Davis, MD, Eugene Braunwald, MD,FACC, Peter R. Maroko, MD,FACC Peter B Brigham Hosp/Mass Gen Hosp, Boston, MA

Demonstration of anatomic reduction in infarct size (IS) is hindered by wide variation in quantity of ischemic tissue below coronary artery occlusion (CAO) due to variable coronary collateral circulation. We sought a marker for determining the ischemic area at risk (IAR) which was: 1) assessed prior to permanent vascular changes and prior to treatment and 2) that was physiologically distributed to the heart. Thus, 21 dogs underwent left anterior descending CAO, and at 30 min, 600,000 albumin microspheres (28μ diameter) heavily labeled for autoradiography with ^{99}Tc (3-11 mC) were injected into the left atrium. At one hour 12 dogs received the calcium antagonist Verapamil (0.2 mg/kg loading, 0.6 mg/kg/hr for 7 hrs). Nine dogs served as controls. At 8 hrs, the hearts were sectioned into 3 mm slices, infarcts delineated with triphenyl tetrazolium chloride and planimetered. Autoradiographs of the slices were made and the IAR as represented by "cold spot" images on the autoradiographs were planimetered. All numbers were expressed as % of the left ventricle below CAO.

RESULTS	Control	Verapamil	P
IAR (Ischemic Area)	37.3±2.8	36.6±2.0	NS
Infarct Size	35.2±3.2	26.1±2.5	<.05
% of IAR that infarcted	92.6±4.3	70.5±5.1	<.01

We conclude that this model allows quantification of infarct size as a percentage of a physiologically determined area at risk. This improves the ability to determine protective effects of pharmacologic agents.

REDUCTION OF EXPERIMENTAL MYOCARDIAL INFARCTION SIZE BY ORTHO-IODO SODIUM BENZOATE

Robert E. Rude, MD, Robert A. Kloner, MD, PhD, John Tumas, BS, Laurence W.V. DeBoer, MD, Marcel Gunst, MD, Myron Laver, MD, and Peter R. Maroko, MD, FACC. Peter B Brigham Hosp/Mass Gen Hosp, Boston, MA

Ortho-iodo sodium benzoate (OISB) diminishes the affinity of hemoglobin for oxygen, thus enhancing potential tissue oxygen delivery. We sought to determine the effects of OISB on myocardial ischemic damage in anesthetized dogs. Nine dogs underwent 2 temporary 15 minute coronary artery occlusions (CAO) of the left anterior descending artery (LAD) with intervening reperfusion. Saline (4 dogs) or OISB (500 mg/kg; 5 dogs) was infused intravenously prior to the second CAO. Mean epicardial ST segment elevation from ischemic zones was the same during both CAO's in saline-treated dogs (3.4±0.7 mV), but decreased from 3.7±0.3 mV to 1.1±0.4 mV ($p<.001$) after OISB treatment. Thirty-one dogs undergoing permanent CAO of the LAD were then randomized to treatment with OISB 500 mg/kg intravenously (n=15), administered just prior to CAO or to a control group (n=16). Twenty-four hrs after CAO, the hearts were excised, transverse slices of the left ventricle (LV) were stained with triphenyl tetrazolium chloride, and infarct size (IS) as a percent of total LV weight, was calculated after dissection of each LV slice into necrotic and non-infarcted portions. Control and OISB treated dogs, respectively, were similar with regard to distance from aorta to CAO (2.6±0.7 and 2.5±0.5 cm), but IS was less in the OISB treatment group (22.6±2.3%) than in controls (31.0±1.6%, $p<.01$). In 6 dogs, OISB treatment raised the pO_2 at 50% oxyhemoglobin saturation (P_{50}) from 31.9±0.5 to 35.7±0.7 mmHg ($p<.01$). We conclude that OISB administration before experimental CAO lessens the degree of acute myocardial ischemia and the ultimate amount of ischemic necrosis.

REDUCTION OF ISCHEMIC MYOCARDIAL NECROSIS BY LIDOCAINE ADMINISTRATION.

Fred N. Nasser, MD; Makoto Sunamori, MD; William E. Edwards, MD; Carlos E. Harrison, MD, FACC, Mayo Medical School, Rochester, Minnesota.

This investigation assessed the effects of therapeutic doses of lidocaine on myocardial cell respiration, creatine kinase depletion (CPK), left ventricular stroke work (LVSW), and cardiac necrosis in anesthetized open-chested dogs. The animals were subjected to 40 minutes of occlusion of the left anterior descending coronary artery followed by 5 hours of reperfusion. Alpha-Zurine blue dye was used to delineate ischemic areas and triphenyl tetrazolium chloride to demarcate necrotic areas. Cellular necrosis was confirmed by histologic sections and the necrotic tissue was resected for comparison with LV weight. Mitochondrial respiration was assessed by a polarographic technique after isolation of mitochondria by centrifugation. Pressures were measured in the LA, LV, aorta and cardiac output determined by the cardiogreen dye method. Group I (n=12) had saline infusion; Group II (n=8) had 0.2 mg/kg/min lidocaine infusion (serum, 16.8 $\pm$ 1.4 µg/ml); Group III (n=5) received 0.04 mg/kg/min (serum 3.6 µg/ml). Ischemic regional myocardial blood flow (measured by Sr^{85} 9 µ spheres) was 6.34 $\pm$ 1.62 ml/100 mg/min (I); 1.48 $\pm$ 0.59 ml in II ($p<0.05$); 1.32 $\pm$ 0.50 in III ($p<0.05$). Oxygen consumed during conversion of adenosinediphosphate to adenosinetriphosphate in mitochondria from control and lidocaine treated ischemic tissue was depressed ($p<0.05$) and correlated ($r=0.63$) with CPK depletion. LVSW was not significantly different among the 3 groups. Control infarct size was 12.6 $\pm$ 2.0% LV weight; II was 4.8 $\pm$ 1.2 ($p<0.01$); III was 4.8 $\pm$ 2.5 ($p<0.05$). The data suggest that the reduction of myocardial infarct size by lidocaine was not dependent upon enhanced myocardial blood flow and independent of LVSW.

COMPARATIVE HEMODYNAMIC EVALUATION OF THE CARPENTIER-EDWARDS AND ANGELL-SHILEY PORCINE XENOGRAFTS

Bernard R. Chaitman, MD, FACC; Juan Luis Delcan, MD; Raoul Bonan, MD; Ramiro Rivera, MD; Julio F. Tubau, MD; Lorenzo Lopez-Bescos, MD; Vicente Fernandez Vallejo, MD; Gilles Lepage, MD, Montreal Heart Institute, Montreal, Quebec and Ciudad Sanitaria Provincial de Madrid, Madrid, Spain.

Few postoperative hemodynamic data are available for the Carpentier-Edwards (CE) and Angell-Shiley (AS) porcine valves. In this multicenter study, 80 patients in NYHA class I-II with CE (N=40) and AS (N=40) valves were catheterized 6-12 months after operation. Cardiac output and simultaneous transvalvular gradient (grad) were recorded at rest and during moderate supine exercise following the same hemodynamic protocol. The following results (CE vs AS) were obtained ($\bar{X}\pm SD$).

	Rest grad (mmHg)		Exercise grad (mmHg)		Areas (CM^2)	
AV replacement						
AV size (mm)	CE	AS	CE	AS	CE	AS
21-23 (n=10)	21±8	29±13	28±6	32±17	1.2±.3	.74±.2
25-27 (n=21)	15±7	28±10†	24±10	38±10†	1.4±.3	1.0 ±.2†
28-31 (n=18)	17±7	22±10	18±7	33±10†	1.9±.7	1.4 ±.3*
MV replacement						
MV size (mm)			*p<.05; †p<.01			
27-29 (n=14)	7±3	14±7*	17±11	26±12	2.1±.6	1.0 ±.3†
30-33 (n=17)	5±1	12±5†	11±4	23±9*	2.9±.9	1.5 ±.4†

The average increase in cardiac output during exercise was 78% for the CE series and 59% for the AS series ($p<.05$). Grade 1/4 regurgitation was noted in 4 pts with CE valves and 5 pts with AS valves.

It is concluded that the hemodynamic performance of the Carpentier-Edwards valve is substantially better than the Angell-Shiley valve for each group of stent sizes evaluated. The Angell-Shiley valve is moderately obstructive and has suboptimal hydraulic function.

ST. JUDE AORTIC VALVE PROSTHESIS: POST-OPERATIVE HEMODYNAMIC EVALUATION AT REST AND EXERCISE.

James Hoback,MD; Yang Wang, MD; D. Nicoloff, MD; R. W. Emery, MD; Charles R. Jorgensen, MD; R. W. Anderson, MD; W. G. Lindsay, MD. U of MN; Mpls., MN.

From 10/3/77 to 3/20/79 32 patients received St. Jude aortic valve (AV) prostheses at the U. of Minnesota Hospitals. 22 patients had follow-up catheterizations at a post-operation interval of 4 months; 9 had exercise studies with aortic valve gradient measurements. Hemodynamic data included simultaneous left ventricular (LV) and aortic pressures for determination of aortic valve systolic gradient (AVSG) at rest and, in 9 patients, at 3 minutes of exercise at a load of 50-75 watts. LV pressure was obtained transseptally using an 8F pigtail catheter in the LV during the exercise study. Other data included cardiac output, pulmonary artery wedge pressure (PAWP), and left ventriculography. For the entire group mean resting AVSG (peak to peak) was 2.2 mm Hg (0 mmHg - 10 mmHg) with a mean cardiac output of 6.5 l/min (4.1 l/min - 10.8 l/min). Mean PAWP was 9 mmHg at rest and 22 mmHg at exercise. The 9 patients in the exercise group had a mean exercising AVSG of 3.7 mmHg (0 mmHg - 12 mmHg), with a mean cardiac output of 9.7 l/min (8.5 l/min - 12.0 l/min). We conclude that the new St. Jude prosthetic valve in the aortic position has excellent in vivo hemodynamic characteristics at rest and with exercise and may offer a significant advantage over the AV prostheses currently in use.

HEMODYNAMIC EVALUATION OF PORCINE HETEROGRAFTS IN THE MITRAL POSITION FOR MORE THAN FIVE YEARS

Lewis C.Lipson, MD, Kenneth M.Kent, MD, FACC; Charles L. McIntosh, MD; Douglas R.Rosing, MD; Robert O.Bonow, MD; John Condit, BS; Stephen E.Epstein, MD, FACC; Andrew G.Morrow, MD, NHLBI, NIH, Bethesda, Md.

Porcine heterografts are widely used for mitral valve replacement (MVR). However, concern has arisen about the long term durability of these valves because of documented deterioration of their collagen architecture. Prior to October, 1973, 54 pts had MVR with porcine valves at the NIH, thereby providing a follow-up of >5years. Of 49 pts surviving operation, 17 died >1 month postop of causes not definitely related to valve failure and 8 were either lost to follow-up or refused another catheterization. Of the remaining 24 pts, 5 subsequently died or required MVR because of valve failure at a mean of 77 mo (range 56-100). Cath data available prior to 2nd operation on 3 of the 5 late failures showed, compared to data obtained shortly after first operation, an increase in mean mitral valve gradient (MVG) from 7 to 17 mmHg, and a decrease in mitral valve area (MVA) from 2.4 to 0.89 cm^2; all had severe mitral regurgitation. The remaining 19 pts were clinically stable: 14 had repeat hemodynamic evaluation and these late data were compared to the 6 mo. postop data. Five pts (36%) had acquired significant mitral stenosis, as manifest by a decrease in MVA $\geq$0.5cm^2 or an increase in mean MVG >5mmHg. Thus, there is not only an appreciable incidence of late porcine valve failures requiring valve replacement, but also a high incidence of late hemodynamic deterioration even in pts whose clinical status remains as yet unchanged. As a result of these data, porcine heterografts are no longer used for MVR at the NIH except in older pts or those with contraindications to anticoagulation.

ALTERATIONS IN COLLAGEN OF PORCINE VALVE HETEROGRAFTS IN PLACE FROM 3 TO 94 MONTHS: THE CAUSE OF LEAFLET CALCIFIC DEPOSITS AND OF PERFORATIONS AND TEARS

Victor J. Ferrans, MD, Steven W. Boyce, BA, Margaret E. Billingham, MD, Michael Jones, MD., and William C. Roberts, MD, FACC, National Heart, Lung, and Blood Institute, Bethesda, Md., and Stanford University Hospital, Stanford, Ca.

Morphologic studies were made of 14 porcine valvular heterografts (PVH) containing calcific deposits (CD) in 14 patients (pts) aged 2.5 to 65 years at the time of implantation. Eleven PVH had been in the mitral position, 1 in the aortic, 1 in the tricuspid, and 1 in a pulmonic conduit. Thirteen PVH were recovered at reoperation (because of stenosis in 8, regurgitation in 3, infection in 1 and perivalvular leak in 1) and 1 at necropsy. Six PVH had leaflet perforations. CD were evident grossly in 11 PVH and only microscopically in 3; the CD were located within the leaflets in 13 pts and in vegetations only in 1 pt. The most important CD were localized in the spongiosa and produced elevated plaques. When minimal, CD tended to be located in areas adjacent to the aortic wall near commissures; when extensive, they were multiple and also involved more central areas of the cusps. CD were grossly, histologically and ultrastructurally similar in young and older pts. Known factors predisposing to CD were present in only 1 pt (chronic renal disease). Leaflet perforations were related to breakdown of collagen fibrils. This fact was confirmed by study of unimplanted PVH cycled in a valve tester for times equivalent to up to 6 years of clinical use. In conclusion, collagen alterations are responsible for the 2 principal modes of PVH failure: stenosis (due to CD) and regurgitation (due to breakdown of fibrils, leading to perforations and tears).

PROGNOSTIC SIGNIFICANCE OF PREOPERATIVE EJECTION FRACTION IN DIFFERENT AORTIC VALVE LESIONS

Robert Forman, MD, FACC; Brian G. Firth, MD; Marius S. Barnard, MCh, University of Cape Town Medical School, Cape Town, South Africa.

Patients with aortic regurgitation (AR) and depressed ejection fraction (EF) have been reported to show poor recovery of L.V. function postoperatively. The prognositc significance and frequency of occurrence of depressed EF and other parameteres were therefore examined in 229 successive patients undergoing aortic valve replacement. Aortic stenosis (AS) was present in 29%, AR in 39% and mixed aortic disease (M) in 31%. Significantly fewer patients with AS (19%) had EF's < 0.50 compared with AR (37%) and M (38%) ($p < 0.05$). The 3 year survival was not significantly different in patients with either AS or M whether they had EF $>$ or < 0.50, CI $>$ or < 2.5 L/m/M^2 or LVEDP $>$ or < 15 mmHg. Patients with AR had the following 3 year postoperative survival; EF $< 0.50 = 64 \pm 10\%$, EF $> 0.50 = 93 \pm 4\%$ ($p < 0.02$); CI $< 2.5 = 63 \pm 10\%$, CI $> 2.5 = 94 \pm 4\%$ ($p < 0.02$); LVEDP $> 15 = 76 \pm 7\%$, LVEDP $\leq 15 = 96 \pm 4\%$ ($p < 0.05$). CI was ≤ 2.5 in 40% AR patients and LVEDP was > 15 in 73%. Age, sex, prosthetic valve type did not affect prognosis. Depressed EF in patients with AR carried a poorer long term prognosis with six of ten late deaths being due to CHF or occurring suddenly. We therefore recommend monitoring EF non-invasively in asymptomatic patients with significant AR and consider aortic valve replacement with the development of depressed EF.

FAILURE OF DIASTOLIC ABNORMALITIES TO REGRESS AFTER CORRECTION OF AORTIC STENOSIS: A CASE FOR EARLIER OPERATION?

Martin St.John Sutton; Marianne St.John Sutton; Itai Rozovsky; Daniel Marier; Philip Wong; Derek Gibson. Brompton Hospital, London, England, U.K.

Relief of aortic stenosis is accompanied by symptomatic benefit provided operation (op) is performed before the onset of irreversible left ventricular (LV) disease. Suitable criteria for such timing of op do not exist. We therefore recorded LV echocardiograms in 50 patients(pts) pre-op, and 40 pts post-op and compared them with 15 normals to assess whether there was regression of LV abnormalities post-op. All pts had LV outflow gradients (50-225 mean 88 mm Hg) and LV hypertrophy on ECG. Echocardiograms were obtained pre-op and from 1 month to 5 years post-op and digitized to display the duration of rapid LV filling(RF),delay in mitral valve opening(MVO) with respect to minimum LV dimension, and peak rates of 1) increase in LV dimension, dD/dt,2) systolic LV shortening, VCF, 3) wall thickening,+dW/dt, and 4) wall thinning,-dW/dt. (* = $p<0.02$)

Patients.	dD/dt	VCF	+dW/dt	-dW/dt	RF	MVO
Normals	14.5	2.6	4.7	9.7	160 ms	1ms
(n=15)	+2.3	+0.4	+1.4	+4.3	+50	+6
Pre-op.	10.9	2.5	5.3	6.2*	213	59
(n=50)	+4.0	+1.1	+2.2	+2.7	+85	+31
Post-op.	11.5	2.2	4.8	6.4*	189	49
(n=40)	+3.8	+0.9	+1.7	+2.5	+56	+35

Pre-op systolic function(VCF,+dW/dt) was normal but severe pre-op diastolic abnormalities(dD/dt,-dW/dt,MVO)failed to regress post-op,reflecting persistence of LV disease which might be prevented if timing of operation was based on digitized echo plus clinical data rather than on clinical data alone.

MITRAL VALVE REPLACEMENT FOR ISOLATED MITRAL REGURGITATION: EARLY AND LATE RESULTS

Harry R. Phillips, MD; Frederick H. Levine, MD; Jane E. Carter, RN; Charles A. Boucher, MD, FACC; Gerald M. Pohost, MD, FACC; Mortimer J. Buckley, MD, FACC, Massachusetts General Hospital, Boston, Ma 02114

Ninety-five consecutive patients (pts) underwent mitral valve replacement (MVR) for isolated mitral regurgitation (MR) from 1974 to 1979. Pts with coronary artery disease, primary cardiomyopathy, mitral stenosis and active endocarditis were excluded. Ages ranged from 17 to 75, mean 57 yrs. Etiology of MR was rheumatic in 15%, ruptured chordae or floppy valve in 82%, and unknown in 3%. Preoperative NYHA Class was I or II in 20% and III or IV in 80%. Left ventricular function (LVF) was qualitatively normal in 83% ejection fraction (EF) range 50-79%, and abnormal in 17%, EF range 30-49%. Mean pulmonary artery pressure ($\overline{PAP}$) was <40 mmHg in 77% and $\geq$40 in 23%. Left ventricular end-diastolic pressure (LVEDP) was <20 mmHg in 86% and $\geq$20 in 14%. Cardiac index (CI) was $\geq$2.0 L/min/M^2 in 73% and <2.0 in 27%. Operative mortality was 3% with no operative deaths since 1976. At followup (mean 24 mos.) there were 9 late deaths: 4 sudden, all in pts who had $\overline{PAP} \geq 40$, were Class III or IV preoperatively, and who became Class I or II postoperatively; 3 due to cerebrovascular complications, all in pts with ball-valve prostheses; 1 due to probable bacterial endocarditis; 1 non-cardiac. Predicted 3 year survival rate for operative survivors was 89%+4SE. Preoperative NYHA Class, LVF, $\overline{PAP}$, LVEDP and CI did not appear to predict early or late survival. Ninety-five percent of operative survivors were NYHA Class I or II, and 5% Class III. MVR can be safely performed in severely symptomatic pts with MR at a low mortality and with excellent functional recovery. Long term survival is good but unexplained sudden death may occur late after surgery despite a good clinical result.

COMPLETE AORTIC ROOT AND VALVE REPLACEMENT WITH REIMPLANTATION OF THE CORONARY ARTERIES - ? SOLUTION TO TUNNEL OBSTRUCTION

Jane Somerville, MD, FACC; Donald Ross, FACC
National Heart Hospital, London, England.

Between 1976-1979, 20 selected patients aged 5-27 years with serious congenital left ventricular outflow lesions had total aortic root and valve replacement with "fresh" adult aortic homograft and reimplantation of the coronary arteries. 13 were second or third reoperations. 7 were first procedures. Severe obstruction was present in 16 related to valve stenosis (12) or fixed subvalvar rings (4); 14 had diffuse long ("tunnel") obstruction. 2 of the 4 with aortic regurgitation had failed valve replacements and 2 had aortic root disease. There was one perioperative death from poor treatment of left ventricular failure. Complications encountered were difficulty in aligning coronary arteries (3) and early left ventricular dysfunction (5) possibly caused by myocardial ischaemia or "preservation" techniques. One late death unrelated to the root replacement occurred after 3 years; there was normal function of the aortic valve and outflow. 18 of 19 survivors remained asymptomatic with maintained improved left ventricular function. Reinvestigation with Isuprel stimulation and angiography in 15 confirmed no or low resting outflow gradients (4), low Isuprel gradients (6), trivial aortic regurgitation (4) and improved or normal left ventricular function (12) with both coronaries normally filled (14). The aortic wall calcified quickly in young patients. We conclude that this technically more complex operation is indicated in patients with diffuse left ventricular outflow obstruction and diseased aortic roots and should be the procedure of choice with actual or potential tunnel obstruction.

FOLLOW-UP RADIONUCLIDE ASSESSMENT OF LEFT VENTRICULAR FUNCTION AND PERFUSION IN PATIENTS REQUIRING INTRAAORTIC BALLOON PUMP TO WEAN FROM CARDIOPULMONARY BYPASS.

Ross Davies, MD, Hillel Laks, MD, FACC, Harvey Berger, MD, Byron Williams, MD, Frans Wackers, MD, FACC, Graeme Harmond, MD, FACC, Alexander Geha, MD, FACC, Alexander Gottschalk, MD, Barry Zaret, MD, FACC, Yale University, New Haven, Ct.

Intraaortic balloon pump (IABP) assistance was required intraoperatively (intraop) for weaning from cardiopulmonary (CP) bypass in 67 patients (pt) since 1975. Of the 30 current survivors, 22 (8 coronary bypass, 7 valve replacement, 7 both) underwent rest radionuclide left ventricular (LV) function and thallium-201 (Tl-201) perfusion studies at a mean of 19 mos postop. Fifteen pts also had exercise (EX) LV function studies. Fifty percent of survivors studied (11/22) had periop myocardial infarction (MI) documented by rest Tl-201 defects not explained by preop MI or periop serum CK-MB elevation $\geq$5%. The incidence of periop MI's in survivors was identical to that in pts who died intraop or immediately postop (17/34).

Among survivors studied, there was no difference between mean ($\pm$SEM) preop and postop resting LV ejection fraction (EF) (48$\pm$5 vs 45$\pm$4%). Similarly, postop resting LVEF was not different in patients with or without periop MI (44$\pm$7% vs 47$\pm$5%). Postop LVEF rose by $\geq$10% compared to preop in 5 pts, while LVEF fell by $\geq$10% in 10 pts (6 with periop MI). Although only 3/15 pts had a normal (nl) LV response to EX ($\geq$5% increase in LVEF), 20/22 had dramatic symptomatic improvement.

Thus, IABP successfully weaned many pts from CP bypass, and about half are long-term survivors with minimal symptoms. Periop MI occurred equally in survivors and nonsurvivors. Although most survivors had abnl EX LV reserve, postop resting LVEF generally was preserved, indicating a component of reversible intraop LV dysfunction.

PULMONARY EMBOLECTOMY

Zev Davis, M.D., FACC; Robert L. Berger, M.D., FACC; John R. McCormick, M.D., FACC; Martha E. Fay, M.A., Boston University Medical Center, Boston, Massachusetts.

Despite intensive medical support, survival remains low following an acute massive pulmonary embolus (PE) and shock. We reviewed our experience from 1965-1979 with 22 patients (pts) having pulmonary embolectomy to determine whether a surgical approach for this condition is warranted. There were 12 males and 10 females with an age range from 33-78, and a mean age of 54.4 years. Twenty pts had pulmonary angiography which demonstrated 50% or greater obstruction of the major pulmonary vasculature. Operation was performed within 12 hours of embolization in 19 pts, and within 24 hours in 3 pts. All were in deep shock despite intensive inotropic support. Cannulation of the femoral artery and vein for cardiopulmonary bypass (CPB) was performed under local anesthesia, prior to induction for general anesthesia. Institution of partial bypass for circulatory support was necessary in 17 pts because of deepening hypotension or cardiac arrest. Sixteen pts had inferior vena caval (IVC) interruption procedure. Operative mortality was 6/22 (27.2%). Two deaths were unrelated to the procedure and a third was due to IVC tear following attempted ligation. In 7 pts studied immediately post embolectomy and at 16 to 56 months postoperatively, mean pulmonary artery pressure decreased from 40 mm Hg preop to 10 mm Hg and mean right atrial pressure from 16 mm Hg preop to 5 mm Hg. No residual obstruction was noted on angiograms. Definitive diagnosis through angiography, early intervention and preoperative circulatory support make pulmonary embolectomy a life saving procedure with acceptable mortality. Extended use of this procedure is recommended.

CONGESTIVE CARDIOMYOPATHY PATIENTS AS HEART-TRANSPLANT RECIPIENTS.

Lewis A. Hassell, BS; Robert E. Fowles, MD; Charles P. Bieber, MD; Edward B. Stinson, MD, FACC, Stanford University School of Medicine, Stanford, California.

To assess prognosis for cardiomyopathy (CM) patients (pts) as transplant candidates, records were analyzed for 105 pts receiving heart transplants from January 1971 to August 1978, including 59 pts with end-stage coronary artery disease (CAD-T) and 46 pts (CM-T) with congestive cardiomyopathy (43 idiopathic, 2 ethanolic and 1 familial). 36 non-transplanted CM pts (CM-NT) clinically comparable to the CM-T group were also evaluated. Overall 1 year survival rates for the 3 groups were as follows:

CAD-T	CM-T	CM-NT
55%	64% (n.s. vs. CAD-T)	23% ($p < 0.001$, vs. CAD-T, CM-T)

CM-T pts who survived the first 3 months after surgery had a 1 year survival rate of 85% overall. CM-T and CAD-T pts did not differ significantly in the time to second early rejection episode. Deaths due to infection and rejection were 46% and 31% in the CM-T group compared with 56% and 28% in the CAD-T pts. For CM-T pts under age 40, the average time to second rejection episode was significantly longer ($p=0.027$) than in CM-T pts age 40 or older. Deaths due to infection and rejection were also lower for the younger CM-T group, 42% and 17% vs. 50% and 36% in the older group, though the overall survival was comparable in the 2 age groups. 50% of the total number of CM-T pts or 80% of 3 month survivors returned to functional class I.

We conclude that 1) CM pts fare as well or better than comparable CAD pts following cardiac transplantation, 2) younger CM-T pts have lower risks for infection and rejection, and 3) cardiac transplantation is an appropriate consideration for end-stage CM pts.

LONG-TERM SURVIVAL FOR 184 PATIENTS WITH TREATED AORTIC DISSECTION

R.M. Doroghazi, MD; E.E. Slater, MD, FACC; R.W. DeSanctis, MD, FACC; S.V. Rosenthal, PhD; W.G. Austen, MD, FACC; M. J. Buckley, MD, FACC, Mass. General Hosp., Boston, Ma.

Evaluation of therapy for aortic dissection has been hampered by the limited number of patients per series, failure to classify patients by location and duration of dissection, and lack of extended follow-up. From 1963-78, 184 patients with spontaneous aortic dissection as proven by angiogram, surgery or autopsy were seen at Mass. General Hosp. Long-term follow-up was accomplished in 180 cases, mean follow-up was 48.4 months, range 1-147 months. Patients were classified by type of dissection (P=proximal, types I&II, D=distal, type III); duration (A=acute, ≤2 weeks; C=chronic, >2 weeks); mode of therapy (S=surgical, M=medical). The previously published guidelines for choice of S vs M therapy were used. Number of patients in each category was: PAS=39 PCS=24 DAS=43 DCS=7 PAM=10 PCM=0 DAM=34 DCM=7. 20 patients received no therapy. Hospital survival was: PAS=51% PCS=92% DAS=49% DCS=86% PAM=60% DAM=82% DCM=86%. Overall long-term survival was: PAS=36% PCS=67% DAS=40% DCS=57% PAM=40% DAM=48% DCM=86%. Late survival for those patients discharged from the hospital was: PAS=70% PCS=73% DAS=81% DCS=67% PAM=67% DAM=60% DCM=86%. Chi square analysis showed a significant ($P \leq 0.02$) dissociation for hospital survival between A vs C and S vs M; for overall long-term survival between A vs C; and for late survival of those patients discharged, no significant differences. These data suggest that chronic presentation is the most significant determinant of early and late survival; that the significant difference between initial S vs M therapy was due to the more critically ill condition of the surgically treated patients; and that initially successful surgical or medical therapy for aortic dissections is sustained on long-term follow-up.

THURSDAY, MARCH 13, 1980
AM
RESPONSE TO EXERCISE AND CARDIAC EFFECTS OF THERAPY
8:30-10:00

VALUE OF BLOOD PRESSURE RESPONSE TO EXERCISE IN THE RECOGNITION OF LATENT OR EARLY BORDERLINE HYPERTENSION

Surjit S. Bhasin, MD; Subhash C. Khullar, MD, FACC; Arnold M. Weissler, MD, FACC, Wayne State University, Detroit, MI.

This study was undertaken to determine whether patients (pts) showing a hypertensive response to graded treadmill exercise (GTX) are at a higher risk of developing subsequent hypertension (HTN). The study is comprised of 313 patients undergoing GTX between 1975 and 1977. 185 were male and 101 were black. The mean age of the group was 56.7 ± 12.6 years. A physician recorded the blood pressure by cuff sphygmomanometer before, during and after GTX. All pts had resting pressure of less than 140/90 mmHg. Exercise blood pressure was labelled Normal, Abnormal or Borderline when the peak pressure was less than 180/100 mmHg (218 pts), greater than 210/110 mmHg (46 pts) and between 180/100 and 210/110 mmHg (49 pts) respectively. During the subsequent followup period of 16-48 months (mean 27.2 ± 7.6 months) thirty nine patients developed sustained HTN requiring anti-hypertensive therapy.

TOTAL NO. OF PATIENTS			PATIENTS DEVELOPING HTN			
ABNORMAL	M 26 W 29	20(43.4%)	M 12	W 11	$p<0.001$
(n=46)	F 20 B 17		F 8	B 9	
NORMAL	M 126 W 155	13(5.9%)	M 8	W 7	
(n=218)	F 92 B 63		F 5	B 6	
BORDERLINE	M 33 W 28	6(12.3%)	M 3	W 1	$p>0.05$
(n=49)	F 16 B 21		F 3	B 5	

M=Male F=Female W=White B=Black

Patients demonstrating a hypertensive response to GTX showed a significantly higher incidence of developing subsequent HTN. Graded treadmill exercise test appears to be a simple and useful method for the recognition of latent or early borderline hypertension.

HYPERTROPHIC OBSTRUCTIVE CARDIOMYOPATHY--19-YEAR POSTSURGICAL SURVIVORSHIP

Margaret M. Beahrs, MD; Abdul J. Tajik, MD, FACC; James B. Seward, MD, FACC; Emilio R. Giuliani, MD, FACC; Dwight C. McGoon, MD, FACC, Mayo Clinic, Rochester, MN.

The purpose of this study is to report the very long-term postoperative follow-up of patients with hypertrophic obstructive cardiomyopathy (HOCM). We reviewed the outcome of the first 36 consecutive patients (pts) (22 male, 14 female; mean age 31 yr) who survived surgery (myectomy/myotomy) at the Mayo Clinic between 1960 and 1972. All 36 surviving pts have been followed for a mean of 12 yr. Nine (25%) postoperative deaths have occurred: sudden death in 4 pts (after a mean follow-up of 4.3 yr), intractable heart failure with atrial fibrillation in 4 pts (after a mean follow-up of 12 yr), and noncardiac death in 1 pt. Thus the postoperative deaths appear to fall into an earlier (sudden death) group and a later (congestive heart failure) group. Presently, 27 pts are alive after a mean follow-up of 13 yr (range 6.7-19 yr, with 22 pts followed for >10 yr); 13 are NYHA Class I, 11 Class II, and 3 Class III, as compared with 19 of 27 who were Class III preoperatively. Twelve pts do not take cardiac medication, whereas 15 pts are taking propranolol or digitalis, or both. Three pts have required permanent pacemakers: 1 for operative complete heart block, 1 for acquired complete heart block 4 yr after surgery, and 1 for symptomatic slow atrial fibrillation 18 yr after surgery. Five other patients are in atrial fibrillation. Conclusion: This study, which contains the most complete (100%) and the longest follow-up data on pts surviving surgery for HOCM, documents that the majority--27 of 36 pts (75%)--are alive with good to excellent alleviation of symptoms as long as 19 yr-->10 yr in 22 pts. We therefore continue to recommend surgery in these pts when this is clinically indicated.

BENEFICIAL EFFECTS OF ENDURANCE EXERCISE TRAINING IN ADOLESCENT HYPERTENSION.

James M. Hagberg, PhD; Ali A. Ehsani, MD; Gregory W. Heath, DHSc; David Goldring, MD; Tony Hernandez, MD; John O. Holloszy, MD. Washington University School of Medicine, St. Louis, MO.

The effects of 8 mo of endurance exercise-training on blood pressure (BP) were evaluated in 9 adolescents, 17 ± 0.6 yr old, with essential hypertension. The training program induced an improvement in cardiovascular fitness, evidenced by a 10% increase in maximum O_2 uptake capacity ($\dot{V}O_2max$) ($P<0.01$), and a significant ($P<0.01$) decrease in heart rate. Despite this improvement in fitness, the $\dot{V}O_2max$ of the subjects was still below average for their age after training. Body weight and percent body fat were unchanged. Systolic BP decreased from an average of 140 ± 7 to 132 ± 7 ($P<0.01$). Diastolic BP decreased from 86 ± 5 to 79 ± 6 ($P<0.01$). Resting cardiac output, measured by the CO_2 rebreathing method, was elevated initially in two of the subjects; the exercise-training resulted in a decrease in resting cardiac output in these subjects and was responsible for the decrease in their BP. The other 7 subjects initially had an elevated peripheral vascular resistance and normal cardiac output. In these 7 individuals the decrease in blood pressure was due to a decrease in peripheral resistance ($P<0.01$) without a significant change in cardiac output. In addition to a lower resting BP, the subjects had a lower BP during standardized exercise following training. These results provide preliminary evidence that exercise-training can lower BP in children who have increased peripheral vascular resistance or an increased cardiac output.

IMPROVED CARDIAC PERFORMANCE WITH LONG TERM REDUCTION OF BLOOD PRESSURE IN OLD SPONTANEOUSLY HYPERTENSIVE RATS. Janice Pfeffer,Ph.D., Marc Pfeffer,MD, Peter Fletcher,MD, Eugene Braunwald, MD,FACC, Harvard Medical School and Peter Bent Brigham Hospital, Boston, MA.

To determine whether blood pressure reduction by chronic antihypertensive therapy reduces cardiac mass and improves performance in long-term hypertension, 12 mo. male spontaneously hypertensive(SHR) and normotensive(NWR) rats were treated with hydralazine(H), guanethidine(G) or tap water (C) for 6 mo. Functional performance was assessed by peak cardiac index(pCI,ml/min/kg) and stroke index(pSI,ml/kg) attained during volume load and by maximum left ventricular(LV) pressure developed during aortic occlusion. Peak ejection fraction index(pEFI,%) was derived from peak stroke volume during volume load and from passive diastolic pressure volume curves. Further LV hypertrophic growth in SHR was arrested by treatment with H or G. This reduced cardiac mass was associated with an improvement in pCI and pSI to NWR levels and with a significant increase in pEFI compared to untreated SHR. The ability of SHR to develop pressure was reduced to NWR levels also by treatment. H or G had no effect on these indices in NWR.

	NWR		SHR		
	C = 20	H = 5	C = 10	H = 10	G = 10
LV/B	2.04±.04	2.06±.04	3.38±.09	3.08±.11	2.74±.07*
pCI	395±15	390±57	314±18	432±21*	429±10*
pSI	1.04±.03	1.07±.14	0.83±.03	1.14±.06*	1.25±.04*
pEFI	73±4	---	44±2	64±4*	61±4†
pDP	222±4	220±4	270±17	245±9	226±1¶

*p<.001, †p<.01, ¶p<.05, H and G versus C SHR.

Thus, chronic treatment with G, a sympatholytic agent or H, an agent which enhances sympathetic activity, arrested the progression of LV hypertrophy in old SHR. This reduction in cardiac mass was associated with a restoration of cardiac performance toward normal, as peak pumping ability was improved and pressure generating capacity was reduced.

LONG-TERM MINOXIDIL THERAPY - EFFECTS ON THE HEART Walter M. Kirkendall, M.D., F.A.C.C., Jeremy J. Hammond, M.D.; Verne L. Jacks, R.N.; Bert Dougherty, M.D. and Peter Ostrow, M.D., University of Texas Medical School, Houston, Texas.

Nineteen patients received minoxidil (M) therapy for severe hypertension (mean duration 14 months, range 6-37 months). M (mean daily dose 27 mg) lowered the average blood pressure from 202/130 to 149/91 mm Hg (p < 0.001) in combination with furosemide (mean daily dose 324 mg) and propranolol (mean daily dose 290). Progressive loss of renal function was halted in 14 patients. In 5 patients with serum creatinine levels ≥ 6.4 mg % progression of renal disease was not halted. Left ventricular hypertrophy (LVH) was assessed by the Romhilt-Estes point score system in 16 patients. (Score: 5=LVH, 4=probable LVH). Mean score before treatment was 5.6 (±2.5), this rose to 7.1 (±2.5) (p < 0.05) on the latest ECGs. LVH score worsened in 15 of the 16 patients. Cardiothoracic ratios (CTR) were measured in 12 patients before M and on recent chest x-rays. Overall, the CTR did not alter from 0.49 (±0.05) before M to 0.55 (±0.10) currently. In 4 patients M was associated with severe heart failure and in these the CTR rose from 0.49 (±0.05) to 0.68 (±0.05). Two of these patients had pericardial effusions. Two patients had severe angina on M and 2 suffered myocardial infarctions, one of which was fatal. Autopsy showed a localized pericarditis and white-yellow fibrous plaques over the right atrium. Angioblasts were seen microscopically. This lesion is analogous to the right atrial lesion reported in dogs given M. These observations suggest that M, although preserving renal function and successfully controlling the blood pressure in severely hypertensive patients, may be harmful to the heart.

EFFECT OF ANTIHYPERTENSIVE THERAPY ON CALCIUM TRANSPORT BY CARDIAC SARCOPLASMIC RETICULUM OF SPONTANEOUSLY HYPERTENSIVE RATS (SHRs). Constantinos J. Limas, MD; University of Minnesota, Minneapolis, MN.

Cardiac hypertrophy develops during the course of blood pressure elevation in SHRs and is associated with defective calcium transport by cardiac sarcoplasmic reticulum (SR). At 20 weeks of age, calcium uptake is reduced in SHRs (42±1.3 nmol/mg/min vs. 64±1.6 nmol/mg/min in age-matched normotensive WKYs, p<0.01), while Ca++ ATPase activity is enhanced (44±1.1 nmol/mg/min vs. 35±0.7 in WKYs, p=0.02); this results in low stoichiometry between calcium uptake and ATP hydrolysis in SHRs. The steady-state levels of the phosphoprotein intermediate [EP] of the transport ATPase are higher in WKYs (0.97±0.1 nmmol/mg vs. 0.67±0.08 nmol/mg in SHRs, p<0.01) but the Ca++ and ATP-dependency are similar in the two groups. In order to study the relative roles of hypertension and cardiac hypertrophy in the depression of SR function, 20-week old SHRs and WKYs were treated for 10 weeks with either hydralazine (100 mg/L) or α-methyl dopa (8 gm/L). Both therapeutic regimens resulted in near normalization of blood presures of SHRs (hydralazine: 136±4 mm Hg; α-methyl dopa: 132±3 mm Hg). Regression of cardiac hypertrophy, however, was seen only in the α-methyl dopa-treated group, as judged by changes in left ventricular weight, RNA/DNA ratio, and hydroxyproline content. Furthermore, improvement in calcium transport capacity by the SR, as reflected in higher calcium uptake and stoichiometric ratio between uptake and ATP hydrolysis, was found after α-methyl dopa, but not hydralazine, treatment. These results indicate that reversal of cardiac hypertrophy is required for improvement in calcium transport by cardiac SR after antihypertensive therapy of SHRs.

VERIFICATION OF PHYSICIAN ASSESSMENT OF ANTIHYPERTENSIVE THERAPY BY AMBULATORY BLOOD PRESSURE RECORDING. Harold L. Kennedy, M.D., M.P.H., F.A.C.C.; Neil E. Padgett, B.S.; Michael J. Horan, M.D., ScM.; Madeleine A. Boruta, Department of Cardiovascular Services and Clinical Investigations, U.S. Public Health Service Hospital, Baltimore, Maryland.

To verify physician clinical assessment of antihypertensive therapy, 28 patients age 24 to 73 on antihypertensive medication for elevated (systolic ≥ 140 and diastolic ≥ 90 mm Hg) blood pressure (BP) were evaluated by 24 hour ambulatory BP recording. Prior to evaluation 14 patients were judged to have adequate antihypertensive BP control, while the remaining 14 patients were thought to be not controlled by their attending physicians. BP recordings were obtained every 7.5, 15, or 30 minutes using a noninvasive automatic 24 hour ambulatory BP recorder (Del Mar Avionics). Analysis of 3633 individual BP readings showed that in patients assessed to have antihypertensive control, 6 of 14 pts. had > 10% elevated BP readings, 3 of 14 pts. had > 25% elevated readings, and 2 of 14 pts. had > 50% elevated BP readings. In patients thought not controlled, 9 of 14 pts. had > 10%, 7 of 14 had > 25%, and 5 of 14 had > 50% elevated BP readings.

We find that a physician's clinical assessment of antihypertensive control was in general an accurate predictor of BP measurements obtained during a 24 hour period. However, a substantial proportion of patients thought to be not controlled in fact had predominantly normal blood pressures.

These findings indicate the pitfalls of determining the need for antihypertensive therapy based on a single clinical visit, and demonstrate the usefulness of 24 hour ambulatory blood pressure recordings.

CARDIOMYOPATHY-HYPERTROPHIC
10:30-12:00

HYPERTROPHIC CARDIOMYOPATHY AND VENTRICULAR PRE-EXCITATION.
E.Rowland, M.J.Davies, D.M.Krikler and J.F.Goodwin. Royal Postgraduate Medical School, London W.12 OHS.

Death in hypertrophic cardiomyopathy (HCM) is often sudden, possibly related to paroxysmal arrhythmias. 3 patients (aged 19-64) with HCM had detailed examinations of the conducting system at post-mortem. Two had died suddenly, the third following an intractable atrial arrhythmia. Case 1 had WPW Type B for 25 years and arrhythmias for 15. There was a family history of HCM and she died suddenly while performing strenuous effort. Case 2 who had no evidence of overt pre-excitation also had a strong family history of HCM. She had noticed palpitations for 5 years and died when an atrial arrhythmia induced ventricular fibrillation. Case 3 had remained well until persisting atrial fibrillation had developed which was conducted rapidly to the ventricles (mean ventricular rate 180 bpm): he died one week later.

In all 3 cases the histological picture showed accessory atrioventricular (AV) pathways, these connections showing the typical arrangement of HCM. In case 1 the location of the pathway was on the right side while in the other 2 the pathways were septal.

The presence of accessory AV pathways provides a mechanism for arrhythmias to occur and may explain sudden death in some patients. These appear to be the first cases in whom accessory pathways were shown to consist of HCM tissue: such connections should be sought in all patients with HCM who die suddenly, in case a subset at risk of sudden death can be better identified.

ASYMMETRIC LEFT VENTRICULAR HYPERTROPHY - A STUDY OF ANATOMY AND FUNCTION BY CROSS-SECTIONAL ECHOCARDIOGRAPHY AND RADIONUCLIDE ANGIOGRAPHY
Pravin M. Shah, MD, FACC; Richard D. Taylor, MD; Harvey S. Hecht, MD, FACC; Maylene Wong, MD, Wadsworth VA Medical Center and University of California, Los Angeles, California

Thirty-five patients (pts) with asymmetric left ventricular hypertrophy (ALVH) diagnosed by cross-sectional echocardiography (CSE) were analyzed for regional distribution of hypertrophy and wall motion. Two groups of pts were compared: 19 with systolic anterior motion (SAM) of the mitral valve (Group I) and 16 without (Group II). Distribution of ALVH on CSE was: upper septum (S) (13 pts); mid S (16 pts), upper antero-lateral (AL) wall (5 pts), mid AL (4 pts), lower S and AL (4 pts each), posteroinferior (PI) (2 pts). More than one segment was involved in 17 pts. Distribution of ALVH was similar in the 2 groups. The S, AL and PI walls were analyzed for wall motion as akinetic, hypokinetic, normal or hyperkinetic. Hyperkinesia of AL or PI walls was significantly more prevalent ($p<.05$) in Group I (79%) than in Group II pts (38%).

Equilibrium radionuclide angiography in 12 Group I pts and in 9 Group II pts showed ejection fractions to be $0.85 \pm .09$ and $.76 \pm .09$ ($p<.01$), maximum ejection velocities (volume/second) to be 6.36 ± 1.54 and 5.09 ± 1.24 ($p<0.10$), and average ejection velocities to be 3.05 ± 1.06 and 2.41 ± 0.32 ($p<.10$) respectively.

Thus, ALVH is variable in its distribution. SAM is more frequently associated with hyperkinetic free walls and increased ejection fraction.

OBSTRUCTIVE VERSUS NON-OBSTRUCTIVE SAM: A CRUCIAL DISTINCTION.
Harry Rakowski, MD; Brian W. Gilbert, MD, FACC; Milutin Drobac, MD; Charles Pollick, MD; Derek Boughner, MD; E. Douglas Wigle, MD, FACC; Toronto General Hospital, Toronto, Canada.

Systolic anterior mitral motion (SAM) has recently been called an unreliable marker for dynamic LV outflow tract (LVOT) obstruction (OBST). To test this hypothesis, we reviewed 100 consecutive patients (pts) with SAM on both M-mode and 2-dimensional echo (2DE studies).

Asymmetric septal hypertrophy (ASH), (IVS/PW $\geq$ 1.5/1) was present in 84/100 (84%) pts. Sixty-eight of these 84 pts had resting or provocable OBST with both (i) prolonged SAM-septal contact $>$ 30% of systole (PSSC) on M-mode and (ii) narrowing of the LVOT by the body of the anterior mitral leaflet (AML) on 2DE. In the remaining 16/84 pts without OBST, PSSC was absent and on 2DE, SAM involved only the leaflet tip and/or chordae without significant change after amyl nitrite inhalation.

ASH was absent in 16/100 (16%) pts. One of these pts, with a hyperkinetic heart and OBST after provocation, had PSSC involving the body of the mitral leaflet. In the other 15/16 pts PSSC was absent, with SAM due to chordal and/or leaflet tip motion in 13, and non-leaflet structures in 2.

SAM causing LVOT OBST is characterized by PSSC and 2DE involvement of the body of the AML. Non-OBST SAM does not have PSSC and on 2DE involves only the chordae and/or leaflet tip, not the body of the AML. This distinction helps resolve the current controversial role of SAM in LVOT OBST.

PATTERNS AND SIGNIFICANCE OF THE DISTRIBUTION OF LEFT VENTRICULAR HYPERTROPHY IN A LARGE POPULATION OF PATIENTS WITH HYPERTROPHIC CARDIOMYOPATHY: A WIDE-ANGLE TWO-DIMENSIONAL ECHOCARDIOGRAPHIC STUDY
Barry J. Maron, MD, FACC; John S. Gottdiener, MD; Stephen E. Epstein, MD, FACC, NHLBI, Bethesda, Md.

M-mode echocardiography has shown asymmetric hypertrophy of the ventricular septum (VS) relative to the posterior left ventricular (LV) free wall to be a consistent feature of hypertrophic cardiomyopathy (HCM). However, M-mode echo permits assessment of hypertrophy in only a limited area of the ventricular walls. To better characterize distribution of hypertrophy throughout the entire LV wall, and determine whether different patterns of hypertrophy are of clinical significance, 74 pts with HCM were studied by wide-angle 2-dimensional (2D) echo. Hypertrophy was confined to VS in only 20 pts, but involved both VS and anterolateral LV free wall in 43 pts and selectively involved only the LV free wall in 11 pts. Posterior LV free wall (through which the M-mode beam passes) was usually the least hypertrophied area of the LV. In 46 of the 74 pts hypertrophy was judged to be marked and diffuse, involving LV free wall and/or VS; those pts were compared to 28 pts with mild, localized hypertrophy. Moderate-severe symptoms were more common with diffuse, (38/46, 83%) than with localized hypertrophy (6/28, 21% ; $p<0.001$). LV outflow obstruction was also more common with diffuse (29/46, 63%) than with localized hypertrophy (4/28, 14%, $p<.001$). Hence, 1) 2D echo shows a wide variety of patterns and a greater distribution of hypertrophy in pts with HCM than is appreciated by M-mode echo; 2) while hypertrophy is asymmetric in these pts, it often involves the anterolateral LV free wall and is not usually limited to VS; 3) functional limitation and outflow obstruction are most common in those pts with marked diffuse hypertrophy (ie., with the greatest cardiac mass).

IS NONFAMILIAL ASYMMETRIC SEPTAL HYPERTROPHY A DIFFERENT HISTOLOGICAL DISORDER?

John R. Darsee, MD, Steven Anton, MD, Candace L. Miklozek, MD, Ayten O. Someren, MD. Emory University School of Medicine, Atlanta, Georgia

Both clinical and HLA-tissue typing studies have demonstrated 2 different forms of hypertrophic cardiomyopathy (HCM): a familial (F) variety, and a non-familial (NF) form often found in a hypertensive (H) patient. Since myofiber disarray (MD) is the histological hallmark of the F form of HCM, we wished to determine whether the NF form is also characterized by MD. We studied 91 necropsy hearts, 60 from non-H patients, 28 from H patients, and 3 with the NF form of HCM (who had detailed family studies). Hearts were breadloafed from apex to base in 1 cm transverse sections. The thickness of each anterior and posterior septal border was compared to their respective free wall thicknesses. Sections from the 4 most basal sections were stained and a photographic blowup (x1000) was prepared. The areas of MD were measured by planimetry and expressed as % of the total cross-sectional area of the section examined. Five of the 28 H hearts had asymmetric septal hypertrophy (ASH=septum: free wall >1.5:1) (but ASH was absent in 22 1st degree relatives) as did all 3 with the NF form of HCM, but none of the non-H hearts. All of the 8 hearts with ASH had <3% septal or free wall area occupied by MD, compared to >50% reported in other studies of the F form of HCM. We conclude: 1) MD is not typically present in the NF form of HCM or in H hearts with ASH; and 2) the absence of significant MD is further evidence that at least 2 clinically and histologically distinct forms of HCM exist.

ADVANTAGES OF NITROPRUSSIDE INFUSION IN DIAGNOSIS AND ASSESSMENT OF OUTFLOW OBSTRUCTION IN IDIOPATHIC HYPERTROPHIC SUBAORTIC STENOSIS: IMPROVED ACCURACY AND SAFETY THAN AMYL NITRITE INHALATION

James A. Joye, MD, FACC; Garrett Lee, MD; Douglas Warren, BS; Anthony N. DeMaria, MD, FACC; Dean T. Mason, MD, FACC, University of California, Davis, California.

Pharmacologic maneuvers during cardiac catheterization are useful in establishing the diagnosis and severity of left ventricular outflow (LVO) obstruction in idiopathic hypertrophic subaortic stenosis (IHSS). Since amyl nitrite inhalation may produce sudden profound vasodilation with marked hypotension and tachycardia, an alternative method was investigated using a progressively increasing dose infusion of intravenous nitroprusside (NP) 16-50 µg/min in nine IHSS patients. NP increased peak systolic LVO tract gradient (LVOT grad) from 8 to 62 mm Hg ($p<.001$), decreased mean arterial pressure 92 to 71 mm Hg ($p<.001$) without significant changes in heart rate (78 bpm) or left ventricular end-diastolic pressure (12 mm Hg). In 3 of these patients, amyl nitrite did not increase LVOT grad, whereas NP raised LVOT grad more than 50 mm Hg without adverse effects. Larger doses of NP were required for LVOT grad provocation in patients with little or no resting gradient, and lower NP concentrations for patients with higher existing resting gradients. This study shows that NP is a valuable pharmacologic maneuver in the clinical evaluation of idiopathic hypertrophic subaortic stenosis. Furthermore, since nitroprusside administration is controlled by intravenous infusion, nitroprusside can be appropriately titrated to increase LVOT obstruction, thereby obviating untoward hemodynamic effects while affording greater diagnostic accuracy than amyl nitrite inhalation.

CORONARY SINUS RHYTHM IN DOGS: INDUCTION, RECORDING AND CHARACTERISTICS

Robert J. Hariman, MD, Marvin Cramer, MD, Robert E. Naylor, MD, Brian F. Hoffman, MD. Dept. of Pharmacology, College of Physicians & Surgeons, Columbia University, New York, N. Y.

To study coronary sinus (CS) rhythm in anesthetized dogs, we designed an electrode catheter with ten terminals and a lumen. Unipolar electrograms were recorded through the catheter terminals, placed within and just outside of the CS, and an indifferent electrode on the superior vena cava at 100 µV/cm and a time constant of 0.1 sec. We looked for extracellular potential changes that might result from automatic impulse generation. Stable CS rhythm was induced in three dogs by excision of the sinus node and in five dogs by excision of the sinus node and infusion of epinephrine (1 µg/min) through the catheter into the CS. The presence of CS rhythm was proven by a) recording of a slow negative diastolic slope followed by primary negativity from the CS ostium, and b) the ability to reproduce P waves by pacing the CS ostium, identical to the spontaneous P waves in CS rhythm. Coronary sinus rhythm was characterized by: 1) a short PR interval with an inverted, upright or biphasic P wave recorded through lead II of the electrocardiogram, 2) overdrive suppression following rapid atrial pacing, 3) atrial slowing associated with a decrease in diastolic slope induced by vagal stimulation, and 4) no atrial slowing induced by an intravenous bolus of verapamil (10 mg). This study suggests that CS rhythm is an automatic and "fast response" dependent rhythm, which is modulated by the autonomic nervous system.

DETERMINANTS OF STABILITY OF TACHYCARDIA IN AN EXPERIMENTAL MODEL

Michael B. Simson, MD; Joseph F. Spear, PhD, FACC; E. Neil Moore, DVM, PhD, FACC; John A. Kastor, MD, University of Pennsylvania, Philadelphia, Pa.

The factors leading to spontaneous block and instability of a reentrant tachycardia were studied using both a computer model and 8 dogs having an electronically simulated bypass tract (RV→RA). The bypass tract delay was changed in programmed sequences while AV nodal refractoriness was altered with verapamil. Stability of the bypass tract tachycardia was assessed by noting how rapidly the cycle length changes resulting from a transient alteration in the delay would dampen out as well as the tendency of the bypass tract tachycardia to spontaneous block. There was close agreement between the computer model predictions and experimental results. After a transient change in bypass delay, oscillations of cycle length were noted. The degree of dampening of the oscillations was related to the slope of the AV nodal refractory curve (A-H versus A-A). When the bypass tract tachycardia operated on a steep (slope <-1) portion of the refractory curve, spontaneous oscillations and block occurred. Bypass tract tachycardias terminated spontaneously either with an increase in oscillations or from a cumulative effect of increased AV nodal refractoriness. Conclusions: For stability reentrant arrhythmias must be able to dampen transient perturbations. Reentrant tachycardias are unstable if they contain conducting segments with steep refractory curves.

FUNCTIONAL PROPERTIES OF REENTRANT CIRCUITS DEDUCED FROM DIRECT MYOCARDIAL RECORDING DURING SUSTAINED VENTRICULAR TACHYCARDIA

Glenn Kabell, PhD; Benjamin J. Scherlag, PhD, FACC; Lura Harrison, PhD; Ronald R. Hope, MD, FACC; Ralph Lazzara, MD, FACC, Veterans Adm. and University Hospitals, University of Oklahoma, Oklahoma City, Oklahoma

We used composite electrodes to record regular patterns of electrical activity (RPEA) which bridge diastole during sustained ventricular tachycardia (VT) in dogs. Twenty-three anesthetized dogs were studied 24 or 96 hours after ligation of the left anterior descending coronary artery. ECG, leads II and aVR, His bundle electrograms and composite electrograms from the epicardium overlying the infarct zone (IZ) and normal zone (NZ) were recorded. In some cases electrode catheter recordings from the IZ on the endocardium were also made. Atrial pacing or ventricular pacing induced sustained VT in 19 dogs. The RPEA during diastole was divided into temporal compartments: 1) an initial portion or time of entrance of the impulse into the IZ; 2) a mid-diastolic portion (MDP) or time of slow conduction in the reentrant pathway; 3) terminal portion or exit or impulse into the NZ. Using these criteria we could explain: The spontaneous termination of VT due to Wenckebach-type delay in the exit; inability of pacing to initiate VT because the impulse engaged an inappropriate entrance; 2:1 and 3:1 patterns in the MDP with constant entrance and exit during VT; the occurrence of Torsade de Pointe caused by the transfer of the exit, e.g., from an epicardial to an endocardial site; localization of antiarrhythmic action of procaineamide to the MDP with abolition of VT; alteration in QRS morphology associated with changes in exit configuration. Deductive analysis of RPEA provides new insights into functional properties of reentrant circuits, their relation to the ECG and effects of pharmacologic agents.

DISSOCIATION OF CORONARY ARTERY LIGATION ARRHYTHMIAS AND THE FRACTIONATION OF LOCAL ELECTROGRAMS

C. William Balke, BA; Eleiser Kaplinsky, MD, FACC; Eric L. Michelson, MD; Masahito Naito, MD; and Leonard S. Dreifus, MD, FACC; Jefferson Medical College, Phila., PA

It has been suggested that the degree of fractionation (DF) of local electrograms after experimental acute coronary artery ligation (CAL) is important to the occurrence of malignant ventricular arrhythmias (VA) (≥ 5 ectopic beats/min (VE), ventricular tachycardia (VT), or ventricular fibrillation (VF)). In order to evaluate this hypothesis, a total of 21 dogs underwent one-stage complete CAL of the proximal left anterior descending coronary artery followed by release after 5 min in 10 dogs and after 10 min in 11 dogs. Dogs were allowed to recover 1 hour between each of 3 identical CALs. The DF was defined as the total duration of ventricular activity (normal 15-30 msec) recorded via local intramural plunge electrodes within the distribution of occluded vessels. DF was consistent for each of the 3 CAL periods for both 5 min and 10 min CALs in 16/21(76%) dogs and was consistent for 2 of 3 CAL periods in the remaining 5/21 (24%) dogs.

Maximum DF	No VA	Total VA	VE-VT	VF
Mild (≤ 50 msec)	27/40	13/40	12/40	1/40
N=40 CAL periods	68%	32%	30%	2%
Moderate (> 50-100 msec)	6/19	13/19	10/19	3/19
N=19 CAL periods	32%	68%	53%	15%
Severe (> 100 msec)	1/4	3/4	3/4	0/4
N=4 CAL periods	25%	75%	75%	0%

Conclusions: 1) Although VA were more commonly associated with moderate or severe DF, this was not consistent, and even marked DF could not predict the occurrence of VF. 2) The inconsistent association of DF with the incidence and severity of VA during CAL suggests that the mechanism of CAL-VA cannot be explained solely by electrophysiologic mechanisms dependent on DF.

THE COMPOSITE CARDIAC ELECTROGRAM: FACT OR ARTIFACT?

E. Neil Moore, DVM, PhD, FACC; Joseph F. Spear, PhD, FACC; Michael B. Simson, MD; Eric L. Michelson, MD, University of Pennsylvania, Philadelphia, Pa.

The composite cardiac electrogram (CCE) is the electrical signal generated when multiple electrodes are connected to the input of a single amplifier. It has been suggested that the CCE reflects the overall activation time of the area within which the electrodes are localized. The present experiments demonstrate the limitations of the standard method of recording the CCE. The CCE was compared with the summated signal generated using a custom-built analog summation amplifier system (ASAS). In this system 8 individual bipolar cardiac electrograms are recorded and the output of each differential amplifier summed to provide a single analog signal. The ASAS signal was compared and contrasted when a) each of the 8 individual amplifiers had identical gains; b) when the gain of each amplifier was optimized for best visualization of each bipolar electrogram; c) when the polarity of a single electrode pair was reversed and d) when amplifier filter settings were altered. The standard CCE and the signal from the ASAS with each amplifier having identical gain often resulted in a poor estimation of the overall duration of activation. The degree of fractionation and continuous activity recorded in the CCE or in the ASAS signal could be exaggerated or minimized by electrode interconnections. When the bipolar electrogram of each electrode pair was individually optimized then the ASAS signal gave a reasonable indication of overall cardiac activation. In summary, the composite cardiac electrogram as usually recorded is an unreliable indicator of the duration of cardiac activation.

SUSTAINED VENTRICULAR TACHYCARDIA: ANATOMIC OR FUNCTIONAL BASIS?

Benjamin J. Scherlag, PhD, FACC; Glenn Kabell, PhD; Lura Harrison, PhD; Ronald R. Hope, MD, FACC; Ralph Lazzara, MD, FACC, Veterans Adm. and University Hospitals, University of Oklahoma, Oklahoma City, Oklahoma

Recent studies have associated sustained ventricular tachycardia (VT) and anatomic findings of patches of infarction (I) within normal myocardium (Karagueuzian et al. Circ Res 44: 833, 1979). ECG leads and electrograms from the His bundle, epicardial and intramural areas of the left ventricle were recorded in 31 open-chest anesthetized dogs. Ten dogs with no infarction were studied with ventricular pacing (VP) at 300-360 min. In 1 of 4 normal dogs, sustained VT was induced after intoxication with procaineamide, 80 mg/kg. In 4 of 6, prior to ischemia, VP failed to induce repetitive ventricular responses, whereas after 30 min of LAD occlusion and 10-15 min of stable rhythm following reperfusion, VP induced sustained VT. Twenty-one dogs were studied 4 days after permanent LAD occlusion; 10 were untreated and 11 were given 30 mg/kg methylprednisolone prior to LAD tie. In the untreated group only 2 of 10 showed sustained VT induced by VP whereas 9 of 11 showed sustained VT in the treated group (3 dogs showed spontaneous VT). Sections of myocardium were stained with nitroblue tetrazolium and in both the treated and untreated dogs a viable rim overlying a thicker area of I was found. In both infarcted and non-infarcted hearts, sustained VT was associated with regular patterns of electrical activity bridging diastole in each cardiac cycle during VT. Thus functional alterations induced by ischemia, infarction or drugs, not the presence of the I alone, seem to be the basis of sustained VT. These functional changes are manifest as regular patterns of slow conduction recorded during the diastolic intervals of sustained VT.

LOCALIZATION OF PACING SITES WITHIN INFARCTS BY EPICARDIAL MAPPING

Lura Harrison, PhD; Raymond E. Ideker, MD, PhD; William M. Smith, PhD; Warren M. Smith, MB, ChB, FRACP; Jackie Kasell, Duke University Medical Center, Durham, N.C.

To improve criteria for identifying an arrhythmogenic region from epicardial maps, we examined the relationship between the sites of epicardial breakthrough during pacing and the location of the pacing site within an infarct. Infarction was produced in 5 dogs by LAD occlusion. Epicardial maps were obtained a week later from 50 epicardial electrodes by a computerized system for data acquisition and display. During sinus rhythm earliest left ventricular epicardial excitation appeared at a single region apico-laterally to the infarct. Each dog was then paced from 3-5 sites subjacent to the infarct. During pacing from each location, multiple (mean=3) sites of left ventricular epicardial breakthrough (defined as activation of one electrode earlier than all adjacent electrodes) occurred around the infarct. The earliest site of breakthrough during pacing yielded an estimate of the location of stimulation ranging 0.6-5.3 (mean=2.9) cm from the actual pacing site. In 12 of the 19 cases of pacing, earliest left ventricular breakthrough was at the same apico-lateral site as during sinus rhythm. When the second earliest site of breakthrough was used for these 12 cases, the estimate of the site of stimulation for all 19 cases ranged 0.5-2.6 (mean=1.5) cm from the pacing site. Purkinje spikes recorded from plunge electrodes within the infarct always preceded breakthrough during both sinus rhythm and pacing. We conclude that 1) subendocardial conduction within an infarct occurs along Purkinje pathways, 2) effects of this conduction are seen in sinus rhythm maps, and 3) subtraction of these effects improves localization of ectopic foci from epicardial maps.

INITIATION OF SUSTAINED VENTRICULAR TACHYARRHYTHMIAS IN A MODEL OF CHRONIC INFARCTION: IMPORTANCE OF THE SITE OF STIMULATION.

Eric L. Michelson, MD; Joseph F. Spear, PhD, FACC; E. Neil Moore, DVM, PhD, FACC; University of Pennsylvania and Lankenau Hospital, Philadelphia, Pennsylvania

In a recently developed canine model of chronic infarction sustained ventricular tachyarrhythmias (VT) can be reproducibly initiated using routine methods of programmed electrical stimulation (PES). We evaluated the importance of the site of stimulation to the initiation of ventricular arrhythmias at 5 to 18 sites in 19 dogs during ventricular drive pacing at a cycle length of 300 msec, using unipolar cathodal stimulation at twice diastolic excitability threshold via intramural plunge electrodes. All 19 dogs had inducible sustained VT, vs 0/5 sham-operated controls. Initiation of VT by PES suggested a reentrant mechanism. In individual dogs there were marked disparities in ease of inducibility (ie., number of ventricular extrastimuli (VES) required for initiation). In 6 dogs, single VES from normal sites in close proximity (eg., < 1 cm) to areas of infarction often induced VT whereas even 3 VES from normal sites only 2 cm distant did not. Within areas of infarction there were marked disparities in ease of inducibility at sites only 1-2 mm distant. In addition, transvenous endocardial catheter techniques (9 dogs) often failed (4 dogs) to induce VT in close proximity to sites where VT was initiated using plunge electrodes. The reproducible initiation of more than 3 beats of VT from any one site was a reliable indication of the susceptibility to inducible sustained VT when sufficient sites were evaluated. Thus the importance of the site of stimulation must be considered when PES is applied to the study of ventricular tachyarrhythmias.

TORSADE DE POINTES: ELECTROPHYSIOLOGY ATYPICAL VENTRICULAR TACHYCARDIA

Nguyen Nhon, MD; Ronald R. Hope, MD, FACC; Glenn Kabell, PhD; Benjamin J. Scherlag, PhD, FACC; Ralph Lazzara, MD, FACC; Veterans Adm. Medical Center and University Hospital, University of Oklahoma, Oklahoma City, OK

Ventricular tachycardia (VT) was studied in 60 dogs 1-5 days after myocardial infarction (MI) due to left anterior coronary artery ligation. In addition to the standard ECG, composite and electrode catheters recorded epicardial (epi) and endocardial (endo) potentials from the infarct zone (IZ). Two or more stimuli with a constant interval between stimuli (180-225 msec) were delivered during normal sinus rhythm to the right ventricular outflow tract. Regular VT was initiated in 51 of 60 dogs (85%) and showed uniform QRS morphology with regular patterns of continuous electrical activity in epi (95%) and endo (5%) recordings. Atypical VT or torsade de pointes was seen in 38 of 60 dogs (63%) and was characterized by cyclical changes in QRS morphology. In 60% of dogs showing only regular VT, torsade de pointes was induced after giving procaineamide 5-80 mg/kg or lidocaine 2-8 mg/kg. During torsade de pointes, IZ electrograms showed changing patterns of continuous activity in the epi alone, endo alone, or alternating between epi and endo recordings. In all cases, analysis of electrograms revealed evidence of a reentrant mechanism. Changes in the reentrant pathways were seen prior to changes in QRS morphology and distinguished torsade de pointes from regular VT.

MECHANISMS OF BRADYCARDIA-DEPENDENT ARRHYTHMIAS IN ACUTE MYOCARDIAL ISCHEMIA

Benjamin J. Scherlag, PhD, FACC; Glenn Kabell, PhD; Lura Harrison, PhD, Ronald R. Hope, MD, FACC, Ralph Lazzara, MD, FACC, Veterans Administration and University Hospitals, University of Oklahoma, Oklahoma City, Oklahoma

Bradycardia has been critically implicated in lethal ventricular arrhythmias (VA) during the early phases of myocardial infarction. In 18 anesthetized dogs the left anterior descending (LAD) coronary artery was ligated. ECG leads and electrograms from the His bundle, endocardium, epicardium and intramural zones were recorded in open-chest preparations. Within 15 min after LAD ligation, 15 dogs showed varying degrees of fractionation (Fr) and delay (D) in epicardial or intramural electrograms which preceded the onset of VA. Slowing of the heart rate (40-90/min) by vagal stimulation reduced Fr, D and VA. In contrast, 30 min to 3 hours after LAD ligation slowing of the heart rate (60-90/min) caused ventricular ectopic beats (VEB) which were coupled to the initial beat. Bradycardia (30-45 min) induced VA (2 dogs) sustained ventricular tachycardia (2 dogs) and ventricular fibrillation (2 dogs). In all instances of VA, electrical activation bridging the diastolic intervals between the sinus beats and VEB or between successive VEB were observed in either or both epicardial or intramural zone electrograms. We conclude that in ischemic myocardium, in which Fr and D have stabilized, bradycardia may exacerbate Fr and D thus provoking VEB or lethal ventricular tachycardia and fibrillation. The association of these lethal VA with bridging electrical activity between sinus beats and VEB suggests that reentry is the causative mechanism. Although bradycardia inhibits VA in the first few minutes of ischemia, in the first few hours it may provoke sudden death by inducing lethal VA.

THE EFFECT OF CATECHOLAMINES RELEASED BY TRAINS OF PULSES ON VENTRICULAR VULNERABILITY TO FIBRILLATION

David E. Euler, Ph.D.; Walter C. Randall, Ph.D., FACC,
Loyola University Medical Center, Maywood, Illinois

The ventricular fibrillation threshold (VFT) for a train of pulses is consistently less than the VFT for a single pulse. To determine if local catecholamine release might be one of the factors involved, VFTs were measured in 8 autonomically decentralized dogs. During atrial pacing either a train of 14 pulses (4 msec, 100 Hz, bipolar) or a single pulse (10 msec) was applied to either the right (RV) or left ventricle (LV) during the vulnerable period of every 15th paced cycle. Under control conditions the mean values (mA ± SE) for trains were: RV, 7.0 ± .9; LV, 14.4 ± 1.6. Single pulses required a significantly greater amount of current ($p<0.01$). Following beta-adrenergic blockade with propranolol (.5 mg/kg), the relative changes (% increase ± SE) in the train VFTs were: RV, 225 ± 31; LV, 193 ± 26. The changes in single pulse VFTs were significantly less: RV, 32 ± 11; LV, 29 ± 6 ($p<0.01$). In another 8 dogs, subjected to chronic cardiac denervation, the absolute VFTs for trains were: RV, 18.6 ± 1.6 mA; LV, 34.5 ± 3.6 mA. These VFTs were not different from the train VFTs of the beta-blocked, innervated hearts ($p>0.05$). Furthermore, the VFTs of the chronically denervated hearts were not altered by propranolol ($p>0.05$). In the control dogs, a strain gauge arch attached close to the stimulation site showed a marked augmentation of local contractile force during the delivery of a series of pulse trains. The positive inotropic responses were eliminated by either propranolol or chronic cardiac denervation. The data indicate that trains of pulses release local stores of catecholamines which exert a profound influence on the amount of current necessary for a train to evoke fibrillation.

DEVELOPMENTAL SYMPATHETIC EFFECTS ON VULNERABILITY TO VENTRICULAR FIBRILLATION IN PUPPIES

Fany A. Kralios, M.D.; C. Kay Millar, M.D.;
University of Utah, Salt Lake City, Utah

To investigate the effect of previously shown asymmetrical development of cardiac sympathetic nerves (CSNs) on vulnerability to fibrillation, 43 puppies of 6 age groups 1-6 weeks were studied. Ventricular fibrillation threshold (VFT) determinations were obtained in the control state and during stimulation of CSNs, using the single pulse scanning technique. Compared to the control values, left stellate ganglion (SG) stimulation raised VFT linearly from 0.9 ± 0.7mA in the first week to 5.6 ± 2.7mA in the sixth ($\Delta VFTmA = 0.6 + 0.91 \cdot week$, $r = 0.95$, $p<0.01$). Right SG stimulation increased VFT more than the left in the first week (3.0 ± 1.1mA) but effects did not increase during subsequent weeks (3.25 ± 1.9mA) in the sixth. In contrast, stimulation of the more regionally distributed left ventrolateral nerve changed VFT compared to the control values, linearly from -1.0 ± 0.4mA in the first week to -3.9 ± 2.3mA in the sixth ($\Delta VFTmA = -0.34 - 0.62 \cdot week$, $r = -0.98$, $p<0.02$). Other regionally distributed distal CSNs had no consistent effect in any week. Findings suggest that sympathetic effect on vulnerability to fibrillation during the first week is minimal, but progressively increases through the sixth. This is probably due to the poor functional development of CSNs at birth and their subsequent maturation. The opposite arrhythmiogenic effects of SG and distal CSN stimulation may be due to more diffuse distribution of the SG which may have a more homogeneous effect on recovery properties than that of the more regionally distributed ventrolateral nerve.

ACKNOWLEDGMENT

The Program Committee gratefully acknowledges the assistance of the following individuals in the selection of abstracts for presentation at the 29th Annual Scientific Session.

SUBJECT INDEX: ABSTRACTS

Acetyl strophanthidin
Comparison of the response of depressed and normal myocardium to acetyl strophanthidin, 413
Adenosine triphosphate
Characterization of myocardial ATP degradation following coronary artery occlusion, 415
Adriamycin
Adriamycin cardiotoxicity—assessment of late left ventricular dysfunction by radionuclide cineangiography, 410
Anthracycline heart: analysis of 69 patients treated with either adriamycin or daunorubicin showing a lack of correlation between clinical and morphologic findings, 396
Effect of first-dose adriamycin on the cyclic nucleotide levels and function of the human myocardium, 416
Reversibility of adriamycin induced reduction in myocardial thallium-201 uptake by intravenous digoxin, 482
Afterload
Afterload reduction therapy for chronic severe aortic insufficiency: beneficial effects during rest and exercise, 441
Beneficial hemodynamic and energetic effects of afterload reduction with prostaglandin E-1 in patients with severe chronic congestive heart failure, 438
Long term afterload reduction therapy in children, 429
Age
Age related changes in propensity to ventricular fibrillation in puppies, 444
Age related changes in the left ventricular ejection fraction response to exercise, 391
Amrinone
Characterization of the inotropic and biochemical properties of amrinone—a novel cardiotonic agent, 412
Inotropic effect of amrinone in severe congestive heart failure: lack of attenuation with sequential doses, 433
Amyl nitrite
Advantages of nitroprusside infusion in diagnosis and assessment of outflow obstruction in idiopathic hypertrophic subaortic stenosis: improved accuracy and safety than amyl nitrite inhalation, 492
Amyloid heart disease
Amyloid heart disease: a simulator of coronary, (myocardial infarction, sudden death), pericardial, (constriction and/or effusion), valvular (floppy atrioventricular valves) and myocardial (hypertrophic cardiomyopathy) heart diseases, 475
Aneurysm
Incidence of thrombus in left ventricular aneurysm; sensitivity of the angiogram and relation between anticoagulation and embolization, 423
Resection of ventricular aneurysm modified by electrophysiologic assessment in patients with intractable ventricular tachycardia and left ventricular aneurysm, 417
Sensitivity and specificity of two-dimensional echocardiography in the detection of left ventricular aneurysms, 436
Angina pectoris
See also Chest pain; Coronary artery disease
Adrenergic responsiveness following abrupt propranolol withdrawal in patients with angina pectoris, 438
Antianginal action of verapamil—a controlled study, 389
Comparison of twice daily and four times daily therapy with propranolol in angina pectoris, 478
Do beta blocking agents prevent the more rapid onset of effort angina during the postprandial state? 438
Dose response and duration of action of oral isosorbide dinitrate during sustained therapy in angina pectoris, 478
Effectiveness of combined verapamil and nitrate therapy in Prinzmetal's variant angina, 439
Efficacy of diltiazem in variant angina, 439
Efficacy of nifedipine in the intermediate syndrome refractory to propranolol and nitrate therapy, 390
Ergonovine stress test: a provocative test for diffuse esophageal spasm or variant angina? 440
Frequency of myocardial infarction and sudden death in 44 variant angina patients: a high risk ischemic heart disease subset, 454
Frequency of provocated coronary artery spasm in 273 patients with chest pain, 390
Increased levels of thromboxane A_2 in peripheral and coronary circulation in patients with angina pectoris, 454
Increased platelet prostaglandin generation and abnormal platelet sensitivity to prostacyclin and thromboxane A_2 in angina pectoris, 454
Influence of bypass surgery on mortality and morbidity in stable angina: a prospective randomized study, 455
Long-term results of coronary artery bypass for unstable angina: mortality, myocardial infarction and angina, 419
Mechanism of the beneficial effect of intra-aortic balloon pumping in patients with refractory angina, 478
Medical vs. surgical therapy: quality of life after 5 years, 418
Myocardial cell damage during vasospastic anginal attacks with promptly reversible electrocardiographic changes, 455
Use of noninvasive clinical parameters to characterize prognosis in patients with angina pectoris, treated medically or surgically, 456
Variability of treadmill exercise testing results in patients with angina pectoris, 469
Angiocardiography
Adriamycin cardiotoxicity—assessment of late left ventricular dysfunction by radionuclide cineangiography, 410
Asymmetric left ventricular hypertrophy—a study of anatomy and function by cross-sectional echocardiography and radionuclide angiography, 491
Axial angiography in atrioventricular canal malformations: anatomical-angiographic study, 428
Biplane apex echocardiography versus biplane cineangiography in the assessment of left ventricular volume and function: validation by direct measurements, 471
Comparative efficacy of cross-sectional echocardiography and gated equilibrium radionuclide angiography for assessing left ventricular size and performance, 403
Comparison of radionuclide and contrast techniques in assessing ejection fraction at rest and during exercise, 422
Contribution of interventricular septal wall motion to right and left ventricular function: visualization by biventricular angiography, 397
Detection and quantitation of atrial shunts in adults by gated radionuclide angiography, 409
Follow-up of patients with chest pain and normal coronary arteriography, 447
Inability to detect coronary artery disease at rest by patterns of ventricular emptying using contrast angiography and radionuclide angiography, 409
Incidence of thrombus in left ventricular aneurysm; sensitivity of the angiogram and relation between anticoagulation and embolization, 423
Left ventricular diastolic performance during exercise in coronary artery disease: assessment of peak filling rate with first pass radionuclide angiography, 408
Radionuclide angiographic evaluation of left ventricular performance during ventricular pacing, 458

Right ventricular function and angiography in patients with right ventricular tachycardia without ischemic heart disease, 405
Right ventricular volume: analysis by equilibrium radionuclide angiography in normal subjects and patients with coronary disease, 398
Sensitivity and specificity of exercise radionuclide angiography in detecting coronary disease, 408
Thallium-201 stress myocardial scintigraphy: comparison of multiple pinhole tomography with planar imaging in the assessment of patients undergoing coronary arteriography, 481
Two-dimensional echo sector angiographic diagnosis of ventricular septal defect following acute myocardial infarction, 436

Anthracycline
Anthracycline heart: analysis of 69 patients treated with either adriamycin or daunorubicin showing a lack of correlation between clinical and morphologic findings, 396

Antiarrhythmic therapy
Abolition of ventricular arrhythmias during chronic oral therapy with encainide in man, 451
Clinical significance of the ECG interval prolongation accompanying effective encainide therapy, 473
Control of ventricular rate in paroxysmal supraventricular tachycardia and atrial flutter-fibrillation with intravenous verapamil: a double blind randomized crossover study, 452
Kinetics of antiarrhythmic effects of bretylium: correlation with myocardial drug concentrations, 474
Long term therapy with tocainide, 452
Modification of ventricular tachycardia by procainamide, 452
Paradoxical acceleration of ventricular tachycardia by group II antidysrhythmics, 451
Prediction of effects of oral aprindine utilizing intravenous aprindine, 451
Temporal dispersion of refractoriness: lack of correlation with antiarrhythmic efficacy in a model of chronic infarction, 474

Anticoagulation
Incidence of thrombus in left ventricular aneurysm; sensitivity of the angiogram and relation between anticoagulation and embolization, 423

Antiplatelet drugs
Effects of an antiplatelet drug on myocardial ischemia in patients with coronary artery disease, 424

Aorta
Assessment of left ventricular function by determination of maximum acceleration of blood flow in the aorta using continuous Doppler ultrasound, 398
Responsiveness of atherosclerotic rabbit aorta to adrenergic and cholinergic stimulation, 454

Aorta, thoracic
Two-dimensional echocardiographic recognition of the descending thoracic aorta: value in differentiating pericardial from pleural effusions, 401

Aortic dissection
Long-term survival for 184 patients with treated aortic dissection, 489

Aortic insufficiency
Afterload reduction therapy for chronic severe aortic insufficiency: beneficial effects during rest and exercise, 441
Importance of pre-operative wall stress in predicting regression of left ventricular dilatation in chronic aortic insufficiency, 476
Late survival after valve replacement for severe isolated aortic incompetence, 440
Mechanism of improved cardiac performance with afterload reduction in aortic insufficiency, 410

Aortic regurgitation
Systolic and diastolic left ventricular function in patients with aortic regurgitation before and after bioprosthetic valve replacement, 441

Aortic root
Early detection of aortic root abnormalities in ankylosing spondylitis by two-dimensional echocardiography, 441

Aortic stenosis
Doppler cardiographic assessment of severity of aortic and mitral valve stenosis, 437
Extended result after operation for congenital aortic stenosis, 449
Failure of diastolic abnormalities to regress after correction of aortic stenosis: a case for earlier operation? 487
Hemodynamic results of repeat valvulotomy for aortic stenosis in children, 449
Natural history of unoperated aortic stenosis: hemodynamic progression, 440
Selection criteria for echocardiographic assessment of left ventricular pressure and peak gradient in patients with valvular aortic stenosis, 471

Aprindine
Management of refractory ventricular tachycardia with aprindine, 445
Prediction of effects of oral aprindine utilizing intravenous aprindine, 451

Arrhythmias
See also specific type
Abbreviated rapid onset exercise stress testing for the exposure of ventricular arrhythmia, 420
Abolition of ventricular arrhythmias during chronic oral therapy with encainide in man, 451
Atrial enlargement can cause arrhythmias without altering transmembrane potentials, 426
Cardiac rhythm after the Mustard operation for transposition of the great arteries, 430
Cardiac rhythm in sudden infant death syndrome, 431
Comparative effects of verapamil and nifedipine on reactive hyperemia, and ventricular arrhythmias during coronary artery reperfusion, 461
Dissociation of coronary artery ligation arrhythmias and the fractionation of local electrograms, 493
Hospital recurrence of ventricular fibrillation in acute ischaemic heart disease, 462
Hypertrophic cardiomyopathy and ventricular pre-excitation, 491
Initiation of sustained ventricular tachyarrhythmias in a model of chronic infarction: importance of the site of stimulation, 494
Lethal late consequences of small infarcts, 460
Mechanisms of bradycardia-dependent arrhythmias in acute myocardial ischemia, 494
Mitral regurgitation in mitral valve prolapse: detection by pulsed Doppler echocardiography versus angiography and cardiac auscultation. Correlation with cardiac arrhythmias by ambulatory monitoring, 442
Protective effect of aspirin following acute coronary artery occlusion, 424
Reperfusion arrhythmias: differential effect of lidocaine on reentry and enhanced automaticity, 474
Repetitive ventricular responses in patients with life-threatening ventricular arrhythmias, 406
Severe ventricular arrhythmias in patients late after aortic valve replacement, 441
Torsade de pointes: electrophysiology atypical ventricular tachycardia, 494
Ventricular arrhythmias and ventricular fibrillation in acute myocardial infarction, 462

Arteriography
See Angiocardiography

Aspirin
Modification of platelet function by aspirin and dipyridamole across the myocardial vascular bed in coronary disease patients, 424
Protective effect of aspirin following acute coronary artery occlusion, 424

Atherosclerosis
Responsiveness of atherosclerotic rabbit aorta to adrenergic and cholinergic stimulation, 454

Athletes
Left ventricular function at rest and during exercise in marathon runners, 431
Sudden death while running in conditioned runners: coronary disease is the culprit, 423

Atria
Atrial enlargement can cause arrhythmias without altering transmembrane potentials, 426
Electrophysiology of right atrial hypertrophy in children, 426

Atrial flutter-fibrillation
Control of ventricular rate in paroxysmal supraventricular tachycardia and atrial flutter-fibrillation with intravenous verapamil: a double blind randomized crossover study, 452

Atrial septal defect
Decreased shunt flow in acute ventricular septal defect using 15-methyl-prostaglandin $F_{2\alpha}$ as a pulmonary constrictor, 462
Evaluation of right heart function in adults with atrial septal defect using gated cardiac blood pool scanning, 409

Atrioventricular canal defects
Axial angiography in atrioventricular canal malformations: anatomical-angiographic study, 428

Atrioventricular node
Atrio-ventricular nodal "memory" studied by random atrial stimulation, 459

Atrium, left
Cor triatriatum (subdivided left atrium) anatomy, hemodynamics, surgery, and late followup of twenty-one patients, 450

Atrium, right
Evaluation of right heart function in adults with atrial septal defect using gated cardiac blood pool scanning, 409
Beta adrenergic blocking agents
Do beta blocking agents prevent the more rapid onset of effort angina during the postprandial state? 438
Pulmonary effects of a "cardioselective" beta blocker, 437
Bifascicular block
Significance of H-V interval in 515 patients with chronic bifascicular block, 405
Blalock-Taussig shunt
Use of carotid artery flow (CAF) patterns as assessed by Doppler ultrasonography for the noninvasive evaluation of Blalock-Taussig shunt (BTS) patency, 429
Blood flow
Assessment of left ventricular function by determination of maximum acceleration of blood flow in the aorta using continuous Doppler ultrasound, 398
Effects of digoxin on left ventricular performance and myocardial blood flow distribution during isometric exercise in coronary disease, 432
First derivative of diastolic aortic root motion as a measure of transmitral flow, 436
Quantitation of regional myocardial blood flow by positron emission tomography, 465
Selective vulnerability of the papillary muscles to sequential blood flow changes induced by isoproterenol, 477
Use of carotid artery flow (CAF) patterns as assessed by Doppler ultrasonography for the noninvasive evaluation of Blalock-Taussig shunt (BTS) patency, 429
Blood flow, coronary
Atrial hyperemia and ischemia during acute mitral regurgitation, 477
Coronary critical closing pressure during control and maximal vasodilation, 477
Effect of coronary blood flow and site of injection on ^{99m}Tc-PYP detection of early canine myocardial infarcts, 464
Effects of intra-aortic balloon pumping on regional and total coronary flow in patients with coronary disease, 395
Increased levels of thromboxane A_2 in peripheral and coronary circulation in patients with angina pectoris, 454
Relation of treadmill exercise results to flow-limitation and perfusion-size of the affected coronary artery, 469
Relationship of coronary flow to Tl-201 redistribution, 480
Blood platelets
Identification of left ventricular thrombi in humans using Indium-111 labelled autologous platelets, 463
Increased platelet prostaglandin generation and abnormal platelet sensitivity to prostacyclin and thromboxane A_2 in angina pectoris, 454
Modification of platelet function by aspirin and dipyridamole across the myocardial vascular bed in coronary disease patients, 424
Physical conditioning reduces epinephrine-induced platelet aggregation following myocardial infarction, 425
Quantitation of platelet deposition in Gore-Tex femoral artery implants in the canine model and its reduction with dipyridamole and prostacyclin, 424
Blood pool scanning
Determination of absolute left ventricular volume from gated blood pool imaging with an attenuation corrected count rate method, 407
Evaluation of right heart function in adults with atrial septal defect using gated cardiac blood pool scanning, 409
Multiple gated bloodpool cardiac scan (MUGA) during right atrial pacing (RAP): a sensitive method to detect myocardial ischemia, 408
Viewer specified projection: a new method of computer display of LAO acquired gated blood pool data in any projection desired, 407
Blood pressure
See also Hypertension; Hypotension
Time course study of blood pressure in children after three years—Bogalusa Heart Study, 446
Verification of physician assessment of antihypertensive therapy by ambulatory blood pressure recording, 490
Blood pressure, coronary
Coronary critical closing pressure during control and maximal vasodilation, 477
Blood pressure monitoring
Use of ambulatory blood pressure monitoring in the evaluation of patients with borderline hypertension, 446
Bogalusa Heart Study
Time course study of blood pressure in children after three years—Bogalusa Heart Study, 446
Brain
Digoxin-quinidine interaction: increased digoxin brain concentration, 453
Bretylium tosylate
Kinetics of antiarrhythmic effects of bretylium: correlation with myocardial drug concentrations, 474
Bundle branch block
Significance of H-V interval in 515 patients with chronic bifascicular block, 405
Calcification
Predictive accuracy of coronary artery calcification and positive exercise test in asymptomatic non-hyperlipidemic men for coronary artery disease, 400
Calcium
Effect of antihypertensive therapy on calcium transport by cardiac sarcoplasmic reticulum of spontaneously hypertensive rats (SHRs), 490
Captopril
Oral captopril in ambulatory management of severe congestive heart failure: sustained beneficial effects on ventricular function with 6 months therapy shown by cardiac catheterization, nuclear scintigraphy, echography, treadmill exercise and symptomatology, 411
Carbon dixoide
Significance of the late fall in myocardial pCO_2 following acute coronary occlusion, 416
Cardiac arrest
Electrophysiologic findings in patients suffering cardiac arrests, 406
Cardiac catheterization
New ultrasound technique for assessment of femoral vascular anatomy before and after cardiac catheterization (CC) in children and infants, 466
Cardiac conduction
Characteristic alteration of the retrograde atrial activation sequence in patients with dual atrioventricular nodal pathway conduction, 404
Differential effect of verapamil in overt and concealed WPW syndrome: new evidence from intracardiac recordings, 453
Dual atrioventricular nodal pathway conduction—a common electrophysiological phenomenon in children without arrhythmias, 430
Effect of lidocaine on the rate of atrioventricular junctional escape pacemakers, 451
Effects of hyperkalemia on sinus node function: sino-ventricular conduction and sino-atrial reentry, 425
Hereditary progressive cardiac conduction and muscle disease: clinical staging, 396
Lethal late consequences of small infarcts, 460
Localization of pacing sites within infarcts by epicardial mapping, 494
Mechanisms of termination of aberrant conduction due to retrograde concealed penetration of the bundle branches during circus movement tachycardia utilizing an accessory pathway, 405
Reperfusion arrhythmias: differential effect of lidocaine on reentry and enhanced automaticity, 474
Role of elevated extracellular K^+ activity in conduction slowing during acute myocardial ischemia, 460
Ventricular refractoriness at twice diastolic excitability threshold: an unpredictable source of variability, 427
Cardiac output
Cardiac output during ventricular fibrillation in the coughing dog, 445
Cardiac transplants
Non-invasive monitoring of cardiac transplants, 410
Cardiomyopathy
Congestive cardiomyopathy patients as heart-transplant recipients, 488
Diagnosis of Chagas cardiomyopathy by thallium 201 perfusion imaging, 396
Effect of verapamil on left ventricular relaxation and filling in hypertrophic cardiomyopathy, 393
Hereditary progressive cardiac conduction and muscle disease: clinical staging, 396
Hypertrophic cardiomyopathy and ventricular pre-excitation, 491
Hypertrophic obstructive cardiomyopathy—19-year postsurgical survivorship, 489
Importance of left ventricular filling in differentiating constrictive pericarditis vs. restrictive cardiomyopathy, 475
Is nonfamilial asymmetric septal hypertrophy a different histological disorder? 492
Patterns and significance of the distribution of left ventricular hypertrophy in a large population of

patients with hypertrophic cardiomyopathy: a wide-angle two-dimensional echocardiographic study, 491
Carotid artery
Use of carotid artery flow (CAF) patterns as assessed by Doppler ultrasonography for the noninvasive evaluation of Blalock-Taussig shunt (BTS) patency, 429
Catecholamines
Effect of catecholamines released by trains of pulses on ventricular vulnerability to fibrillation, 495
Cells
Conditions for liposome uptake by myocardial cells, 414
Chagas' disease
Diagnosis of Chagas cardiomyopathy by thallium 201 perfusion imaging, 396
Chest pain
See also Angina pectoris
Follow-up of patients with chest pain and normal coronary arteriography, 447
Relief of chest pain and reduction of Q-wave evolution in acute myocardial infarction by large dose sublingual nitroglycerin, 483
Cholesterol
Angiographic correlation of coronary artery disease with high density lipoprotein cholesterol in asymptomatic men, 447
Cigarettes, coffee, and other associations with HDL cholesterol in the general population, 447
Total cholesterol/high density lipoprotein ratio correlates with the presence but not severity of coronary artery disease, 447
Cholinergic blockade
Evidence supporting a direct cholinergic effect on ventricular muscle refractory period in man, 473
Cigarettes
Cigarettes, coffee, and other associations with HDL cholesterol in the general population, 447
Cineangiography
See Angiocardiography
Coarctation of aorta
Management of the infant with coarctation of the aorta and ventricular septal defect, 450
Coffee
Cigarettes, coffee, and other associations with HDL cholesterol in the general population, 447
Collagen
Alterations in collagen of porcine valve heterografts in place from 3 to 94 months: the cause of leaflet calcific deposits and of perforations and tears, 487
Concordance between mitral valve prolapse and abnormal collagen synthesis in phenotypically expressed and occult Ehlers Danlos syndrome, 442
Computers
Computer analysis of thallium-201 myocardial perfusion scintigraphy: circumferential mapping, 481
Computerized analysis of biplane left ventriculography: intra-method variation in the ability to identify and quantify regional wall motion abnormalities, 397
Computerized image processing in cross-sectional echocardiography, 403
Multiple gated acquisition thallium scintigrams with computer enhancement: improved sensitivity in asymptomatic men with abnormal treadmill tests, 463
Viewer specified projection: a new method of computer display of LAO acquired gated blood pool data in any projection desired, 407
Congenital disease
Mitral valve prolapse: possible manifestation of a congenital neuro-ecto-mesodermal histodysplasia, 443
Congenital heart defects
Axial angiography in atrioventricular canal malformations: anatomical-angiographic study, 428
Cardiac rhythm after the Mustard operation for transposition of the great arteries, 430
Comprehensive assessment of atrio-ventricular valve morphology in single ventricle, 428
Cor triatriatum (subdivided left atrium) anatomy, hemodynamics, surgery, and late followup of twenty-one patients, 450
Electrophysiologic consequences of Mustard repair of transposition of the great arteries, 430
Extended result after operation for congenital aortic stenosis, 449
Factors affecting real-time cross-sectional (2D) echocardiographic (ECHO) imaging of ventricular septal defects (VSD), 467
Hemodynamic results of repeat valvulotomy for aortic stenosis in children, 449
Intraatrial repair of transposition of the great arteries in infancy, early and late results, 448
Management of the infant with coarctation of the aorta and ventricular septal defect, 450
Pulmonary vascular bed (PVB) in patients with tetralogy of fallot (TOF) with or without pulmonary atresia, 429
Recurrent tachycardia associated with Ebstein's anomaly, 405
Right ventricular growth in pulmonary atresia with intact ventricular septum, 448
Systemic ventricular function in patients with congenital heart disease repaired during infancy, 468
Transposition of the great vessels with ventricular septal defect: long term surgical results, 448
Truncus arteriosus with pulmonary vascular obstructive disease—medical vs surgical management, 450
Two dimensional echocardiographic features of corrected transposition, 466
Use of carotid artery flow (CAF) patterns as assessed by Doppler ultrasonography for the noninvasive evaluation of Blalock-Taussig shunt (BTS) patency, 429
Congestive heart failure
Activation of vasoconstrictor mechanisms during vasodilator therapy: a factor modifying drug response in heart failure, 433
Can hydralazine therapy for severe, chronic, heart failure be safely and effectively initiated outside the hospital? 410
Comparative effects of oral pirbuterol versus intravenous dobutamine on left ventricular function and energetics in chronic congestive heart failure: unique advantage of pirbuterol due to vasodilator and inotropic properties, 412
Effects of dobutamine on myocardial oxygen consumption and left ventricular function in patients with chronic heart failure due to ischemic heart disease, 479
Inotropic effect of amrinone in severe congestive heart failure: lack of attenuation with sequential doses, 433
Is the vasoconstriction of chronic heart failure related to the renin angiotensin system? 411
Long term trimazosin therapy in cardiac failure, 411
Oral captopril in ambulatory management of severe congestive heart failure: sustained beneficial effects on ventricular function with 6 months therapy shown by cardiac catheterization, nuclear scintigraphy, echography, treadmill exercise and symptomatology, 411
Sympathetic and renin response to orthostasis in congestive heart failure, 433
Coronary arteries
Complete aortic root and valve replacement with reimplantation of the coronary arteries—? solution to tunnel obstruction, 488
Follow-up of patients with chest pain and normal coronary arteriography, 447
Improved echocardiographic technique for examining the left main coronary artery, 435
Long term followup of patients manifesting severe ST depression during maximal Bruce exercise testing and having angiographically normal coronary arteries, 419
Coronary arteritis
Heart in polyarteritis nodosa: a clinicopathologic study of 36 patients, 395
Coronary artery disease
Angiographic correlation of coronary artery disease with high density lipoprotein cholesterol in asymptomatic men, 447
Antianginal action of verapamil—a controlled study, 389
Body surface distribution of ST depression during exercise testing in patients with coronary artery disease, 469
Chronotropic incompetence in stress testing in patients with coronary artery disease, 401
Combined treadmill-scintiscan score to predict the presence and extent of coronary artery disease, 463
Coronary artery constriction and hemodynamic responses during isometric handgrip in patients (pts) with coronary artery disease (CAD), 431
Coronary heart disease in 48 autopsy patients 30 years of age and younger, 422
Cross-sectional echocardiographic

evaluation of coronary artery abnormalities in children, 467
Detection and localization of ≥40% coronary stenosis in patients: comparison of exercise and dipyridamole thallium-201 myocardial imaging, 399
Detection of multivessel disease by exercise thallium-201 scintigraphy, 482
Early post-myocardial infarction treadmill stress testing: an accurate discriminator of multi and single vessel coronary disease, 421
Effect of crossovers on estimates of survival in medically treated patients with coronary artery disease, 455
Effect of nifedipine on exercise tolerance in coronary artery disease, 439
Effects of an antiplatelet drug on myocardial ischemia in patients with coronary artery disease, 424
Effects of digoxin on left ventricular performance and myocardial blood flow distribution during isometric exercise in coronary disease, 432
Effects of intra-aortic balloon pumping on regional and total coronary flow in patients with coronary disease, 395
Effects of verapamil on coronary hemodynamics and vasomobility in patients with coronary artery disease, 389
Efficacy of nifedipine in the intermediate syndrome refractory to propranolol and nitrate therapy, 390
Exercise cross sectional echocardiographic diagnosis of coronary artery disease, 404
Fixed vs. non-fixed coronary stenosis: the response to a fall in coronary pressure, 390
Frequency of provocated coronary artery spasm in 273 patients with chest pain, 390
Healing of coronary artery intimal dissection after percutaneous transluminal angioplasty, 423
Heavy mediastinal irradiation causing severe coronary narrowing in patients 15 to 33 years of age: a poorly appreciated cause of coronary heart disease in young people, 476
Heterogeneity of myocardial metabolism: evidence of lactate production during net chemical extraction in man, 401
Improved myocardial perfusion and function following percutaneous transluminal coronary angioplasty (PTCA), 478
Inability to detect coronary artery disease at rest by patterns of ventricular emptying using contrast angiography and radionuclide angiography, 409
Integrated format for multiple testing in coronary artery disease, 463
Localization of single vessel coronary artery disease by exercise electrocardiography and thallium scanning, 422
Mechanisms of increased R wave magnitude with exercise in patients with coronary artery disease, 420
Modification of platelet function by aspirin and dipyridamole across the myocardial vascular bed in coronary disease patients, 424
Natural history study of asymptomatic coronary disease, 422
Patterns of disturbed myocardial perfusion in patients with coronary artery disease, 464
Predictive accuracy of coronary artery calcification and positive exercise test in asymptomatic non-hyperlipidemic men for coronary artery disease, 400
Predictive accuracy of positive exercise electrocardiogram: relation of heart rate at which ischemic response initially appears to presence of coronary artery disease, 470
Predictive and prognostic value of exertional hypotension, 456
Preservation of ischemic myocardium with glucose-insulin-potassium in patients with isolated left anterior descending stenosis, 484
Progression and regression of coronary artery disease in post-infarction patients under age 40, 479
Quantification of the exercise test that best maximizes the prediction of severe coronary disease, 470
Refractory ergonovine induced coronary vaspspasm: importance of intracoronary nitroglycerin, 390
Relation of treadmill exercise results to flow-limitation and perfusion-size of the affected coronary artery, 469
Reproducibility of symptoms, cardiac and electrocardiographic responses during symptom-limited exercise in preoperative coronary patients, 469
Right ventricular volume: analysis by equilibrium radionuclide angiography in normal subjects and patients with coronary disease, 398
Sensitivity and specificity of exercise radionuclide angiography in detecting coronary disease, 408
Specificity, sensitivity and accuracy of the nitroglycerin ventriculogram as a predictor of surgically reversible wall motion abnormalities, 399
Subclinical abnormalities of left ventricular function in coronary patients detected by 2-D echo, 404
Sudden death while running in conditioned runners: coronary disease is the culprit, 423
Systemic and coronary hemodynamic effects of intravenous diltiazem in patients with coronary artery disease, 439
Thallium-201 exercise scintigraphy for detection of multivessel disease in patients with prior inferior myocardial infarction, 398
Total cholesterol/high density lipoprotein ratio correlates with the presence but not severity of coronary artery disease, 447
Wall thickness in single vessel coronary disease: evidence against a causal association of ischemia and hypertrophy, 423

Coronary care, mobile
Effect of a mobile coronary care unit on mortality in acute myocardial infarction. A randomized study, 461
Reduction of myocardial infarction mortality by prudent patient activation of mobile coronary care, 461

Coronary collateral vessels
Coronary collateral circulation—"a function-less quirk?", 455
Effect of coronary collaterals on exercise performance, 392

Coronary occlusion
Can intracardiac volume changes adequately explain R-wave variations associated with acute coronary ischemia? 477
Cellular electrophysiology of a mottled infarct in dogs 4 and 15 days after coronary occlusion and reperfusion, 426
Characterization of myocardial ATP degradation following coronary artery occlusion, 415
Correlation of the incidence of reperfusion ventricular arrhythmias with the duration of experimental coronary artery ligation, 460
Dissociation of coronary artery ligation arrhythmias and the fractionation of local electrograms, 493
Effects of nefedipine on ischemic myocardium: preservation of contraction during partial coronary occlusion, 485
Myocardial cyclic adenosine monophosphate and high energy phosphates in ventricular vulnerability to fibrillation in the isolated rat heart after coronary artery ligation, 461
No-reflow phenomenon: not a time-limiting factor for reperfusion following coronary occlusion, 394
Prediction of biochemical derangement in ischemic myocardium following experimental coronary artery occlusion, 415
Protective effect of aspirin following acute coronary artery occlusion, 424
Reversal of propranolol induced myocardial depression during partial and total coronary occlusion by nitroglycerin, 437
Significance of the late fall in myocardial pCO_2 following acute coronary occlusion, 416

Coronary perfusion
Evaluations of pre- and postoperative myocardial perfusion by thallium 201 graded exercise testing, 456
Improved cardiac function during coronary perfusion with low oxy-hemoglobin affinity human red blood cells, 479

Coronary reperfusion
Comparative effects of verapamil and nifedipine on reactive hyperemia, and ventricular arrhythmias during coronary artery reperfusion, 461
Correlation of the incidence of reperfusion ventricular arrhythmias with the duration of experimental coronary artery ligation, 460
Effect oftransient ischemia with reperfusion on thallium clearance from the myocardium, 480
Effects of pulsatile and nonpulsatile reperfusion on the post-ischemic myocardium, 394
No-reflow phenomenon: not a time-limiting factor for reperfusion following coronary occlusion, 394
Reperfusion arrhythmias: differential effect of lidocaine on reentry and enhanced automaticity, 474

Coronary sinus
Coronary sinus rhythm in dogs: induction, recording and characteristics, 492

Coronary spasm
Coronary osstruction in anterior myocardial infarction: thrombus or spasm? 483
Frequency of provocated coronary artery spasm in 273 patients with chest pain, 390
Influence of ergonovine-induced coronary artery spasm on vulnerability to ventricular fibrillation, 455
Refractory ergonovine induced coronary vaspspasm: importance of intracoronary nitroglycerin, 390
Cor triatriatum
Cor triatriatum (subdivided left atrium) anatomy, hemodynamics, surgery, and late followup of twenty-one patients, 450
Cough
Cardiac output during ventricular fibrillation in the coughing dog, 445
Creatine kinase
An improved, rapid radioimmunoassay for individual human CK isoenzymes, 400
Detection of elevated mitochondrial CK in plasma after infarction by a specific radioimmunoassay, 414
Release of MB creatine kinase following coronary artery bypass grafting in the absence of myocardial infarction, 416
Cyclic adenosine monophosphate
Myocardial cyclic adenosine monophosphate and high energy phosphates in ventricular vulnerability to fibrillation in the isolated rat heart after coronary artery ligation, 461
Daunorubicin
Anthracycline heart: analysis of 69 patients treated with either adriamycin or daunorubicin showing a lack of correlation between clinical and morphologic findings, 396
Death, sudden
Cardiac rhythm in sudden infant death syndrome, 431
Frequency of myocardial infarction and sudden death in 44 variant angina patients: a high risk ischemic heart disease subset, 454
Sudden death after myocardial infarction: runs of ventricular premature beats and R on T as high risk factors, 444
Sudden death while running in conditioned runners: coronary disease is the culprit, 423
Defibrillation
Chronic cardiac changes following transthoracic ventricular defibrillation in the dog, 446
Effects of ethmozine and lidocaine on ventricular fibrillation and defibrillation in anesthetized dogs, 474
Electrophysiological characterization of myocardial injury induced by defibrillatory shocks on dogs, 446
Diabetes mellitus
Diabetic neuropathy of the heart and arteries, 475
Effects of chronic diabetes on cardiac performance and metabolism in rats, 433
Digoxin
Combination quinidine-digoxin: unique electrophysiologic changes produced in canine purkinje fiber, 428
Digoxin disposition in premature infants, 429
Digoxin-quinidine interaction: increased digoxin brain concentration, 453
Effects of digoxin on left ventricular performance and myocardial blood flow distribution during isometric exercise in coronary disease, 432
Effects of oral digoxin on ventricular ectopy and its relation to left ventricular function, 453
Onset and dose dependence of the digoxin-quinidine interaction, 413
Quinidine decreases both renal and metabolic clearance of digoxin, 453
Reversibility of adriamycin induced reduction in myocardial thallium-201 uptake by intravenous digoxin, 482
Diltiazem
Efficacy of diltiazem in variant angina, 439
Systemic and coronary hemodynamic effects of intravenous diltiazem in patients with coronary artery disease, 439
Dipyridamole
Comparison of planar and tomographic thallium-201 scintigrams following coronary vasodilatation with dipyridamole, 482
Detection and localization of ≥40% coronary stenosis in patients: comparison of exercise and dipyridamole thallium-201 myocardial imaging, 399
Modification of platelet function by aspirin and dipyridamole across the myocardial vascular bed in coronary disease patients, 424
Quantitation of platelet deposition in Gore-Tex femoral artery implants in the canine model and its reduction with dipyridamole and prostacyclin, 424
Dobutamine
Comparative effects of oral pirbuterol versus intravenous dobutamine on left ventricular function and energetics in chronic congestive heart failure: unique advantage of pirbuterol due to vasodilator and inotropic properties, 412
Effects of dobutamine on myocardial oxygen consumption and left ventricular function in patients with chronic heart failure due to ischemic heart disease, 479
Doppler ultrasound
Assessment of left ventricular function by determination of maximum acceleration of blood flow in the aorta using continuous Doppler ultrasound, 398
Doppler cardiographic assessment of severity of aortic and mitral valve stenosis, 437
Mitral regurgitation in mitral valve prolapse: detection by pulsed Doppler echocardiography versus angiography and cardiac auscultation. Correlation with cardiac arrhythmias by ambulatory monitoring, 442
New ultrasound technique for assessment of femoral vascular anatomy before and after cardiac catheterization (CC) in children and infants, 466
Pulsed echo Doppler measurements of beat to beat changes in stroke volume in dogs, 437
Use of carotid artery flow (CAF) patterns as assessed by Doppler ultrasonography for the noninvasive evaluation of Blalock-Taussig shunt (BTS) patency, 429
Ebstein's anomaly
Recurrent tachycardia associated with Ebstein's anomaly, 405
Echocardiography
See also Doppler ultrasound
Abnormal systolic motion of the posterolateral basal left ventricle in mitral valve prolapse: a new cross-sectional echocardiographic sign, 434
Accurate volume determination in the isolated ejecting canine heart from a limited number of two-dimensional echocardiographic cross-sections, 470
Asymmetric left ventricular hypertrophy—a study of anatomy and function by cross-sectional echocardiography and radionuclide angiography, 491
Biplane apex echocardiography versus biplane cineangiography in the assessment of left ventricular volume and function: validation by direct measurements, 471
Can ejection fraction be measured non-invasively in children after ventricular septal patching? 468
Clinical spectrum of left ventricular mural thrombi in a large cardiac population: assessment by two-dimensional echocardiography, 435
Comparative efficacy of cross-sectional echocardiography and gated equilibrium radionuclide angiography for assessing left ventricular size and performance, 403
Comparison of two-dimensional echocardiography, gated heart pool scan, and left ventriculography in the detection of regional wall motion abnormalities, 403
Computerized image processing in cross-sectional echocardiography, 403
Contrast echocardiography: transmission of echoes to the left heart across the pulmonary vascular bed, 401
Contrast two-dimensional echocardiography in inter-atrial shunts, 402
Cross-sectional echocardiographic evaluation of coronary artery abnormalities in children, 467
Differentiation of A-mode ultrasound signals from normal and ischemic myocardium by multivariate discriminant analysis of waveform parameters, 403
Discrete subaortic obstruction: two-dimensional echocardiographic features, 434
Early detection of aortic root abnormalities in ankylosing spondylitis by two-dimensional echocardiography, 441
Echocardiographic detection of patients at high risk for recurrent ventricular fibrillation, 444
End-systolic retraction of the left ventricular posterior wall: a specific echocardiographic marker of prolapsing mitral valve, 442
Evaluation of cardiac chamber size and left ventricular function in children using two dimensional apex

echocardiography, 468
Evaluation of left ventricular function during upright exercise using continuous echocardiographic monitoring (CEM), 467
Exercise cross sectional echocardiographic diagnosis of coronary artery disease, 404
Factors affecting real-time cross-sectional (2D) echocardiographic (ECHO) imaging of ventricular septal defects (VSD), 467
First derivative of diastolic aortic root motion as a measure of transmitral flow, 436
Identification of prominent Eustachian valves by M-mode and two-dimensional echocardiography: differentiation from right atrial masses, 402
Improved echocardiographic technique for examining the left main coronary artery, 435
Left ventricular microcavitations in patients with Beall valves, 402
Obstructive versus non-obstructive SAM: a crucial distinction, 491
Patterns and significance of the distribution of left ventricular hypertrophy in a large population of patients with hypertrophic cardiomyopathy: a wide-angle two-dimensional echocardiographic study, 491
Practical two-dimensional echocardiographic model to assess volume in the ischemic left ventricle, 471
Preoperative M-mode echocardiography as a predictor of surgical results in chronic mitral insufficiency, 442
Pulsed echo Doppler measurements of beat to beat changes in stroke volume in dogs, 437
Pulsus alternans determined by biventricular simultaneous echocardiographic systolic time intervals, 476
Quantitation of human left ventricular (LV) mass and volume by cross-sectional echocardiography: in vitro anatomic validation, 470
Real time two-dimensional echocardiography in right ventricular infarction, 436
Relationship between right anterior oblique cine angiographic and M-mode echographic left ventricular dimensions, 397
Selection criteria for echocardiographic assessment of left ventricular pressure and peak gradient in patients with valvular aortic stenosis, 471
Sensitivity and specificity of two-dimensional echocardiography in the detection of left ventricular aneurysms, 436
Serial evaluation for left ventricular thrombus during acute transmural myocardial infarction using two-dimensional echocardiography (2DE), 483
Statistical comparison of the M-mode and two-dimensional echocardiographic diagnosis of flail mitral leaflets, 435
Subclinical abnormalities of left ventricular function in coronary patients detected by 2-D echo, 404
Three-dimensional display and volume determination of the left ventricle by two-dimensional echocardiography, 471
Two-dimensional echocardiographic recognition of the descending thoracic aorta: value in differentiating pericardial from pleural effusions, 401
Two-dimensional echocardiographic recognition of mural thrombi: in-vivo and in-vitro studies, 435
Two dimensional echocardiographic features of corrected transposition, 466
Two-dimensional echo sector angiographic diagnosis of ventricular septal defect following acute myocardial infarction, 436
Wide-angle two-dimensional echocardiographic assessment of fetal cardiac anatomy, 466
Wide-angle two-dimensional echocardiographic criteria for ventricular morphology, 466

Ehlers-Danlos syndrome
Concordance between mitral valve prolapse and abnormal collagen synthesis in phenotypically expressed and occult Ehlers Danlos syndrome, 442

Ejection fraction
Age related changes in the left ventricular ejection fraction response to exercise, 391
Can ejection fraction be measured non-invasively in children after ventricular septal patching? 468
Comparison of radionuclide and contrast techniques in assessing ejection fraction at rest and during exercise, 422
Exercise ejection fraction diminishes after recovery in postoperative aortocoronary bypass patients, 420
Prognostic significance of preoperative ejection fraction in different aortic valve lesions, 487

Electrocardiography
Can intracardiac volume changes adequately explain R-wave variations associated with acute coronary ischemia? 477
Clinical significance of the ECG interval prolongation accompanying effective encainide therapy, 473
Composite cardiac electrogram: fact or artifact? 493
Coronary sinus rhythm in dogs: induction, recording and characteristics, 492
Influence of left ventricular dimensions on endocardial and epicardial QRS amplitude and ST segment elevations during acute myocardial ischemia, 414
Myocardial infarcts in the lateral third of the left ventricle: size and ECG recognition, 473
Relief of chest pain and reduction of Q-wave evolution in acute myocardial infarction by large dose sublingual nitroglycerin, 483
Sustained ventricular tachycardia: anatomic or functional basis? 493

Electrocardiography, ambulatory
Holter 24 hr recordings in post MI patients in double blind treatment with sulfinpyrazone, 445
Treatment of PVCs with tocainide, quinidine sulfate, and placebos, 445

Electrocardiography, exercise
Integrated format for multiple testing in coronary artery disease, 463
Localization of single vessel coronary artery disease by exercise electrocardiography and thallium scanning, 422
Mechanisms of increased R wave magnitude with exercise in patients with coronary artery disease, 420
Predictive accuracy of positive exercise electrocardiogram: relation of heart rate at which ischemic response initially appears to presence of coronary artery disease, 470
Reproducibility of symptoms, cardiac and electrocardiographic responses during symptom-limited exercise in preoperative coronary patients, 469
Terminal T in exercise electrocardiograms, 472
Total body surface potential mapping during exercise: QRS changes in normal young adults, 472

Electrophysiologic studies
Afterpotentials as a cause of long QT syndrome?—electrophysiological studies of a case, 472
Analysis of ischemic myocardial injury in vitro—a microelectrode study, 426
Atrial enlargement can cause arrhythmias without altering transmembrane potentials, 426
Atrio-ventricular nodal "memory" studied by random atrial stimulation, 459
Cellular electropharmacology in experimental ischemic lesions: comparison in acute and healed ischemic injury, 473
Cellular electrophysiology of a mottled infarct in dogs 4 and 15 days after coronary occlusion and reperfusion, 426
Characteristic alteration of the retrograde atrial activation sequence in patients with dual atrioventricular nodal pathway conduction, 404
Combination quinidine-digoxin: unique electrophysiologic changes produced in canine purkinje fiber, 428
Developmental sympathetic effects on vulnerability to ventricular fibrillation in puppies, 495
Differential effect of verapamil in overt and concealed WPW syndrome: new evidence from intracardiac recordings, 453
Dissociation of coronary artery ligation arrhythmias and the fractionation of local electrograms, 493
Dual atrioventricular nodal pathway conduction—a common electrophysiological phenomenon in children without arrhythmias, 430
Effect of catecholamines released by trains of pulses on ventricular vulnerability to fibrillation, 495
Effect of lidocaine on the rate of atrioventricular junctional escape pacemakers, 451
Effect of procainamide on excitability in man, 452
Electrophysiological characterization of myocardial injury induced by defibrillatory shocks on dogs, 446
Electrophysiologic consequences of Mustard repair of transposition of the great arteries, 430

Electrophysiologic findings in patients suffering cardiac arrests, 406
Electrophysiologic properties of normal neonatal and adult canine cardiac purkinje fibers, 431
Electrophysiology of right atrial hypertrophy in children, 426
Evidence supporting a direct cholinergic effect on ventricular muscle refractory period in man, 473
Functional properties of reentrant circuits deduced from direct myocardial recording during sustained ventricular tachycardia, 493
Intracellular potassium activity in guinea-pig atrial muscle, 425
Localization of pacing sites within infarcts by epicardial mapping, 494
Mechanism of ventricular fibrillation of the normal myocardium, 427
Mechanisms of termination of aberrant conduction due to retrograde concealed penetration of the bundle branches during circus movement tachycardia utilizing an accessory pathway, 405
Myocardial cell damage during vasospastic anginal attacks with promptly reversible electrocardiographic changes, 455
Pathophysiology of epicardium overlying transmural myocardial infarction, 460
Quinidine toxicity: an electrophysiological evaluation in cardiac purkinje fibers, 428
Recurrent tachycardia associated with Ebstein's anomaly, 405
Regional differences in transmembrane action potential (AP) in guinea pig heart during global ischemia, 427
Reperfusion arrhythmias: differential effect of lidocaine on reentry and enhanced automaticity, 474
Repetitive beating after single ventricular extrastimuli: incidence and prognostic significance in patients with recurrent ventricular tachycardia, 407
Repetitive ventricular responses in patients with life-threatening ventricular arrhythmias, 406
Resection of ventricular aneurysm modified by electrophysiologic assessment in patients with intractable ventricular tachycardia and left ventricular aneurysm, 417
Significance of H-V interval in 515 patients with chronic bifascicular block, 405
Sustained ventricular tachycardia: anatomic or functional basis? 493
Systolic (ST) current flow across infarct boundaries, 472
Temporal dispersion of refractoriness: lack of correlation with antiarrhythmic efficacy in a model of chronic infarction, 474
Torsade de pointes: electrophysiology atypical ventricular tachycardia, 494
Transmembrane action potential characteristics of ventricular cells during ventricular fibrillation, 427
Ventricular refractoriness at twice diastolic excitability threshold: an unpredictable source of variability, 427

Emax
Emax during exercise in children with left-sided cardiac disease, 467

Embolism
Pulmonary embolectomy, 488

Encainide
Abolition of ventricular arrhythmias during chronic oral therapy with encainide in man, 451
Clinical significance of the ECG interval prolongation accompanying effective encainide therapy, 473

Epicardium
Pathophysiology of epicardium overlying transmural myocardial infarction, 460

Epidemiology
Angiographic correlation of coronary artery disease with high density lipoprotein cholesterol in asymptomatic men, 447
Cigarettes, coffee, and other associations with HDL cholesterol in the general population, 447

Ergonovine
Ergonovine stress test: a provocative test for diffuse esophageal spasm or variant angina? 440
Influence of ergonovine-induced coronary artery spasm on vulnerability to ventricular fibrillation, 455
Refractory ergonovine induced coronary vaspspasm: importance of intracoronary nitroglycerin, 390

Esophageal spasm
Ergonovine stress test: a provocative test for diffuse esophageal spasm or variant angina? 440

Ethmozine
Effects of ethmozine and lidocaine on ventricular fibrillation and defibrillation in anesthetized dogs, 474

Eustachian valve
Identification of prominent Eustachian valves by M-mode and two-dimensional echocardiography: differentiation from right atrial masses, 402

Exercise
Age related changes in the left ventricular ejection fraction response to exercise, 391
Characteristics of exercise performance in men with previous myocardial infarction: (non) influence of infarct location, 391
Effect of coronary collaterals on exercise performance, 392

Exercise testing
See also Electrocardiography, exercise
Abbreviated rapid onset exercise stress testing for the exposure of ventricular arrhythmia, 420
Acute and long-term effect of vasodilators on resting and exercise hemodynamic measurements and exercise tolerance, 432
Advantages of exercise imaging in patients with equivocal treadmill exercise tests, 421
Afterload reduction therapy for chronic severe aortic insufficiency: beneficial effects during rest and exercise, 441
Body surface distribution of ST depression during exercise testing in patients with coronary artery disease, 469
Chronotropic incompetence in stress testing in patients with coronary artery disease, 401
Combined treadmill-scintiscan score to predict the presence and extent of coronary artery disease, 463
Comparison of radionuclide and contrast techniques in assessing ejection fraction at rest and during exercise, 422
Coronary artery constriction and hemodynamic responses during isometric handgrip in patients (pts) with coronary artery disease (CAD), 431
Detection and localization of ≥40% coronary stenosis in patients: comparison of exercise and dipyridamole thallium-201 myocardial imaging, 399
Early post-myocardial infarction treadmill stress testing: an accurate discriminator of multi and single vessel coronary disease, 421
Effect of nifedipine on exercise tolerance in coronary artery disease, 439
Emax during exercise in children with left-sided cardiac disease, 467
Evaluation of left ventricular function during upright exercise using continuous echocardiographic monitoring (CEM), 467
Evaluations of pre- and postoperative myocardial perfusion by thallium 201 graded exercise testing, 456
Exercise capacity after valve replacement in children and adolescents, 468
Exercise cross sectional echocardiographic diagnosis of coronary artery disease, 404
Exercise ejection fraction diminishes after recovery in postoperative aortocoronary bypass patients, 420
Five year follow-up of maximal treadmill stress test in asymptomatic women and men, 419
Hemodynamic responses to static exercise are dependent on the mass of muscle activated, 420
Immediate psychological impact of exercise testing soon after myocardial infarction, 421
Integrated format for multiple testing in coronary artery disease, 463
Left ventricular diastolic performance during exercise in coronary artery disease: assessment of peak filling rate with first pass radionuclide angiography, 408
Left ventricular function at rest and during exercise in marathon runners, 431
Long term followup of patients manifesting severe ST depression during maximal Bruce exercise testing and having angiographically normal coronary arteries, 419
Mechanisms of increased R wave magnitude with exercise in patients with coronary artery disease, 420
Multiple gated acquisition thallium scintigrams with computer enhancement: improved sensitivity in asymptomatic men with abnormal treadmill tests, 463
Predictive accuracy of coronary artery calcification and positive exercise test in asymptomatic non-hyperlipidemic men for coronary artery disease, 400
Predictive accuracy of positive exercise electrocardiogram: relation of heart rate at which ischemic response initially appears to presence of coronary artery disease, 470
Predictive and prognostic value of

exertional hypotension, 456
Quantification of the exercise test that best maximizes the prediction of severe coronary disease, 470
Quantitation of Tl-201 myocardial distribution and washout: normal standards for graded exercise studies, 480
Relation of treadmill exercise results to flow-limitation and perfusion-size of the affected coronary artery, 469
Reproducibility of exercise testing at two and six weeks post myocardial infarction, 400
Reproducibility of symptoms, cardiac and electrocardiographic responses during symptom-limited exercise in preoperative coronary patients, 469
Response to exercise early after uncomplicated acute myocardial infarction in unmedicated patients, 421
Sensitivity and specificity of exercise radionuclide angiography in detecting coronary disease, 408
Spontaneous improvement in aerobic capacity between 3 and 11 weeks after myocardial infarction, 391
Value of blood pressure response to exercise in the recognition of latent or early borderline hypertension, 489
Variability of treadmill exercise testing results in patients with angina pectoris, 469

Exercise training
Beneficial effects of endurance exercise training in adolescent hypertension, 489
Physical conditioning in patients with severely depressed left ventricular function, 392
Physical conditioning reduces epinephrine-induced platelet aggregation following myocardial infarction, 425
Training effect: do athletes have improved left ventricular performance during exercise? 391

Familial disease
Hereditary progressive cardiac conduction and muscle disease: clinical staging, 396

Femoral artery
New ultrasound technique for assessment of femoral vascular anatomy before and after cardiac catheterization (CC) in children and infants, 466

Femoral vein
New ultrasound technique for assessment of femoral vascular anatomy before and after cardiac catheterization (CC) in children and infants, 466

Fetal heart
Wide-angle two-dimensional echocardiographic assessment of fetal cardiac anatomy, 466

^{18}Fluoro-2-deoxyglucose
Glucose metabolism of regional myocardial ischemia evaluated by ^{18}fluoro-2-deoxyglucose and positron emission computed tomography, 465

Fluorophotography
Two and three dimensional display of myocardial ischemic "borderzone" in the rabbit, dog, pig and monkey, 413

Glucose
Glucose metabolism of regional myocardial ischemia evaluated by ^{18}fluoro-2-deoxyglucose and positron emission computed tomography, 465

Glucose-insulin-potassium
Preservation of ischemic myocardium with glucose-insulin-potassium in patients with isolated left anterior descending stenosis, 484

Grafts
Sulfinpyrazone decreases vein graft occlusion in patients following coronary artery bypass surgery, 425

Heart rate
Chronotropic incompetence in stress testing in patients with coronary artery disease, 401
Control of ventricular rate in paroxysmal supraventricular tachycardia and atrial flutter-fibrillation with intravenous verapamil: a double blind randomized crossover study, 452
Predictive accuracy of positive exercise electrocardiogram: relation of heart rate at which ischemic response initially appears to presence of coronary artery disease, 470

Heart transplantation
Congestive cardiomyopathy patients as heart-transplant recipients, 488

Hematocrit
Infarct size manipulation by alteration of hematocrit, 484

Hemodynamics
Activation of vasoconstrictor mechanisms during vasodilator therapy: a factor modifying drug response in heart failure, 433
Acute and long-term effect of vasodilators on resting and exercise hemodynamic measurements and exercise tolerance, 432
Adrenergic responsiveness following abrupt propranolol withdrawal in patients with angina pectoris, 438
Beneficial hemodynamic and energetic effects of afterload reduction with prostaglandin E-1 in patients with severe chronic congestive heart failure, 438
Chronic cardiac changes following transthoracic ventricular defibrillation in the dog, 446
Comparative hemodynamic effects of nitroglycerin and nitroprusside during recovery, 394
Comparative hemodynamic evaluation of the Carpentier-Edwards and Angell-Shiley porcine xenografts, 486
Coronary artery constriction and hemodynamic responses during isometric handgrip in patients (pts) with coronary artery disease (CAD), 431
Cor triatriatum (subdivided left atrium) anatomy, hemodynamics, surgery, and late followup of twenty-one patients, 450
Deleterious influence of hypometabolism on evolving myocardial infarction in conscious dogs, 484
Distribution of pressure across the left ventricular wall in the beating and arrested heart: evidence of epicardial muscle tone during diastole, 393
Effects of verapamil on coronary hemodynamics and vasomobility in patients with coronary artery disease, 389
Fixed vs. non-fixed coronary stenosis: the response to a fall in coronary pressure, 390
Hemodynamic effects of intact human pericardium after coronary bypass surgery, 417
Hemodynamic evaluation of porcine heterografts in the mitral position for more than five years, 486
Hemodynamic responses to static exercise are dependent on the mass of muscle activated, 420
Hemodynamic results of repeat valvulotomy for aortic stenosis in children, 449
Hydralazine effects on hemodynamics, cardiac contractile function and myocardial energetics in isolated myocardium, 440
Mechanism of improved cardiac performance with afterload reduction in aortic insufficiency, 410
Natural history of unoperated aortic stenosis: hemodynamic progression, 440
Pulmonary venous regurgitation: etiology of hemodynamic deterioration during ventricular tachyarrhythmias and pacing, 457
Spontaneous improvement in aerobic capacity between 3 and 11 weeks after myocardial infarction, 391
St. Jude aortic valve prosthesis: post-operative hemodynamic evaluation at rest and exercise, 486
Systemic and coronary hemodynamic effects of intravenous diltiazem in patients with coronary artery disease, 439

Histodysplasia
Mitral valve prolapse: possible manifestation of a congenital neuro-ecto-mesodermal histodysplasia, 443

Histologic studies
Is nonfamilial asymmetric septal hypertrophy a different histological disorder? 492

H-V interval
Significance of H-V interval in 515 patients with chronic bifascicular block, 405

Hyaluronidase
Reduction of acute myocardial ischemia in isolated rabbit heart by hyaluronidase, 485

Hydralazine
Afterload reduction therapy for chronic severe aortic insufficiency: beneficial effects during rest and exercise, 441
Can hydralazine therapy for severe, chronic, heart failure be safely and effectively initiated outside the hospital? 410
Hydralazine effects on hemodynamics, cardiac contractile function and myocardial energetics in isolated myocardium, 440
Mechanism of improved cardiac performance with afterload reduction in aortic insufficiency, 410

Hypertension
Beneficial effects of endurance exercise training in adolescent hypertension, 489
Effect of antihypertensive therapy on calcium transport by cardiac sarcoplasmic reticulum of spontaneously hypertensive rats (SHRs), 490
Improved cardiac performance with long

term reduction of blood pressure in old spontaneously hypertensive rats, 490
Long-term minoxidil therapy—effects on the heart, 490
Use of ambulatory blood pressure monitoring in the evaluation of patients with borderline hypertension, 446
Value of blood pressure response to exercise in the recognition of latent or early borderline hypertension, 489
Verification of physician assessment of antihypertensive therapy by ambulatory blood pressure recording, 490

Hypertension, pulmonary
Effects of acute volume loading on right ventricular function in chronic pulmonary hypertension, 432

Hypertension, renovascular
Papillary muscle function in renovascular hypertension, 434

Hypertrophy
See also Cardiomyopathy
Asymmetric left ventricular hypertrophy—a study of anatomy and function by cross-sectional echocardiography and radionuclide angiography, 491
Is nonfamilial asymmetric septal hypertrophy a different histological disorder? 492
Obstructive versus non-obstructive SAM: a crucial distinction, 491
Passive stiffness characteristics of the volume-overload hypertrophied myocardium, 434
Patterns and significance of the distribution of left ventricular hypertrophy in a large population of patients with hypertrophic cardiomyopathy: a wide-angle two-dimensional echocardiographic study, 491
Relationship of ischemic contracture to high energy phosphate content and mitochondrial function in hypertrophied myocardium, 394
Wall thickness in single vessel coronary disease: evidence against a causal association of ischemia and hypertrophy, 423

Hypotension
Predictive and prognostic value of exertional hypotension, 456

Idiopathic hypertrophic subaortic stenosis
See also Cardiomyopathy; Subaortic stenosis
Advantages of nitroprusside infusion in diagnosis and assessment of outflow obstruction in idiopathic hypertrophic subaortic stenosis: improved accuracy and safety than amyl nitrite inhalation, 492

Infants
Cardiac rhythm in sudden infant death syndrome, 431
Digoxin disposition in premature infants, 429
Electrophysiologic properties of normal neonatal and adult canine cardiac purkinje fibers, 431
Intraatrial repair of transposition of the great arteries in infancy, early and late results, 448
Management of the infant with coarctation of the aorta and ventricular septal defect, 450
New ultrasound technique for assessment of femoral vascular anatomy before and after cardiac catheterization (CC) in children and infants, 466
Systemic ventricular function in patients with congenital heart disease repaired during infancy, 468

Interventricular septum
Contribution of interventricular septal wall motion to right and left ventricular function: visualization by biventricular angiography, 397

Intraaortic balloon counterpulsation
Effects of intra-aortic balloon diastolic augmentation and nitroprusside on postoperative regional left ventricular function, 432
Effects of intra-aortic balloon pumping on regional and total coronary flow in patients with coronary disease, 395
Follow-up radionuclide assessment of left ventricular function and perfusion in patients requiring intraaortic balloon pump to wean from cardiopulmonary bypass, 488
Intra aortic balloon pump for shock complicating infarction. Factors influencing outcome, 462
Mechanism of the beneficial effect of intra-aortic balloon pumping in patients with refractory angina, 478
Percutaneous intra-aortic balloon pumping, 395

Ischemia
See also Myocardial infarction
Analysis of ischemic myocardial injury in vitro—a microelectrode study, 426
Atrial hyperemia and ischemia during acute mitral regurgitation, 477
Autoradiography with ^{99}Tc labeled albumin microspheres, a new method for delineation of ischemic tissue at risk of infarction: demonstration of the protective effect of verapamil, 485
Can intracardiac volume changes adequately explain R-wave variations associated with acute coronary ischemia? 477
Cellular electropharmacology in experimental ischemic lesions: comparison in acute and healed ischemic injury, 473
Diabetic neuropathy of the heart and arteries, 475
Differentiation of A-mode ultrasound signals from normal and ischemic myocardium by multivariate discriminant analysis of waveform parameters, 403
Effect of ischemia on myocardial proteolysis, 414
Effect oftransient ischemia with reperfusion on thallium clearance from the myocardium, 480
Effects of an antiplatelet drug on myocardial ischemia in patients with coronary artery disease, 424
Effects of dobutamine on myocardial oxygen consumption and left ventricular function in patients with chronic heart failure due to ischemic heart disease, 479
Effects of nefedipine on ischemic myocardium: preservation of contraction during partial coronary occlusion, 485
Effects of pulsatile and nonpulsatile reperfusion on the post-ischemic myocardium, 394
Frequency of myocardial infarction and sudden death in 44 variant angina patients: a high risk ischemic heart disease subset, 454
Glucose metabolism of regional myocardial ischemia evaluated by ^{18}fluoro-2-deoxyglucose and positron emission computed tomography, 465
Hospital recurrence of ventricular fibrillation in acute ischaemic heart disease, 462
Influence of left ventricular dimensions on endocardial and epicardial QRS amplitude and ST segment elevations during acute myocardial ischemia, 414
Labeled metabolic substrates for positive imaging in ischemia, 465
Mechanisms of bradycardia-dependent arrhythmias in acute myocardial ischemia, 494
Multiple gated bloodpool cardiac scan (MUGA) during right atrial pacing (RAP): a sensitive method to detect myocardial ischemia, 408
Prediction of biochemical derangement in ischemic myocardium following experimental coronary artery occlusion, 415
Preferential uptake of 14-C-lidocaine by acutely ischemic canine myocardium: distribution of drug and blood flow in transmural and lateral border zones, 413
Reduction of acute myocardial ischemia in isolated rabbit heart by hyaluronidase, 485
Reduction of ischemic myocardial necrosis by lidocaine administration, 486
Regional differences in transmembrane action potential (AP) in guinea pig heart during global ischemia, 427
Relationship of ischemic contracture to high energy phosphate content and mitochondrial function in hypertrophied myocardium, 394
Role of elevated extracellular K^+ activity in conduction slowing during acute myocardial ischemia, 460
Surgical relief of myocardial ischemia due to myocardial bridges, 417
Thallium-201 scintigraphic evidence of ischemia in patients with myocardial bridges, 482
Two and three dimensional display of myocardial ischemic "borderzone" in the rabbit, dog, pig and monkey, 413
Wall thickness in single vessel coronary disease: evidence against a causal association of ischemia and hypertrophy, 423

Isoproterenol
Selective vulnerability of the papillary muscles to sequential blood flow changes induced by isoproterenol, 477

Isosorbide dinitrate
Dose response and duration of action of oral isosorbide dinitrate during sustained therapy in angina pectoris, 478
Pharmacokinetics and pharmacologic effects after single and chronic doses of isosorbide dinitrate, 438

Lactate
Heterogeneity of myocardial metabolism: evidence of lactate production during net chemical extraction in man, 401

Lidocaine
Effect of lidocaine on the rate of atrioventricular junctional escape pacemakers, 451
Effects of ethmozine and lidocaine on ventricular fibrillation and defibrillation in anesthetized dogs, 474

Preferential uptake of 14-C-lidocaine by acutely ischemic canine myocardium: distribution of drug and blood flow in transmural and lateral border zones, 413
Reduction of ischemic myocardial necrosis by lidocaine administration, 486
Reperfusion arrhythmias: differential effect of lidocaine on reentry and enhanced automaticity, 474

Lipoprotein
Angiographic correlation of coronary artery disease with high density lipoprotein cholesterol in asymptomatic men, 447
Cigarettes, coffee, and other associations with HDL cholesterol in the general population, 447
Total cholesterol/high density lipoprotein ratio correlates with the presence but not severity of coronary artery disease, 447

Liposomes
Conditions for liposome uptake by myocardial cells, 414

Lysophosphatides
Concentration-dependent effects of arrhythmogenic lysophosphatides on membranes, 415

Mapping, electrocardiographic
Body surface distribution of ST depression during exercise testing in patients with coronary artery disease, 469
Total body surface potential mapping during exercise: QRS changes in normal young adults, 472

Mapping, epicardial
Localization of pacing sites within infarcts by epicardial mapping, 494

Mediastinum
Heavy mediastinal irradiation causing severe coronary narrowing in patients 15 to 33 years of age: a poorly appreciated cause of coronary heart disease in young people, 476
Identification of subclinical cardiac abnormality 5-15 yrs. after therapeutic mediastinal irradiation, 475

Metabolism
Characterization of myocardial ATP degradation following coronary artery occlusion, 415
Concentration-dependent effects of arrhythmogenic lysophosphatides on membranes, 415
Deleterious influence of hypometabolism on evolving myocardial infarction in conscious dogs, 484
Digoxin: the acute effects of vasodilator therapy on renal metabolism, 412
Effect of first-dose adriamycin on the cyclic nucleotide levels and function of the human myocardium, 416
Effects of chronic diabetes on cardiac performance and metabolism in rats, 433
Glucose metabolism of regional myocardial ischemia evaluated by ^{18}fluoro-2-deoxyglucose and positron emission computed tomography, 465
Heterogeneity of myocardial metabolism: evidence of lactate production during net chemical extraction in man, 401
Labeled metabolic substrates for positive imaging in ischemia, 465
Prediction of biochemical derangement in ischemic myocardium following experimental coronary artery occlusion, 415
Relationship of ischemic contracture to high energy phosphate content and mitochondrial function in hypertrophied myocardium, 394
Significance of the late fall in myocardial pCO_2 following acute coronary occlusion, 416
Tomographic quantification of regional myocardial metabolism in vivo, 465
Transient state kinetic studies of Ca^{2+}-dependent ATPase and Ca translocation by cardiac sarcoplasmic reticulum. Role of the 22,000-dalton protein phospholamban, 415

15-Methyl-prostaglandin $F_2\alpha$
Decreased shunt flow in acute ventricular septal defect using 15-methyl-prostaglandin $F_2\alpha$ as a pulmonary constrictor, 462

Minoxidil
Long-term minoxidil therapy—effects on the heart, 490

Mitral insufficiency
Preoperative M-mode echocardiography as a predictor of surgical results in chronic mitral insufficiency, 442

Mitral regurgitation
Atrial hyperemia and ischemia during acute mitral regurgitation, 477
Mitral regurgitation in mitral valve prolapse: detection by pulsed Doppler echocardiography versus angiography and cardiac auscultation. Correlation with cardiac arrhythmias by ambulatory monitoring, 442
Mitral valve replacement for isolated mitral regurgitation: early and late results, 487

Mitral stenosis
Doppler cardiographic assessment of severity of aortic and mitral valve stenosis, 437

Mitral valve
First derivative of diastolic aortic root motion as a measure of transmitral flow, 436

Mitral valve leaflets
Statistical comparison of the M-mode and two-dimensional echocardiographic diagnosis of flail mitral leaflets, 435

Mitral valve prolapse
Abnormal systolic motion of the posterolateral basal left ventricle in mitral valve prolapse: a new cross-sectional echocardiographic sign, 434
Concordance between mitral valve prolapse and abnormal collagen synthesis in phenotypically expressed and occult Ehlers Danlos syndrome, 442
End-systolic retraction of the left ventricular posterior wall: a specific echocardiographic marker of prolapsing mitral valve, 442
First pass radionuclide wall motion abnormalities associated with mitral valve prolapse syndrome, 409
Mitral regurgitation in mitral valve prolapse: detection by pulsed Doppler echocardiography versus angiography and cardiac auscultation. Correlation with cardiac arrhythmias by ambulatory monitoring, 442
Mitral valve prolapse: possible manifestation of a congenital neuro-ecto-mesodermal histodysplasia, 443
Mitral valve prolapse syndrome: anthropometric, sexual and clinical features, 443
Pathogenesis of mitral valve prolapse (MVP) syndrome in children with Duchenne's Muscular Dystrophy: an ultrastructural and histologic basis, 396

Muscular dystrophy
Pathogenesis of mitral valve prolapse (MVP) syndrome in children with Duchenne's Muscular Dystrophy: an ultrastructural and histologic basis, 396

Myocardial bridges
Surgical relief of myocardial ischemia due to myocardial bridges, 417
Thallium-201 scintigraphic evidence of ischemia in patients with myocardial bridges, 482

Myocardial contractility
Effects of nefedipine on ischemic myocardium: preservation of contraction during partial coronary occlusion, 485
Emax during exercise in children with left-sided cardiac disease, 467
Hydralazine effects on hemodynamics, cardiac contractile function and myocardial energetics in isolated myocardium, 440
Preservation of myocardial compliance during ischemic arrest by applied intermittent ventricular stretch, 393

Myocardial depression
Reversal of propranolol induced myocardial depression during partial and total coronary occlusion by nitroglycerin, 437

Myocardial imaging
Advantages of exercise imaging in patients with equivocal treadmill exercise tests, 421
Diagnosis of Chagas cardiomyopathy by thallium 201 perfusion imaging, 396
Increased sensitivity of kinetic vs. static Tl-201 imaging in detecting acute alterations in myocardial perfusion, 480
Localization of single vessel coronary artery disease by exercise electrocardiography and thallium scanning, 422
Mechanisms for the disappearance of Tl-201 defects at rest over time, 479
Reversibility of adriamycin induced reduction in myocardial thallium-201 uptake by intravenous digoxin, 482
^{201}Tl imaging in patients with myocardial infarction: a comparison of planar and seven-pinhole tomographic images, 481

Myocardial infarction
Characteristics of exercise performance in men with previous myocardial infarction: (non) influence of infarct location, 391
Deleterious influence of hypometabolism on evolving myocardial infarction in conscious dogs, 484
Does location or late disappearance of Q waves after myocardial infarction affect prognosis? 400
Holter 24 hr recordings in post MI patients in double blind treatment with sulfinpyrazone, 445
Initiation of sustained ventricular tachyarrhythmias in a model of chronic infarction: importance of the site of stimulation, 494
Myocardial infarcts in the lateral third of the left ventricle: size and ECG recognition, 473

Progression and regression of coronary artery disease in post-infarction patients under age 40, 479
Real time two-dimensional echocardiography in right ventricular infarction, 436
Sudden death after myocardial infarction: runs of ventricular premature beats and R on T as high risk factors, 444
Systolic (ST) current flow across infarct boundaries, 472
Temporal dispersion of refractoriness: lack of correlation with antiarrhythmic efficacy in a model of chronic infarction, 474
Thallium-201 exercise scintigraphy for detection of multivessel disease in patients with prior inferior myocardial infarction, 398
^{201}Tl imaging in patients with myocardial infarction: a comparison of planar and seven-pinhole tomographic images, 481
Treatment of anterior transmural myocardial infarction in man with and without early reperfusion, 417

Myocardial infarction, acute
See also Coronary occlusion; Ischemia
Contraction of the acutely injured left ventricular zone after acute myocardial infarction in man: comparative effects of nitroglycerin and nitroprusside as a function of time, 483
Coronary osstruction in anterior myocardial infarction: thrombus or spasm? 483
Early post-myocardial infarction treadmill stress testing: an accurate discriminator of multi and single vessel coronary disease, 421
Effect of a mobile coronary care unit on mortality in acute myocardial infarction. A randomized study, 461
Effect of coronary blood flow and site of injection on ^{99m}Tc-PYP detection of early canine myocardial infarcts, 464
Frequency of myocardial infarction and sudden death in 44 variant angina patients: a high risk ischemic heart disease subset, 454
Hospital recurrence of ventricular fibrillation in acute ischaemic heart disease, 462
Intra aortic balloon pump for shock complicating infarction. Factors influencing outcome, 462
Lack of effect of associated myocardial infarction on long-term survival of out-of-hospital ventricular fibrillation, 443
Lethal late consequences of small infarcts, 460
Mechanisms of bradycardia-dependent arrhythmias in acute myocardial ischemia, 494
Pathophysiology of epicardium overlying transmural myocardial infarction, 460
Physical conditioning reduces epinephrine-induced platelet aggregation following myocardial infarction, 425
Preservation of ischemic myocardium with glucose-insulin-potassium in patients with isolated left anterior descending stenosis, 484
Protection of ischemic myocardium with intravenous pindolol in acute myocardial infarction, 484
Reduction of myocardial infarction mortality by prudent patient activation of mobile coronary care, 461
Relief of chest pain and reduction of Q-wave evolution in acute myocardial infarction by large dose sublingual nitroglycerin, 483
Reproducibility of exercise testing at two and six weeks post myocardial infarction, 400
Response to exercise early after uncomplicated acute myocardial infarction in unmedicated patients, 421
Serial evaluation for left ventricular thrombus during acute transmural myocardial infarction using two-dimensional echocardiography (2DE), 483
Spontaneous improvement in aerobic capacity between 3 and 11 weeks after myocardial infarction, 391
Two-dimensional echo sector angiographic diagnosis of ventricular septal defect following acute myocardial infarction, 436
Ventricular arrhythmias and ventricular fibrillation in acute myocardial infarction, 462

Myocardial infarcts
Cellular electrophysiology of a mottled infarct in dogs 4 and 15 days after coronary occlusion and reperfusion, 426
Localization of pacing sites within infarcts by epicardial mapping, 494

Myocardial infarct size
Autoradiography with ^{99}Tc labeled albumin microspheres, a new method for delineation of ischemic tissue at risk of infarction: demonstration of the protective effect of verapamil, 485
Infarction sizing and myocardial perfusion measurements using rubidium-82 and positron emission tomography, 399
Infarct size manipulation by alteration of hematocrit, 484
Reduction of experimental myocardial infarction size by ortho-iodo sodium benzoate, 485

Myocardial injury
Electrophysiological characterization of myocardial injury induced by defibrillatory shocks on dogs, 446

Myocardial perfusion
Improved myocardial perfusion and function following percutaneous transluminal coronary angioplasty (PTCA), 478
Infarction sizing and myocardial perfusion measurements using rubidium-82 and positron emission tomography, 399
Patterns of disturbed myocardial perfusion in patients with coronary artery disease, 464

Myocardial revascularization
Effects of pulsatile and nonpulsatile reperfusion on the post-ischemic myocardium, 394
No-reflow phenomenon: not a time-limiting factor for reperfusion following coronary occlusion, 394
Restoration of myocardial blood flow reserve following revascularization, 416

Myocardium
Mechanism of ventricular fibrillation of the normal myocardium, 427
Passive stiffness characteristics of the volume-overload hypertrophied myocardium, 434

Neuropathy
Diabetic neuropathy of the heart and arteries, 475

Nifedipine
Comparative effects of verapamil and nifedipine on reactive hyperemia, and ventricular arrhythmias during coronary artery reperfusion, 461
Effect of nifedipine on exercise tolerance in coronary artery disease, 439
Effects of nefedipine on ischemic myocardium: preservation of contraction during partial coronary occlusion, 485
Efficacy of nifedipine in the intermediate syndrome refractory to propranolol and nitrate therapy, 390

Nitrates
Effectiveness of combined verapamil and nitrate therapy in Prinzmetal's variant angina, 439

Nitroglycerin
Comparative hemodynamic effects of nitroglycerin and nitroprusside during recovery, 394
Contraction of the acutely injured left ventricular zone after acute myocardial infarction in man: comparative effects of nitroglycerin and nitroprusside as a function of time, 483
Nitroglycerin vs post-extrasystolic potentiation in the assessment of the acutely ischaemic left ventricle, 399
Refractory ergonovine induced coronary vaspspasm: importance of intracoronary nitroglycerin, 390
Relief of chest pain and reduction of Q-wave evolution in acute myocardial infarction by large dose sublingual nitroglycerin, 483
Reversal of propranolol induced myocardial depression during partial and total coronary occlusion by nitroglycerin, 437
Specificity, sensitivity and accuracy of the nitroglycerin ventriculogram as a predictor of surgically reversible wall motion abnormalities, 399

Nitroprusside
Activation of vasoconstrictor mechanisms during vasodilator therapy: a factor modifying drug response in heart failure, 433
Advantages of nitroprusside infusion in diagnosis and assessment of outflow obstruction in idiopathic hypertrophic subaortic stenosis: improved accuracy and safety than amyl nitrite inhalation, 492
Comparative hemodynamic effects of nitroglycerin and nitroprusside during recovery, 394
Contraction of the acutely injured left ventricular zone after acute myocardial infarction in man: comparative effects of nitroglycerin and nitroprusside as a function of time, 483
Effect of nitroprusside on end-diastolic pressure-diameter relations of the human left ventricle after pericardiotomy, 393
Effects of intra-aortic balloon diastolic augmentation and nitroprusside on postoperative regional left ventricular function, 432

Nuclear medicine
Adriamycin cardiotoxicity—assessment of late left ventricular dysfunction by radionuclide cineangiography, 410

Asymmetric left ventricular hypertrophy—a study of anatomy and function by cross-sectional echocardiography and radionuclide angiography, 491
Autoradiography with ^{99}Tc labeled albumin microspheres, a new method for delineation of ischemic tissue at risk of infarction: demonstration of the protective effect of verapamil, 485
Can ejection fraction be measured non-invasively in children after ventricular septal patching? 468
Combined treadmill-scintiscan score to predict the presence and extent of coronary artery disease, 463
Comparative efficacy of cross-sectional echocardiography and gated equilibrium radionuclide angiography for assessing left ventricular size and performance, 403
Comparison of planar and tomographic thallium-201 scintigrams following coronary vasodilatation with dipyridamole, 482
Comparison of radionuclide and contrast techniques in assessing ejection fraction at rest and during exercise, 422
Comparison of two-dimensional echocardiography, gated heart pool scan, and left ventriculography in the detection of regional wall motion abnormalities, 403
Computer analysis of thallium-201 myocardial perfusion scintigraphy: circumferential mapping, 481
Continuous monitoring of regional myocardial radiotracer kinetics in laboratory animals, 464
Detection and localization of ≥40% coronary stenosis in patients: comparison of exercise and dipyridamole thallium-201 myocardial imaging, 399
Detection and quantitation of atrial shunts in adults by gated radionuclide angiography, 409
Detection of multivessel disease by exercise thallium-201 scintigraphy, 482
Determination of absolute left ventricular volume from gated blood pool imaging with an attenuation corrected count rate method, 407
Effect of coronary blood flow and site of injection on ^{99m}Tc-PYP detection of early canine myocardial infarcts, 464
Effect oftransient ischemia with reperfusion on thallium clearance from the myocardium, 480
Evaluation of right heart function in adults with atrial septal defect using gated cardiac blood pool scanning, 409
Evaluations of pre- and postoperative myocardial perfusion by thallium 201 graded exercise testing, 456
First pass radionuclide wall motion abnormalities associated with mitral valve prolapse syndrome, 409
Follow-up radionuclide assessment of left ventricular function and perfusion in patients requiring intraaortic balloon pump to wean from cardiopulmonary bypass, 488
Glucose metabolism of regional myocardial ischemia evaluated by ^{18}fluoro-2-deoxyglucose and positron emission computed tomography, 465
Identification of left ventricular thrombi in humans using Indium-111 labelled autologous platelets, 463
Inability to detect coronary artery disease at rest by patterns of ventricular emptying using contrast angiography and radionuclide angiography, 409
Increased sensitivity of kinetic vs. static Tl-201 imaging in detecting acute alterations in myocardial perfusion, 480
Integrated format for multiple testing in coronary artery disease, 463
Labeled metabolic substrates for positive imaging in ischemia, 465
Left ventricular diastolic performance during exercise in coronary artery disease: assessment of peak filling rate with first pass radionuclide angiography, 408
Mechanisms for the disappearance of Tl-201 defects at rest over time, 479
Miniaturized cardiac module for continuous monitoring of left ventricular performance using a semiconductor gamma detector: development of a prototype and initial clinical evaluation, 408
Multiple gated acquisition thallium scintigrams with computer enhancement: improved sensitivity in asymptomatic men with abnormal treadmill tests, 463
Multiple gated bloodpool cardiac scan (MUGA) during right atrial pacing (RAP): a sensitive method to detect myocardial ischemia, 408
Non-invasive monitoring of cardiac transplants, 410
Patterns of disturbed myocardial perfusion in patients with coronary artery disease, 464
Problems with the definition of a normal tomographic thallium-201 perfusion scintigram, 481
Quantification of left ventricular volume by equilibrium radioventriculography, 397
Quantitation of regional myocardial blood flow by positron emission tomography, 465
Quantitation of Tl-201 myocardial distribution and washout: normal standards for graded exercise studies, 480
Radionuclide angiographic evaluation of left ventricular performance during ventricular pacing, 458
Radionuclide ventriculography in 121 survivors of out-of-hospital ventricular fibrillation, 443
Relationship of coronary flow to Tl-201 redistribution, 480
Reversibility of adriamycin induced reduction in myocardial thallium-201 uptake by intravenous digoxin, 482
Right ventricular volume: analysis by equilibrium radionuclide angiography in normal subjects and patients with coronary disease, 398
Sensitivity and specificity of exercise radionuclide angiography in detecting coronary disease, 408
Thallium-201 scintigraphic evidence of ischemia in patients with myocardial bridges, 482
Thallium-201 stress myocardial scintigraphy: comparison of multiple pinhole tomography with planar imaging in the assessment of patients undergoing coronary arteriography, 481
^{201}Tl imaging: a comparison of single photon emission computed tomography and planar imaging employing a standard heart phantom, 464
^{201}Tl imaging in patients with myocardial infarction: a comparison of planar and seven-pinhole tomographic images, 481
Tomographic quantification of regional myocardial metabolism in vivo, 465
Ventricular phase analysis of radionuclide gated studies, 398
Viewer specified projection: a new method of computer display of LAO acquired gated blood pool data in any projection desired, 407

Ortho-iodo sodium benzoate
Reduction of experimental myocardial infarction size by ortho-iodo sodium benzoate, 485

Oxygen
Effects of dobutamine on myocardial oxygen consumption and left ventricular function in patients with chronic heart failure due to ischemic heart disease, 479
Improved cardiac function during coronary perfusion with low oxy-hemoglobin affinity human red blood cells, 479

Pacemakers
Analysis of malfunction and complications of temporary pacing, 459
Are an excessive number of permanent pacemakers being inserted? 458
Evaluation of an implantable programmable multimodal (DVI; DVI-DVO; DOO sequential; and DOO simultaneous) pacemaker for the control of supraventricular tachycardias, 457
Implanted automatic burst pacemakers for termination of ventricular tachycardia, 458
Refractory supraventricular tachycardias: successful therapy with double demand sequential pacing, 457

Pacing, atrial
Multiple gated bloodpool cardiac scan (MUGA) during right atrial pacing (RAP): a sensitive method to detect myocardial ischemia, 408
Nitroglycerin vs post-extrasystolic potentiation in the assessment of the acutely ischaemic left ventricle, 399

Pacing, cardiac
Rhythms underlying the fixed rate pacing of long-term transtelephone monitoring, 459

Pacing, endocardial
Management of paroxysmal ventricular tachycardia and fibrillation associated with the long QT syndrome, 458

Pacing, epicardial
Localization of pacing sites within infarcts by epicardial mapping, 494

Pacing, transvenous
Temporary transvenus pacing and femoral vein thrombosis, 459

Pacing, ventricular
Pulmonary venous regurgitation: etiology of hemodynamic deterioration during ventricular tachyarrhythmias and pacing, 457

Radionuclide angiographic evaluation of left ventricular performance during ventricular pacing, 458
Pancreatitis
Heart in pancreatitis: a combined clinico-pathologic study of 128 cases, 395
Papillary muscles
Papillary muscle function in renovascular hypertension, 434
Selective vulnerability of the papillary muscles to sequential blood flow changes induced by isoproterenol, 477
Pediatric cardiology
Axial angiography in atrioventricular canal malformations: anatomical-angiographic study, 428
Beneficial effects of endurance exercise training in adolescent hypertension, 489
Can ejection fraction be measured non-invasively in children after ventricular septal patching? 468
Cardiac rhythm after the Mustard operation for transposition of the great arteries, 430
Cardiac rhythm in sudden infant death syndrome, 431
Comprehensive assessment of atrio-ventricular valve morphology in single ventricle, 428
Cross-sectional echocardiographic evaluation of coronary artery abnormalities in children, 467
Digoxin disposition in premature infants, 429
Dual atrioventricular nodal pathway conduction—a common electrophysiological phenomenon in children without arrhythmias, 430
Electrophysiologic consequences of Mustard repair of transposition of the great arteries, 430
Electrophysiologic properties of normal neonatal and adult canine cardiac purkinje fibers, 431
Electrophysiology of right atrial hypertrophy in children, 426
Emax during exercise in children with left-sided cardiac disease, 467
Evaluation of cardiac chamber size and left ventricular function in children using two dimensional apex echocardiography, 468
Evaluation of left ventricular function during upright exercise using continuous echocardiographic monitoring (CEM), 467
Exercise capacity after valve replacement in children and adolescents, 468
Factors affecting real-time cross-sectional (2D) echocardiographic (ECHO) imaging of ventricular septal defects (VSD), 467
Late results of reconstruction of the right ventricular outflow tract with valved external conduits in children, 448
Long term afterload reduction therapy in children, 429
Management of the infant with coarctation of the aorta and ventricular septal defect, 450
New ultrasound technique for assessment of femoral vascular anatomy before and after cardiac catheterization (CC) in children and infants, 466
Pathogenesis of mitral valve prolapse (MVP) syndrome in children with Duchenne's Muscular Dystrophy: an ultrastructural and histologic basis, 396
Pulmonary vascular bed (PVB) in patients with tetralogy of fallot (TOF) with or without pulmonary atresia, 429
Pulmonary vasculature in pulmonary valvar stenosis, 450
Right ventricular growth in pulmonary atresia with intact ventricular septum, 448
Selection criteria for echocardiographic assessment of left ventricular pressure and peak gradient in patients with valvular aortic stenosis, 471
Subaortic stenosis: a thirty year experience, 449
Supraventricular tachycardia in children: clinical features, response to treatment and long term follow-up in 217 patients, 430
Systemic ventricular function in patients with congenital heart disease repaired during infancy, 468
Time course study of blood pressure in children after three years—Bogalusa Heart Study, 446
Truncus arteriosus with pulmonary vascular obstructive disease—medical vs surgical management, 450
Two dimensional echocardiographic features of corrected transposition, 466

Wide-angle two-dimensional echocardiographic assessment of fetal cardiac anatomy, 466
Wide-angle two-dimensional echocardiographic criteria for ventricular morphology, 466
Percutaneous transluminal coronary angioplasty
Healing of coronary artery intimal dissection after percutaneous transluminal angioplasty, 423
Improved myocardial perfusion and function following percutaneous transluminal coronary angioplasty (PTCA), 478
Pericardial effusion
Two-dimensional echocardiographic recognition of the descending thoracic aorta: value in differentiating pericardial from pleural effusions, 401
Pericardiotomy
Effect of nitroprusside on end-diastolic pressure-diameter relations of the human left ventricle after pericardiotomy, 393
Pericarditis
Importance of left ventricular filling in differentiating constrictive pericarditis vs. restrictive cardiomyopathy, 475
Pericardium
Hemodynamic effects of intact human pericardium after coronary bypass surgery, 417
Pharmacokinetics
Pharmacokinetics and pharmacologic effects after single and chronic doses of isosorbide dinitrate, 438
Phospholamban
Transient state kinetic studies of Ca^{2+}-dependent ATPase and Ca translocation by cardiac sarcoplasmic reticulum. Role of the 22,000-dalton protein phospholamban, 415
Pindolol
Protection of ischemic myocardium with intravenous pindolol in acute myocardial infarction, 484
Pirbuterol
Comparative effects of oral pirbuterol versus intravenous dobutamine on left ventricular function and energetics in chronic congestive heart failure: unique advantage of pirbuterol due to vasodilator and inotropic properties, 412
Pleural effusion
Two-dimensional echocardiographic recognition of the descending thoracic aorta: value in differentiating pericardial from pleural effusions, 401
Polyarteritis nodosa
Heart in polyarteritis nodosa: a clinicopathologic study of 36 patients, 395
Potassium
Effects of hyperkalemia on sinus node function: sino-ventricular conduction and sino-atrial reentry, 425
Intracellular potassium activity in guinea-pig atrial muscle, 425
Role of elevated extracellular K^+ activity in conduction slowing during acute myocardial ischemia, 460
Prazosin
Long term afterload reduction therapy in children, 429
Long term improvement in left ventricular function after prazosin therapy, 411
Preexcitation
Hypertrophic cardiomyopathy and ventricular pre-excitation, 491
Premature ventricular complexes
Treatment of PVCs with tocainide, quinidine sulfate, and placebos, 445
Pressure ventilation
Paradoxical rise in left ventricular filling pressure with positive end expiratory pressure ventilation: a reversed Bernheim effect, 476
Procainamide
Effect of procainamide on excitability in man, 452
Modification of ventricular tachycardia by procainamide, 452
Temporal dispersion of refractoriness: lack of correlation with antiarrhythmic efficacy in a model of chronic infarction, 474
Prognosis
Predictive and prognostic value of exertional hypotension, 456
Use of noninvasive clinical parameters to characterize prognosis in patients with angina pectoris, treated medically or surgically, 456
Propranolol
Adrenergic responsiveness following abrupt propranolol withdrawal in patients with angina pectoris, 438
Comparison of twice daily and four times daily therapy with propranolol in angina pectoris, 478
Reversal of propranolol induced myocardial depression during partial and total coronary occlusion by nitroglycerin, 437
Prostacyclin
Increased platelet prostaglandin generation and abnormal platelet

sensitivity to prostacyclin and thromboxane A_2 in angina pectoris, 454
Quantitation of platelet deposition in Gore-Tex femoral artery implants in the canine model and its reduction with dipyridamole and prostacyclin, 424
Prostaglandin E_1
Beneficial hemodynamic and energetic effects of afterload reduction with prostaglandin E-1 in patients with severe chronic congestive heart failure, 438
Prostaglandins
Decreased shunt flow in acute ventricular septal defect using 15-methyl-prostaglandin $F_{2\alpha}$ as a pulmonary constrictor, 462
Increased platelet prostaglandin generation and abnormal platelet sensitivity to prostacyclin and thromboxane A_2 in angina pectoris, 454
Proteolysis
Effect of ischemia on myocardial proteolysis, 414
Psychologic studies
Immediate psychological impact of exercise testing soon after myocardial infarction, 421
Pulmonary atresia
Pulmonary vascular bed (PVB) in patients with tetralogy of fallot (TOF) with or without pulmonary atresia, 429
Right ventricular growth in pulmonary atresia with intact ventricular septum, 448
Pulmonary constriction
Decreased shunt flow in acute ventricular septal defect using 15-methyl-prostaglandin $F_{2\alpha}$ as a pulmonary constrictor, 462

Rx: for your cholesterol patient

Sunlite™
is light, tasty, and provides the highest in polyunsaturates of all leading cooking oils—even corn oil. Included in your restricted fat/cholesterol dietary regimens, it can help lower serum cholesterol. Nutriologic study shows that: "The addition of polyunsaturated oils [e.g. Sunlite] will have a cholesterol lowering effect which is about half the cholesterol raising effect of saturated fats."[1]

Sunlite™
can help improve the Polyunsaturated to Saturated Fat (P/S) Ratio. After reducing the total fat intake from 40 to 30 per cent of calories, saturated fat from 18 to 9 per cent, and dietary cholesterol from 700 to 400 mg/day, an increase in the P/S ratio from 0.4 to 1.5 effected approximately a 16 per cent reduction of serum cholesterol when accompanied by weight loss.[1] In another study, increasing the P/S ratio from 0.3 to 1.2 produced comparable lowering of serum lipids.[2]

NEW!
sunlite™
100% Sunflower Oil

the highest of all leading polyunsaturated oils you can recommend

Sunlite™
for food that's medically sound and tastefully done

Hunt-Wesson Foods, Inc.

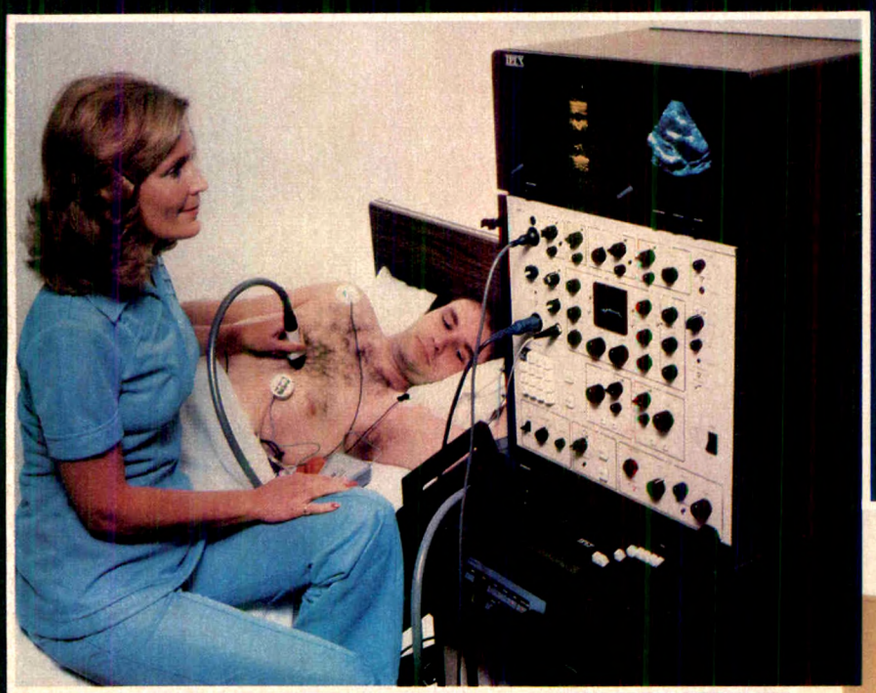
Irex: Three ways



1 The Irex Phased Arr Real Time Sector Scanner

A completely integrated system cardiac ultrasound diagnosis combining to-the-minute, 2-dimensional real t technology, proven M-Mode diagnostic ca bility and the optional Irex heart sound/p and respiration module, all in one comp mobile unit.

2 The Irex System II M-Mode Echocardiograph

The Irex System II is a comprehensive non-invasive ultrasound cardiac diagnostic system. It features a fibre optic recorder that provides superb black and white tracings; a versatile, reliable and easy-to-operate echo module; and the optional Irex heart sound/pulse and respiration module, all in a rugged easy-to-maneuver console.

3 The Irex System II Echocardiograph Stress Test Option

M-Mode echocardiography stress testing in one convenient, cost e tive unit, offering the proven reliability o Irex System II, with black and white reco complete M-Mode echocardiographic c bility; fully integrated 3-channel ECG mo treadmill controller module and rugged e cise treadmill.

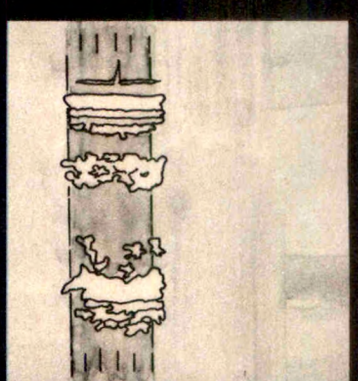
o look at the heart.

When you consider ultrasound cardiac diagnostic systems, consider Irex, the company that offers three ways to look at the heart, three distinct systems that offer superb technology, at an affordable price.

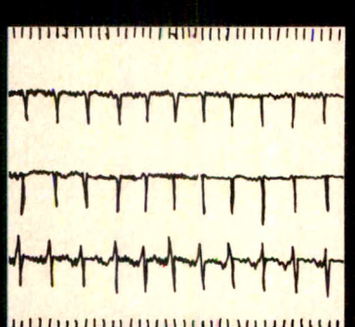
First, the newest, most advanced system, the Irex Phased Array Real Time Sector Scanner. Packed into its trim, mobile cabinet is a dynamically focused phased array system delivering crisp, high resolution images; two derived M-Modes, plus a completely independent M-Mode channel; and, room to add a heart sound/pulse and respiration module.

In short, the new Irex Phased Array Real Time Sector Scanner gives you all the measurements you need to perform a complete cardiac ultrasound study. All at a price that will pleasantly surprise you.

Second, the proven Irex System II M-Mode Echocardiograph System has a well-deserved reputation for performance and reliability. Since its introduction in 1977, the Irex System II has become one of the most widely used M-Mode echocardiography systems in the world. Its fibre optic recorder provides the clearest, most consistent tracings in the industry. The extremely versatile cardiac ultrasound module is highly sensitive for better definition of small anatomical structures, and the large, easy-to-view monitors aid in quick analysis. The optional heart sound/pulse module provides four channels: one each for respiration, heart sound, and pulse; and one for either heart sound or pulse.



Third, the Irex System II Echocardiograph Stress Test Option, loaded with outstanding features for smooth, convenient operator control. The three-channel stress module offers a 12-lead diagnostic ECG, plus X, Y and Z with automatic lead I.D. Plus bright, easy-to-read digital displays of heart rate and elapsed time to quickly and accurately monitor patient progress.



The automatic treadmill control module features fully automatic, operator selectable protocols, with manual interrupt for safety and maximum control. The treadmill is full size, rugged and quiet.

Irex: Three ways to look at the heart. With three outstanding Irex systems. Each is an outstanding addition to your hospital or clinic. Together, they give you the most complete ultrasound cardiac diagnostic center available. And all systems are backed by a responsive national network of factory trained service technicians.

IN THE MANAGEMENT OF ANGINA PECTORIS*

ISORDIL®

(ISOSORBIDE DINITRATE)

HELPS MAKE THE HEART'S JOB EASIER

Recent investigations[1-8] indicate that the peripheral effects of isosorbide dinitrate produce

...arterial dilatation, thus lowering impedance to left ventricular ejection

...venous dilatation, thus causing venous pooling and a fall in right and left ventricular filling pressures.

With afterload and preload reduced, the amount of energy expended and oxygen consumed by the heart should be decreased—and angina greatly reduced or controlled.

2. Danahy DT, Aronow WS: Hemodynamics and antianginal effects of high dose oral isosorbide dinitrate after chronic use. *Circulation* 56:205–212, 1977.
3. Glancy DL, Richter MA, Ellis EV, et al: Effect of swallowed isosorbide dinitrate on blood pressure, heart rate and exercise capacity in patients with coronary artery disease. *Am J Med* 62:39–46, 1977.
4. Hurwitz L, Naughton J, Gorman PA, et al: Isosorbide dinitrate and cardiovascular adaptation to exercise. *Chest* 69:10–14, 1976.
5. Kasparian H, Wiener L, Duca PR, et al: Comparative hemodynamic effects of placebo and oral isosorbide dinitrate in patients with significant coronary artery disease. *Am Heart J* 90:68–74, 1975.
6. Markis JE, Gorlin R, Mills RM, et al: Sustained effect of orally administered isosorbide dinitrate on exercise performance of patients with angina pectoris. *Am J Cardiol* 43:265–271, 1979.
7. Steele PP, Rainwater J, Battock D, et al: Isosorbide dinitrate-induced improvement in left ventricular ejection fraction during exercise in coronary arterial disease. *Chest* 74:526–530, 1978.
8. Willis WH Jr, Russell RO Jr, Mantle JA, et al: Hemodynamic effects of isosorbide dinitrate vs nitroglycerin in patients with unstable angina. *Chest* 69:15–22, 1976.

Four convenient, specifically indicated dosage forms:

to abort or prevent acute angina attacks

ISORDIL® SUBLINGUAL
Sublingual Tablets, 2.5 mg, 5 mg, and 10 mg

ISORDIL® CHEWABLE
Chewable Tablets, 10 mg

for more accurate titration of dosage to prevent angina attacks

ISORDIL® TITRADOSE®†
Oral Tablets with E.Z. Split® scoring:
5 mg, 10 mg, 20 mg, and 30 mg

to provide sustained prophylaxis against angina

ISORDIL® TEMBIDS® Capsules
Sustained-Action Capsules, 40 mg

*Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
"Probably" effective: When taken by the sublingual or chewable route, Isordil Sublingual and Chewable Tablets are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.
"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

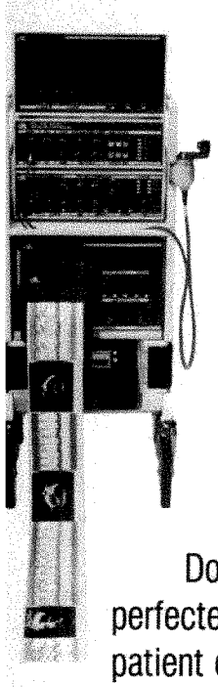
Now, the truth is out in the open

ATL offers on-line real-time hardcopy images with M-mode for echocardiography.



Made possible by unique digital electronics. Making our Mark III an integrated diagnostic system, not a stack of electronic boxes. Unlike analog processing, the ATL Digital Scan Converter captures the signal, however weak, and stores it into memory. Once secured, its accurate reproduction in standard video format is continuously assured. Thus digitized, its wide range of grey scale display offers greater diagnostic utility.

You get line and flicker free images of the moving heart, capturable in freeze-frame, adjacent to a sharp black on white M-mode. Same intracardiac structure. Printed on the same paper. The payoff is a logical integration of the two modes, easy to read hardcopy, easy to handle, for a clear interpretation and report.

Doctor and system interact. Segments of the study may be dealt with and perfected without disturbing the whole. Adequate data is obtainable during the first patient examination, saving valuable time. Serial studies are assured consistent data. Graphics or alphanumerics can be super-imposed. Unique with the Mark III, voice can be recorded during freeze-frame. The study may be taken off line for display or computer processing.

The ultimate payoff is tomorrow. Digital is the future. Because, with digital, growth is from within. State-of-the-need today, the system will grow with your needs and new technology. It's what the world is coming to. And, more and more, the world is coming to ATL for advanced instrumentation.

Advanced Technology Laboratories. 13208 Northup Way, Bellevue, WA. 98005 (206) 641-5410.

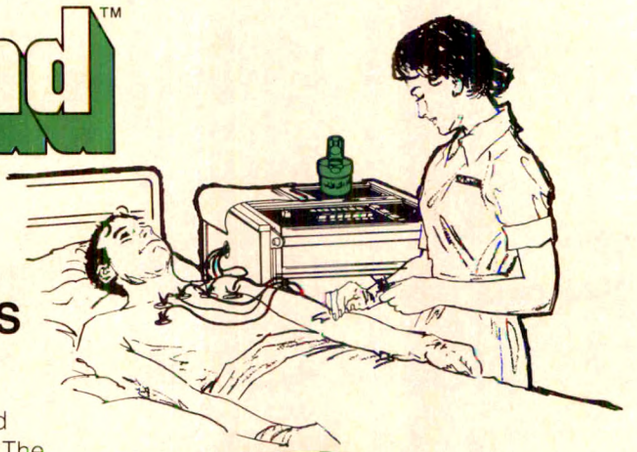
PARKER LABORATORIES INTRODUCES

signa pad™



THE ULTIMATE IN PREMOISTENED ECG ELECTRODE PADS

SIGNAPAD is a major improvement in premoistened electrode pads dispensed individually from a multiple pad source. The ultra thin pad assures less artifacts and more accurate tracings.

- For single and multi-channel use
- Remove SIGNAPAD one at a time, or as many as needed
- Saves preparation and clean-up time
- Eliminates residue build-up . . .
- Antiseptic and bacteriostatic
- Non-irritating
- SIGNAPAD can be used with all ECG electrodes
- Substantial savings over old-fashioned foil pouch pads

Call our Toll-Free Number 800-631-8888 for further information.

Is Bypass Grafting Indicated for All Patients With Atherosclerosis of the Left Main Coronary Artery?*

HENRY D. MCINTOSH, MD, FACC
ROBERT A. BUCCINO, MD, FACC

Lakeland, Florida

Aortocoronary bypass grafting has been demonstrated to relieve the symptoms of angina pectoris and to enhance the functional capacity of many patients. It is not surprising that the procedure continues to gain popularity as a means of treating atherosclerotic occlusive disease of the coronary arteries. However, the benefits of surgery are not always long-lasting and, except for selected subsets of patients, it has not been generally accepted that premature death may be postponed or prevented.[1,2] One such exception, as reported by Loop et al.[3] in the August 1979 issue of the Journal appears to embrace patients with stenosis of the left main coronary artery.

What is critical stenosis of the left main coronary artery?: Loop et al.[3] describe 300 cases of surgically treated patients collected retrospectively on the basis of arteriographic demonstration of 60 percent or greater obstruction of the left main coronary artery. The long-term follow-up data in these patients were compared with findings in "control populations" in previously reported studies. At first glance, such a comparison appears reasonable because there is considerable evidence that, as a group, patients with stenosis of the left main coronary artery have a very poor prognosis. But what constitutes critical stenosis of this artery? Do all patients with such stenosis constitute a homogeneous subset with respect to clinical course? What variables, in addition to the stenosis of the left main coronary artery, influence the prognosis of such patients?

Loop et al.[3] accepted more than 60 percent obstruction as significant. In the Veterans Administration randomized trial[4] the criteria employed were a reduction in luminal diameter of 50 percent or greater; a similar degree of stenosis was used to identify the study population of Campeau et al.[5] But Conley et al.[6] found crucial only lesions that compromised the lumen of the left main coronary artery by at least 70 percent. As noted by Loop et al.,[3] as well as by others,[1,2,4,6] significant obstruction confined to the left main coronary artery is relatively uncommon. In the series of Loop et al.[3] only 38 patients (12.7 percent) had such an isolated lesion. More commonly, significant obstruction of the left main coronary artery occurs in various combinations with occlusive disease in one or more of the other major coronary arteries; often there are multiple lesions distributed diffusely throughout the coronary arterial tree.

Prognosis of subsets of patients with left main coronary disease: There is increasing evidence that patients who have atherosclerotic lesions in the left main coronary artery do not constitute a homogeneous population.[1,2,5,6] Conley et al.[6] concluded that "although the prognosis for the overall group of patients with left main stenosis is undoubtedly grave, the prognosis for individual patients must vary." These investigators carefully studied and prospectively followed up patients with 70 percent or greater stenosis of the left main coronary artery (most of whom had in addition a 70 percent or greater stenosis in all three other major vessels). They concluded that survival was considerably better for periods of up to 3 years when none or at most one of the following clinical characteristics was present: history of congestive failure, chest pain at rest, cardiomegaly on chest X-ray examination and ST-T wave changes in the electrocardiogram at rest. In addition, they found that several factors—abnormal left ventricular contraction patterns, arteriovenous oxygen difference of

5.5 volumes percent or greater or a left ventricular end-diastolic pressure of 15 mm Hg or greater—were associated with an increased mortality at 1 year.

Campeau et al.[5] analyzed the survival of 114 patients who did not undergo operation and 197 surgically treated patients who were followed up for up to 7 years. The benefits of surgery were found to be greatest when the patient had significant lesions in a dominant right coronary artery in addition to stenosis of the left main coronary artery. These investigators concluded that "patients with slight to moderate impairment of left ventricular contraction tend to have an improved survival following surgery, but there is no definite evidence that patients with normal or with markedly abnormal left ventricular function have the same benefit from surgery." They further concluded that in studies "without randomization of patients the difference in survival may be explained by obvious or undetected differences between cohorts."

In view of such evidence it is surprising that Loop et al.[3] failed to distinguish more significant differences in survival among their anatomic subgroups or between their patients with and without left ventricular dysfunction. It is unclear whether the lack of such differences is due to the method by which their patients were selected for surgery or to a failure to compare their patients with nonsurgically treated patients with similar abnormal findings.

On the basis of personal experience and a careful analysis of reported studies[1,8] *we believe that patients with stenosis of the left main coronary artery should be classified into three groups;* (1) those who are clinically symptomatic and are at great risk *because of* the severity of the stenosis of the left main coronary artery; (2) those who are clinically symptomatic and at great risk because of the extent of disease *in other vessels* but who also happen to have arteriographic evidence of occlusive disease of the left main coronary artery; and, (3) those who are neither severely symptomatic nor at great risk but who have stenosis of the left main coronary artery almost as an *incidental arteriographic finding.* Variations in the proportion of each type of patient distributed among surgically treated and nonsurgically treated cohorts might profoundly influence the observed outcome and lead to incorrect conclusions regarding the benefit or lack of benefit of surgery.

Role of completeness of revascularization: It is also surprising that Loop et al.[3] found that the "completeness of revascularization" had little impact on survival after surgery. Only 140 of their 300 patients were said to have "complete" revascularization; the remaining 160 had "incomplete" revascularization. Yet there was no significant difference in the 5 year survival rate (91.6 versus 86.5 percent) of the two groups! This observation is particularly surprising in view of the extent of the atherosclerotic involvement observed in the study population. The number of grafts per patient in this study was not stated but the data supplied for the follow-up angiographic studies suggest that the patients received two or fewer grafts despite the severity and diffuseness of their disease. Does such demonstration of obviously incomplete revascularization in a large percent of patients whose survival was no poorer than that of patients with complete revascularization mean that a large number of patients destined to do well anyway were operated on? Does it support the concept that patients with left main coronary artery stenosis of the left main coronary artery form several subsets of patients with widely varying prognoses? Or does it challenge, as did the study by McNeer et al.,[7] the current philosophy regarding the need for "complete" revascularization?

Identification of patients at low versus patients at high risk: There can be little doubt that coronary bypass surgery postpones premature death in a significant number of patients with stenosis of the left main coronary artery. Why, then, should there be concern about distinguishing between patients with this anatomic finding who are at great risk and those who are at low risk? There are two reasons. First, consider that all patients with arteriographic significant stenosis of the left main coronary artery were at great risk of premature death unless operated on, regardless of their symptomatic state or left ventricular function. If this were true, massive screening with coronary arteriography of large segments of the population would be in order to identify such patients. Epstein et al.[2] recently analyzed "the profound economic implications of such screening studies." They provided a rational and restrained strategy for the use of bypass surgery in the asymptomatic or mildly symptomatic patient with particular reference to patients with stenosis of the left main coronary artery.

Second, identification of a low risk cohort with stenosis of the left main coronary artery is indicated because there is reason to suspect that there may be a proper time in the natural history of the disease in which surgery, if indicated, is best performed. Such a consideration is warranted because surgery is not completely innocuous; there is an operative risk, albeit small. Furthermore, the long-term patency of grafts and the effects of surgery and the grafts on the native circulation have not been clearly established.[1,2,8] This lack was not corrected by observations reported by Loop et al.[3] They studied 51.4 percent of their patients 1 week to 72 months after operation (mean 16.5 months). They did not state how the patients were selected for postoperative evaluation. Although they reported that 84 percent of the grafts were patent, they did not indicate at what time after operation the evaluation was made. They also made no comment about changes in the native circulation.

To avoid introducing bias in patient selection when determining graft patency or changes in the native circulation it is necessary to study, in a predetermined manner according to the issues the investigator is seeking to resolve, a large proportion of consecutive patients treated surgically. Unfortunately, the frequently quoted studies that claim an 80 percent or higher patency rate[9–11] and no significant effect on the native circulation[12,13] were not based on studies of a large proportion of patients *consecutively operated on.*

The currently available knowledge regarding long-term graft patency and the effects of surgery on the native circulation is sketchy and fraught with overt and potential selection bias.[14] It is somewhat like the information that the clinician may obtain about the liver by means of a needle biopsy; the sample may or may not be representative of the whole.

Implications of study by Loop et al.: At first glance the study of Loop et al.[3] appears to establish that survival is prolonged by surgery in patients with stenosis of the left main coronary artery; on closer analysis it raises at least two important questions: (1) Does significant stenosis of the left main coronary artery occur in patients who are destined to do well even with incomplete surgery? Is there not a subset of patients with this lesion who are at low risk? If so, until knowledge about the long-term effect of surgery is more complete, is surgery, or at least immediate surgery, indicated for such patients? (2) The study raises an even more fundamental question: To what extent is the effect of surgery in postponing premature death in any patient dependent on the degree of completeness of revascularization?

Until these and other questions regarding the long-term effects of bypass surgery are clearly answered the physician is cautioned to keep an open mind and consider that even patients with stenosis of the left main coronary artery may constitute a heterogeneous group of patients whose prognosis may vary widely. Until the natural history of patients with this lesion is more carefully defined and the role of surgery clarified it would not appear prudent to initiate large-scale screening efforts of asymptomatic patients to search for this lesion for the purpose of immediate surgery.

Hard and Soft Data on Treatment of Left Main Coronary Lesions*

FLOYD D. LOOP, MD, FACC
BRUCE W. LYTLE, MD
WILLIAM C. SHELDON, MD, FACC

Cleveland, Ohio

Survival in patients with left main coronary disease: A grim natural history for patients with documented left main arterial lesions is clearly evident from virtually all published reports. Longer survival through surgical treatment was first recognized in these patients largely because their plight with medical treatment was worse than that of other groups. In 1975 Lim et al.[1] surveyed 141 such patients who had undergone coronary arteriography in 1963 to 1965. They reported a 51 percent 5 year cardiac mortality rate. More recently, Lim (unpublished data) found a 5 year mortality rate of 54 percent for 120 of the original 141 patients who had more than 60 percent right coronary arterial narrowing compared with a 38 percent mortality rate for the remaining 21 without a severe right coronary lesion. In their series, patients who would have been eligible surgical candidates were also selected retrospectively; of 116 prime candidates the outlook was no better and only 51 percent were alive after 5 years. Oberman et al.[2] reported a 2 year survival rate of 65 percent in 24 patients eligible for surgery but treated medically. The Veterans Administration[3] stopped their controlled study of left main coronary obstruction after 53 patients in the medical cohort experienced a 36 percent 30 month mortality rate, a percentage considered too high to justify further randomization. Campeau et al.[4] suggested that earlier reports of left main coronary lesions may have been grossly exaggerated, but overall their series of medically treated patients had a 49 percent 5 year survival rate. Incidentally, they found no appreciable difference in survival between those treated conservatively in 1968 to 1971 compared with those so treated in 1972 to 1976. These and many other reports attest to the fact that the fate of patients with severe left main coronary lesions is no better and possibly worse than that of patients with three-vessel disease (that is, 50 percent attrition in 5 years).

Recently, Conley et al.[5] renewed interest in patients with left main artery disease. By multivariate analysis, they identified high and low risk subsets which revealed disparate 3 year survival rates of 74 and 25 percent, respectively. In those with no risk factors or only one, the 1 year survival rate (approximately 97 percent) was especially favorable, but thereafter the slope of the comparative actuarial curves was similar. As these investigators point out, separation of patients with left main coronary artery disease into low and high risk groups adds flexibility to management so that patients can be well prepared and surgery deferred, if necessary, for a short time.

Surgical series dealing with late follow-up of patients with left main coronary disease are derived from 1970 to 1974. Before that period insufficient experience led to high mortality rates. After 1975, use of cold potassium cardioplegia combined with systemic or topical hypothermia, or both, vastly improved myocardial protection. Technical experience, higher quality angiography and greater respect for timing surgical intervention have contributed to greater safety and less morbidity. Our first 300 surgically treated left main patients were operated on in the earlier period (1968 to 1973).[6] The actuarial 5 year gross survival rate was 88.2 percent. Approximately two thirds of the patients had greater than 60 percent narrowing of the right coronary artery and their survival rate was 85.3 percent compared with 89.3 percent for those without significant right coronary arterial obstruction.

* Editorials published by the Journal reflect the views of the authors and do not necessarily represent the views of the Journal or of the American College of Cardiology.

In the Montreal experience[4] the difference between surgical and medical survival rates reached statistical significance (80 versus 49 percent in 5 years). However, in the smaller cohorts without right coronary stenosis, the 92 percent surgical survival rate was not significant despite a 68 percent medical survival rate. Regardless of statistical validation, a perceptible trend exists. Bailar's laws of data analysis[7] remind us that statistics should not tell people what to do. The function of data analysis is to indicate as accurately as possible what it is possible to accomplish. Although the Montreal investigators found that surgical results were optimal when the preoperative ejection fraction was between 0.45 and 0.59, the authors' intent was not to advocate strict medical management for all patients whose ejection fraction falls above and below these levels. In our series, as in theirs, the evolution of surgical technique and experience greatly contributed to the difference in survival between patients who were and were not treated surgically.

Graft patency: Concern that a third or more of grafts may close in the first 5 years has not been borne out in the published reports. In near consecutive patients studied serially at 2 to 3 weeks, 6 to 18 months, 3 years, and 5 to 7 years postoperatively, Campeau et al.[8] demonstrated a lack of progression of graft intimal fibrosis and a low graft attrition rate after the 1st year. In 100 patients who had at least one graft patent 6 to 18 months postoperatively, only 17 of 159 grafts were occluded during the subsequent 5 year interval; these data yield an average yearly graft attrition rate of 2.1 percent after the 1st year. The Montreal group attributed improvement in graft patency to changing graft techniques in a second series in which the mean yearly graft attrition rate was 0.7 percent after the first postoperative study. Kouchoukos et al.[9] reported a 1 year graft patency rate of 76 percent in their 1970 to 1973 experience compared with a rate of 85 percent for patients operated on in 1974 to 1976. They also recorded a low mean annual attrition rate of 1.7 percent between 12 and 42 months postoperatively in 116 grafts that were initially patent. Guthaner et al.[10] reported that 26 patients had 39 grafts open at 1 year and 87 percent of these grafts were patent 6.5 years later. They concluded that graft occlusion could not be predicted on the basis of early arteriograms. Lawrie et al.[11] reported that 1 of 38 grafts studied between 15 and 40 months postoperatively had closed and among 193 grafts studied after a mean interval of 70 months postoperatively, 90.7 percent were patent.[12]

Our serial studies[13] were confined to patients operated on in 1971 to 1973. Of 144 vein grafts, 85.4 percent were patent at the initial catheterization (mean 14 months). Of 123 grafts initially open, 109 (88.6 percent) remained patent during a mean interval of 42 months between first and second catheterizations. Thus, 11.4 percent of grafts closed after a mean interval of 3.5 years resulting in a cumulative vein graft patency rate of 76 percent at approximately 5 years. Since our 1977 International Symposium,[14] we have updated figures for 471 patients who had 646 vein grafts studied longer than 48 months postoperatively and found an 81.1 percent patency rate. In contrast, 88 internal mammary artery grafts, predominantly to the left anterior descending coronary artery, had a 94.4 percent patency rate after 48 months. For grafts patent at 1 year there appears to be a low incidence of graft failure and development of late stenosis during the first 5 postoperative years.

Graft sclerosis: Aortocoronary vein grafts are not immune to atherosclerosis, a finding reported by Batayias,[15] Grondin[16] and Lawrie[12] and their colleagues. Correlation between hyperlipemia and vein graft atherosclerosis differs in these reports. Nevertheless, grafts with perceptible focal stenosis observed several years after operation are more prone to late occlusion presumably from atherosclerosis than are those with diffuse narrowing. In the series of Grondin et al.,[16] 138 of 158 (85 percent) of grafts patent 6 years after operation showed no angiographic evidence of atherosclerosis. Therefore, the passing of time alone does not necessarily lead to atherosclerosis. Again, the problem involves identification of those who are susceptible to progressive atherosclerosis and to development of atherosclerosis in the conduit.

Effects of graft on the native coronary circulation: Only one long-term serial catheterization study has addressed the effects of grafts on the native coronary circulation. Bourassa et al.[17] in serial catheterizations of 108 patients concluded that during the 1st postoperative year progression of disease occurred two to five times more frequently in grafted than in nongrafted coronary arteries, and that occlusion occurred predominantly in the segment proximal to the graft. Progression at the site of anastomosis was infrequent and atherosclerosis distal to the graft showed little progression. As one might expect, the nongrafted artery showed slight progression in the 1st postoperative year but, thereafter, progression increased to involve 46 percent of all nongrafted vessels when minimal atherosclerosis was observed preoperatively. A fascinating observation was mentioned by Bourassa,[18] that progression of atherosclerosis seemed to occur abruptly at one point in time and was *not* slowly progressive. The concern that the saphenous vein bypass grafting will accelerate coronary atherosclerosis has relatively little justification in light of these studies.

"Complete" versus "incomplete" revascularization: The effect of more grafts per patient on survival remains unanswered. In reports of surgical series in 1970 to 1974, the number of grafts per patient clusters around 2.0. Today, enhanced myocardial protection and improved grafting techniques have greatly contributed to a rise in number of grafts per patient to 3.0 or greater. Does grafting smaller radicles of obstructed coronary arteries appreciably alter survival? This question is unanswered and thus far no data have been reported about long-term patency in multiple small vessel anastomoses. The simplistic definition of complete or total revascularization relies on the ratio of arteries grafted to arteries severely obstructed. When all the severely narrowed arteries received bypass grafts, the case was classified complete. If not, regardless of the cause, the

procedure was considered incomplete. This definition does not take into context (1) graft patency; (2) presence of transmural infarction scars; (3) area perfused by the target vessel; and (4) size of the artery. An incomplete operation should not imply that the surgeon became tired and stopped grafting. Instead, it means that the stenotic yet ungrafted arteries were too small or too diffusely atherosclerotic or they perfused a large scarred area. In the early 1970's, our incidence of complete revascularization as defined earlier varied between 50 and 60 percent, whereas it was 82 percent in 1978. Buccino and McIntosh[19] report that between 1968 and 1973 the percent of arteriographically identified diseased arteries that were bypassed rose from 40 to 84 percent. Nonetheless, in our series of patients with left main coronary artery disease,[6] complete revascularization did not make a substantial impact on 5 year survival. However, in our 1971 to 1973 composite of isolated revascularization, which included single vessel disease,[13] patients who had complete and incomplete revascularization showed a 5.8 percent difference in 5 year survival.

Implications: If it is true that fewer people die from coronary atherosclerosis today, this is truly cause for celebration. But before we enthusiastically embrace the decrease in prevalence of atherosclerosis, we should be reminded that no data exist to indicate any change in the natural history of documented coronary atherosclerosis once critically obstructive lesions develop. In any group of patients with coronary artery disease, including those with lesions of the left main coronary artery, there are persons destined to survive without revascularization. The problem lies in accurate identification of those patients who have protective factors in their clinical profile. For the individual patient, the survival rate at the end of a specified period is either 0 or 100 percent. Therefore, we rely on the reported outcome of subsets or groups to advise our patients about the best direction of treatment. Thus far, no subset of patients with left main coronary lesions, including the low risk group of Conley et al,[5] has a better survival than that of our surgically treated patients. Present hard survival data support the contention that surgical treatment, at least for the first 5 postoperative years, is *significantly* better than medical treatment alone. When one adds symptom relief to the assessment of therapy, the role of surgery is abundantly clear.

SCINTIGRAPHY IN NONTRANSMURAL MYOCARDIAL INFARCTION

Massie et al.[1] in their paper on scintigraphy in the diagnosis of nontransmural myocardial infarction puzzle over finding a diffuse pattern with almost equal frequency in patients thought to have nontransmural infarction and in those with stable angina. The implication is that the pattern does not distinguish between two very different pathophysiologic processes. Another explanation is as likely: Patients designated as having nontransmural infarction and those said to have angina were in fact indistinguishable because they suffered from the same events; that is, some of the patients in the group with nontransmural infarction in fact had angina. The diagnosis of nontransmural infarction was made on the basis of inverted T waves for at least 48 hours without Q waves. I am not at all convinced that this signifies infarction. It may be that the definition of nontransmural infarction is just as "diffuse" as the radionuclear pattern.

REPLY

We agree that the clinical spectrum of myocardial ischemic events represents a continuum from brief exercise-induced episodes of angina pectoris to extensive transmural myocardial infarction. Certainly some patients with severe or unstable angina may have necrosis; conversely, some with electrocardiographic evidence of nontransmural infarction may have experienced ischemia without necrosis. Some overlap between patients with unstable angina and nontransmural infarction is to be expected, and has been demonstrated by both creatine kinase assays and pyrophosphate scintigraphy.[1,2]

However, we do not feel that such overlap was present in our patient groups. We employed a standard and highly specific definition of nontransmural infarction, which required both the presence of persistent electrocardiographic changes and abnormal levels of MB-creatine kinase. The appearance of MB-creatine kinase appears to be highly specific for myocardial necrosis.[1,3] The patients with angina were all symptomatically stable, had no electrocardiographic changes suggestive of acute ischemia or necrosis, and had normal serum enzyme levels. In addition, none had pyrophosphate uptake that could be localized to the myocardium. Taken together, these findings make necrosis unlikely.

On the other hand, the scintigraphic findings in these patient groups indicate that the diffuse pattern of pyrophosphate uptake was not specific for acute infarction in our study. This finding is consistent with our previous experience, in which we noted diffuse uptake in a similar proportion of patients without evidence of cardiac disease undergoing routine bone scans.[4] As a result, we do not consider scintigrams with this pattern diagnostic of infarction. More perplexing and clinically more important than the presence of diffuse uptake in a low percentage of patients from all these groups is the overall low sensitivity of pyrophosphate scintigraphy in these patients with well documented nontransmural infarctions. It was this latter observation that led us to report our findings.

CORONARY ARTERIOGRAPHY FOR WHOM?

Effler and Gensini[1] state that coronary catheterization "should always be recommended unless a specific contraindication exists." This policy would subject every patient with coronary artery disease to cinearteriography. The advocacy of such indiscriminate testing of large segments of our adult population runs counter to the valuable lessons we have learned in other areas of medicine. To cite just one example, advocacy of intravenous pyelography for every hypertensive patient is no longer practiced because the clinician learned that the information to be gained did not, in any way, modify effective patient management. Yet we are now being asked to subject patients with chest pain to a technique several orders of magnitude more dangerous and costly than intravenous pyelography, without firm evidence of benefit.

The authors' insistence on the patient's "right to know" is admirable, but it is surprising that they are so arbitrary in the application of that principle. For example, the patient should be informed that catheterization nearly always leads to surgery despite public protestations of some surgeons to the contrary. He should be informed of the lack of convincing evidence that coronary bypass surgery prolongs life and that, despite 11 years of such surgery in nearly 500,000 people, much uncertainty prevails among thoughtful physicians as to its role in the management of coronary artery disease. He should also be informed that significant morbidity and mortality are associated with this operation and that medical programs have increasingly improved and now afford excellent control of angina and enhance life expectancy.

It is incumbent on practicing physicians not to be stampeded into this type of merchandising of medical technology because of its burgeoning popularity among some surgeons and angiographers. Nor should we be propelled in such an

unreasonable direction by fear of litigation. If we pursue such a policy instead of focusing precisely on the specific and immediate needs of the individual patient, we stand in jeopardy of further tarnishing our image in the eyes of an already questioning public.

REPLY

Gensini and I believe that selective coronary arteriography is the most precise form of diagnosis available for ischemic heart disease. Properly utilized it excludes the presence of the disease if this is the case; if a myocardial perfusion deficit exists it offers precise localization and helps in determining the needs of the individual patient. If Kowey can come up with any other diagnostic adjunct that will offer this same amount of information at negligible risk to the patient and modest cost I would very much like to hear more about it.

The statement that bypass graft surgery inevitably follows coronary arteriography is without basis in fact. In 1978 the cardiovascular laboratory at St. Joseph's Hospital Health Center under the direction of Gensini performed selective coronary arteriography in more than 700 patients without mortality. During that year 330 patients were operated on for various forms of acquired heart disease; 260 patients were operated on primarily for revascularization surgery. Thirty-two of these patients had catheterization performed elsewhere before surgical referral. By simple arithmetic, this breaks down to about 30 percent of the total patients studied undergoing revascularization surgery.

It is a basic ethic of medicine to advise every patient of his options in diagnosis and therapy. This ethic was not of our invention but it is a reality today. In this regard I suggest that one might consult some of the private practitioners who come to Peter Bent Brigham Hospital and ask them specifically about "informed consent," "second opinion" and the current cost of malpractice insurance.

MEDICAL JOURNALS AND RANDOMIZED TRIALS

Although I respect the objectives and the reasoning of the authors of the group letter by Spodick et al.,[1] I hope the editors and reviewers they address will consider carefully before heeding their plea, which is based on a faulty analogy. Surgical progress entails not only new ideas and new techniques that can be worked out to some extent in the laboratory, but also often fortuitous clinical opportunities provided by unique pathologic processes. And surgical successes, particularly with new operations, depend on teamwork and attention to vital details which must be developed to some extent by experience. One cannot dispense one tumor removal as one dispenses one tablet.

Improvements in surgical technique also take time to become effective. Actuarial survival at 5 years after coronary bypass surgery at the Buffalo General Hospital has risen from 85 percent in the first 362 uncomplicated cases to 94 percent in the 1,050 cases of patients who had surgery between 1973 and 1977 ($p < 0.0002$). Randomization in the first clinical trial may lead to an underestimate of surgical potential.

A more important consideration is the matter of size. Well organized careful randomized trials[2,3] of coronary bypass surgery done in a single institution have still not demonstrated prolongation of survival on statistical analysis. These failures come not from lack of skill in selection of patients or performance of surgery, but because the numbers involved are too small to validate statistically the small differences in survival noted at 5 years.

Size problems can be overcome by cooperative trials involving many institutions, but here randomization from the first case is clearly impossible. In retrospect one can argue that the Veterans Administration cooperative study of coronary bypass surgery, for all it has taught us, might well have been delayed even beyond its second start in order to allow the development of a higher and more uniform level of surgical skill. Had it not been handicapped by a high early mortality rate, the advantages of surgery for survival might have appeared earlier.

I hope this letter will not be construed as a plea against randomized trials. My plea is that the editors and reviewers of this Journal continue to review each paper on its merits, rather than take the position that if it isn't randomized it isn't publishable. Otherwise many good surgical papers will be lost to this Journal.

REPLY

Greene has taken issue quite reasonably with the plea for equal standards for medical and surgical treatment. I think, however, that his points can be rebutted equally reasonably.

We implied no "faulty analogy" between surgical treatment and the administration of a tablet. Our point derives from principle, rather than analogy—the principle of equally valid standards for judging both the results of and the indications for all treatments. Indeed, our particular concern derives from particular differences between medical and surgical therapy: Unlike pills and injections you cannot discontinue or withdraw most surgical treatments. Hence, surgical rearrangements of tissue require particular stringency in assessing whom they help and whom they hurt. Traditional trial and error just will not do.

Developing experience certainly improves operative technique. It is reasonable to consider that if this improves surgical mortality significantly it improves the comparison of a given procedure with nonsurgical methods and might be a confounding factor in assessing a continuing controlled clinical

trial. Yet, those randomized to surgery could always be independently analyzed for the effects of technical changes exactly as they are now in uncontrolled traditional trial and error series. Of course, it would take twice as long. Meanwhile, half the candidates who had not been recognized as inappropriate subjects for a new technique would be spared unnecessary surgery, avoiding a procedure which amounts to unintentional assault and battery. Indeed, one of the important features of random allocation is having a valid comparison group, not only to judge end results, but also to establish genuine indications *and contraindications* for the new therapy.[1] In fact, in the particular instance of aortocoronary bypass surgery this consideration may be much more important than improvements in technique.[2] The carefully worked out experience in a very large group of patients, according to the combined conclusions of the Duke University Departments of Surgery, Cardiology, Medicine and Community Health Sciences, is that the "results demonstrate that the apparent variation in operative mortality over time is *largely a consequence of the changing pattern of patient selection*"[2] (my emphasis). Moreover, the Duke investigation adds to the hard evidence that a component of the ethical imperative[1,3–5] of random allocation from the outset is to give the patient a "50-50 chance" not to get the new procedure.

All of us who sincerely hope for the success of aortocoronary bypass surgery have only wished its success to be genuine, while the identification of patients who should and who should not get the procedure should be equally appropriately established.[1] It is easy to agree that improving surgical experience and, perhaps more so, improving patient selection,[2] have decreased at least operative mortality and increased graft patency. Despite this, many questions remain because of post-bypass deterioration of myocardial function in some patients[6] and improvement in performance despite unsuccessful revascularization (that is, all grafts occluded).[7] It is as much to identify such groups as to determine the technical success of the operation that randomized controlled studies are needed. Indeed, one large scale study by outstanding investigators showed that 47 percent of patients were unchanged and 40 percent of patients deteriorated with respect to chest pain at a mean of 30 months after bypass.[8] Yet this was done without random allocation and without a control group. For that specific reason, these *adverse* results of aortocoronary bypass are unacceptable, just as *favorable* results on the same uncontrolled basis must be unacceptable.[1]

Because we cannot assume the success of any new procedure no matter how "obvious" may be its basis, it is necessary to do a scientifically valid (hence ethical[1,3–5]) study from the outset. This kind of study is best done by randomized controlled clinical trials. Indeed, one of the assumptions at the inception of a new procedure is that it might not work or that it could be harmful to some or all patients and these cannot be known at the outset; *this is the ethical (hence, scientific[1,3–5]) basis for randomizing the first patient.* The valid—though perhaps comparatively small[2]—factor of changing technical skill cannot outweigh these considerations. It can be assessed independently in those randomized to surgery.

ISOPROTERENOL IN PRIMARY HYPERTENSION

The paper by Daoud et al.[1] on the use of isoproterenol as a pulmonary vasodilator in primary pulmonary hypertension demonstrates that some patients with this disease may attain a substantial reduction in pulmonary arterial pressure and resistance when isoproterenol is administered by the intravenous or sublingual route. Sublingual administration also apparently was useful when taken by one patient before exercise.

We[2] reported a similar instance of a favorable effect of intravenous and sublingual isoproterenol in a patient with primary pulmonary hypertension and exertional syncope. Sublingual medication taken before exercise improved exercise performance and ameliorated exercise-associated symptoms. Three years after the patient's initial study, cardiac catheterization studies demonstrated apparent progression of his disease.

This patient has been followed up for 6 years (January 1979). Symptomatic benefit from isoproterenol still persists but to a lesser degree. The current dosage, 20 mg 6 to 12 times daily, permits a modest, transient increase in exercise tolerance and prevention of exertional dizzy spells. However, his disease has continued to progress and he now requires furosemide and digitalis for congestive failure with hepatomegaly and peripheral edema. His episodes of presyncopal dizziness are more frequent and occur at rest and with mild exertion.

It is evident from these studies that some patients with primary pulmonary hypertension may achieve hemodynamic and symptomatic benefit from intravenous or sublingual isoproterenol. Hemodynamic assessment of the patient's response to isoproterenol should be performed before the institution of therapy since it is evident that only a small percentage of patients with the disease will exhibit a favorable response. Progression of the disease does not appear to be prevented by isoproterenol.

REPLY

The points raised by Hultgren et al. serve to emphasize further what we attempted to convey in our report. Our experience

supports their observation that isoproterenol may not alter the outcome of the disease process. The possibility, however, that the chronic use of isoproterenol may slow the progression of the disease should be considered.

ECHOCARDIOGRAM IN MITRAL REGURGITATION

In the article by Antman et al.[1] on aortic stenosis mimicked by mitral regurgitation, Figure 2, panel 2 illustrates an enlarged echocardiographic view of the mitral valve. This illustration appears to have been erroneously labeled; part of the mitral apparatus (chordae tendineae or anulus) is noted as the posterior leaflet and the text describes ". . . excessive mobility of portions of the posterior leaflet in diastole." On closer inspection of the diagram, one can note the true posterior leaflet consistently moving normally in late diastole with clear coaptation at the "c" point in most complexes.

Despite the error, the echocardiographic criteria of prolapse are fulfilled because the true posterior leaflet moves posteriorly during mid to late systole[2] and multiple systolic echoes are noted,[3] thereby correlating with the surgical findings. The echocardiographic diagnosis of flail leaflet[4] with ". . . excessive mobility of the posterior leaflet" is unfulfilled once the true leaflet is identified. It is well known that multiple abnormalities may give rise to the false impression of mitral valve prolapse or "pseudoprolapse" on M mode echocardiographic studies.[3] Perhaps the findings noted here represent "pseudopseudoprolapse."

REPLY

In panel 2 of our Figure 2, two arrows, labeled PL, are used to identify the posterior mitral leaflet. The arrow at left correctly identifies a thin hypermobile segment of the posterior leaflet in diastole; the arrow at right is incorrectly oriented and should have been deleted. Taken together, the two panels of Figure 2 demonstrate the findings of ruptured mitral chordae tendineae: Panel 1 clearly shows segments of the mitral valve prolapsing into the left atrium during systole; panel 2 demonstrates diastolic hypermobility. Both demonstrate that portions of the posterior leaflet have normal motion, a not unexpected finding in view of the localization of chordal rupture to a single posterior leaflet scallop.

CALENDAR OF EXTRAMURAL PROGRAMS

The aim of each program is to increase the theoretical and practical knowledge of the normal and abnormal function of the cardiovascular system in man. Most of the programs are pertinent to direct care of patients with heart disease. The need for such programs increases with the ever increasing amount of scientific and clinical data, the constant changes in technology and methodology, and the greater availability of therapeutic options. Today most cardiologists, internists and family practitioners feel the need of supplementing their professional reading by direct contact with the authors, research workers and leaders in the field.

To solve these problems the Committee selects each year series of carefully supervised programs which are usually preceded by extensive consultations with the program directors recruited among the foremost specialists educators and scientists in the field of clinical cardiology and allied basic science disciplines.

Although each program director is personally responsible for the choice of faculty, and the structure of the program, the National Committee of Continuing Education assumes the overall responsibility for the caliber of the postgraduate education and the relevance to the practice of cardiology. This is accomplished by the processes of meticulous scrutiny of the objectives, analysis of the educational methods, and studying the impact of each course on the knowledge and attitudes of the participants.

These programs should help each physician to keep up with the new knowledge, to put into practice the new advances and to retract gracefully from the obsolete and useless practices. An effective practitioner must learn and relearn, listen to new ideas, share past experiences and observe the work of his peers. The National Program Committee for Continuing Medical Education of the American College of Cardiology believes that these goals can be accomplished by all members and nonmember professionals participating in our continuing education programs.

Leonard S. Dreifus, MD, FACC
Chairman, Continuing Education Committee for Extramural Programs

Programs and faculty are subject to change. For further information write Registration Secretary, Extramural Programs Department, American College of Cardiology, Heart House, 9111 Old Georgetown Road, Bethesda, Maryland 20014.

FEBRUARY THROUGH MAY 1980

To be arranged individually — **Preceptorships in Cardiology.** Arthur Seizer, FACC, director. Pacific Medical Center, San Francisco, CA

MAY 21–23 — **Diagnosis and Treatment of Dysrhyt mias in Children.** Paul C. Gillette, FAC Arthur Garson, Jr. and Dan G. McN mara, FACC, directors. Texas Children Hospital, Houston, TX

LEARNING CENTER: PROGRAM CALENDAR

The American College of Cardiology's newest department, the Learning Center, located at the College's Bethesda Maryland headquarters, began operations in October 1977 with the offering of its first continuing medical education program for physicians with a specialty or an interest in cardiovascular medicine. The purpose of the Learning Center is to support the professional commitment to quality patient care by providing a new standard of excellence in cardiovascular continuing education. For additional information concerning the programs listed below or for a complete schedule of programs through July 1980, contact Program Coordinator, Learning Center, American College of Cardiology, 9111 Old Georgetown Road, Bethesda, Maryland 20014. Telephone (301) 897-5400.

FEBRUARY THROUGH JULY 1980

Month/Dates	Program Director	Title of Program
Feb. 6–8	Bertram Pitt, MD	**Nuclear Cardiology**
Feb. 11–13	Melvin L. Marcus, MD	**New Approaches to the Short and Long Term Treatment of Myocardial Infarction**
Feb. 18–20	Roger A. Winkle, MD	**Antiarrhythmic Therapy: Current Status and Future Promise**

INSTRUCTIONS FOR AUTHORS

The editors of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- Address manuscript to Managing Editor, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- Submit two copies of all elements of the article: text, references, legends, tables and figures.
- Arrange the paper in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- Number all pages in above sequence, beginning with title page as 1, abstract as 2, etc.
- Type all matter: (1) on 8½ × 11 opaque white bond paper; (2) in duplicate; (3) on one side of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- Include first names, degrees and, where applicable, FACC for all authors.
- Provide a short running title of 3 to 6 words.
- Insert at bottom: name and address of institution from which work originated plus information about grants.
- Add at bottom the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- Limit words as follows: 100 to 250 words for major articles; 50 to 100 words for case reports.
- Add at end of abstract: list of 2 to 6 key words and subjects for indexing.

THE TEXT

- Type in duplicate; double-space.
- Do not use abbreviations such as SVC, WPW; write out superior vena cava, Wolff-Parkinson-White.
- Abbreviate measurements (mm, kcal and the like) as recommended in *Uniform Requirements for Manuscripts Submitted to Biomedical Journals,* published in *Am Rev Respir Dis* 1979; 119:3–10; *Ann Intern Med* 1979; 90:95–9; *Br Med J* 1979; 1:532–5; and *Lancet* 1979:1:428–30.
- Cite in numerical order every reference, figure and table. (Order of mention in text determines the number given to each.)
- Place acknowledgments at end of text, before references.

THE REFERENCES

- Type in duplicate; double-space.
- Number the references in order in which they are mentioned in text.
- Provide concluding page numbers for all journal references and specific page numbers for all book references. Indicate all abstracts by the abbreviation (abstr).
- Follow the general arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- Start at top of new page.
- Type in duplicate; double-space.
- Identify at the end of each legend and in alphabetical order all abbreviations in the figure described.

THE TABLES

- Start each table at top of new page.
- Type in duplicate; double-space.
- Give each table a number (in roman numerals: Table I, II, etc) and a title. Number the tables in order in which they are mentioned in the text.
- Provide a footnote to each table—identifying in alphabetical order all abbreviations used.

THE FIGURES

- Submit 2 glossy prints (not originals) of each photo and drawing.
- Please note that art work of published articles will not be returned.
- Use black ink for all charts (line drawings) Make decimals, broken lines, etc. strong enough for reproduction.
- Use arrows to designate special features.
- Crop photomicrographs to show only essential field.
- Identify figures on back by number and author's name.
- Number figures in order in which they are mentioned in the text.
- Indicate top of each figure.
- Submit written permission from publisher and author to reproduce any previously published figures.
- Limit figures to number necessary for clarity. The publisher allows a limited sum toward reproduction.

Examples of Styles of References

For periodicals, follow INDEX MEDICUS, listing *all* authors (if there are 7 or more, list only 3 and add et al.):

31. Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–34.

(Author: please note that no periods are used after authors initials)

For chapter in book:

28. Schiebler GL, Van Mierop LHS, Krovetz LJ. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968:134–9.

For books (personal author or authors):

36. Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

(Author: all book references should have specific page numbers.)

SAFETY ACCURACY CONVENIENCE

Advanced Display

Operating status, alarm conditions, set up procedure errors and internal malfunction are instantly identified on the Liquid Crystal Display Panel. When the "Infusion Complete" legend appears, the 960 automatically reverts to a 1 ml/hr. "keep open" rate, eliminating restarts due to clotting. The clearly defined read-out allows a situation to be easily understood and dealt with. A visual track on the panel moves relative to infusion rate.

IMED'S Proven Accuset

The Imed 960 Volumetric Infusion Pump is designed to utilize the different types of Imed Accuset disposables. Recognized throughout the world for its dependable accuracy and safety, the Accuset is the heart of the 960's pumping and metering functions.

A Protective Door

If the Accuset is incorrectly affixed to the cassette nest, the door will not close and the pump will not operate. The closed door insures that the cassette and tubing in the air detector remain firmly in place.

Announcing
the comprehensive study of...
the most fascinating syndrome
in Cardiology...

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, Univer. of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief Heart Institute, Chaim Sheba Medical Center, Tel-Hashomer, University of Tel Aviv—Sackler School of Medicine

$33.00 SEPTEMBER 1978, 288 PAGES, 110 ILLUS, 1,000 REF.

Every Cardiologist, Internist, Pediatrician, Surgeon — Indeed, *Every Physician* — Should Have a Good Basic Knowledge of The Pre-excitation Syndrome. Here Are Just a Few Reasons Why This is so Essential:

- ⅓ of all pre-excitation cases are misdiagnosed.
- 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

The 13 Chapters Are a Comprehensive Summary

1. General Considerations
2. The Electrocardiogram in the Pre-excitation Syndrome: Complexes and Configurations
3. The Electrocardiogram in the Pre-excitation Syndrome: Disturbances of Rate and Rhythm
4. Pathology
5. Noninvasive Methods of Investigation
6. Invasive Methods of Investigation
7. Prognosis
8. Treatment
9. Problems of Diagnosis — Some Illustrative Cases
10. Summary of Findings and Theories of Pre-excitation Syndrome
11. Concept of Interacting Structural and Functional Factors
12. Explanation of Some Phenomena of the Pre-excitation Syndrome by the Proposed Concept
13. Various QRS Patterns in the Different Forms of Pre-excitation

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals

Beta-blocker Therapy in Cardiovascular Disease: An International Review

A Symposium

The Department of Internal Medicine
Southwestern Medical School
The University of Texas Health Science Center at Dallas

Approved for 10 hours of AMA Category I Credit

Thursday, March 13 - Friday, March 14, 1980
Loews Anatole Hotel, Dallas, Texas

Chairman: Norman M. Kaplan, M.D., Professor of Internal Medicine, University of Texas Health Science Center at Dallas.

Program Sessions will cover the clinical applications of these topics: Beta-blocker Pharmacodynamics: Fact and Theory, Beta-blocker Therapy of Hypertension, Comparison of Beta Blockers in Hypertensive Therapy, Beta-blocker Therapy of Cardiac Abnormalities.

This continuing medical education symposium has been developed to provide clinicians with a definitive review of the growing body of knowledge concerning beta-blocker therapy and includes an eminent international faculty.

For a complete program and registration information, contact: Ms. Norma Wilcox, Department of Internal Medicine, The University of Texas Health Science Center, 5323 Harry Hines Blvd., Dallas, TX 75235. (214) 688-3048

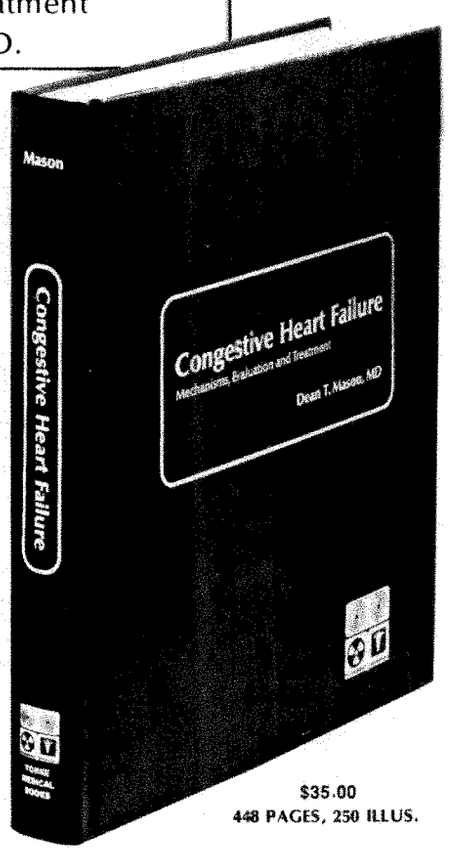
This symposium is supported in part by a grant-in-aid from Stuart Pharmaceuticals, Division of ICI Americas Inc.

Brings you up-to-date on basic research and clinical progress

Congestive Heart Failure

Mechanisms, Evaluation and Treatment

Dean T. Mason, M.D.



$35.00
448 PAGES, 250 ILLUS.

This rare treatment of such a multifaceted subject provides an unusual opportunity for the busy clinician to add to his knowledge in a minimum amount of time. Any area of immediate interest can be rapidly located and as much data as needed can be quickly extracted. The concentration on improved clinical management will be appreciated by every internist, cardiologist, generalist, and any professional involved in cardiovascular medicine.

Dean Mason, President of the American College of Cardiology, has organized this monograph within the three areas relevant to an understanding of congestive heart failure: *mechanisms, evaluation* and *treatment*. Fifty-six recognized authorities have been assembled by Dr. Mason, each contributing their expertise to make this book the foremost text covering the highly important and common disorders of abnormal heart function.

This presentation of recent advances in basic research and clinical progress has been highly acclaimed for its major contribution to the improvement of patient care. We invite you to see if you don't agree. Order and take 30 days to look over the book. If you're not totally satisfied, return it.

About the author . . . Dean T. Mason, M.D.

Professor of Medicine, Professor Physiology, Chief of Cardiovascular Medicine, University of California, School of Medicine, Davis

President, American College of Cardiology

President, Western Society for Clinical Research

Serves on the editorial boards of The American Journal of Cardiology, The Journal of Clinical Investigation, Circulation, Chest, Clinical Pharmacology and Therapeutics, Catheterization and Cardiovascular Diagnosis, and Heart and Lung

"...the finest book on congestive heart failure ever written...completely covers the entire spectrum ...will remain a classic." **Rudolph T. Wagner, MD, FCCP, *Chest*, May 1978**

"Mechanisms, evaluation, and treatment...are well discussed... well illustrated." ***MD*, December 1977**

8. Contractile and Energetic Behavior of Hypertrophied and Failing Myocardium — G. Cooper, IV, J.F. Gunning, C.E. Harrison and H.N. Coleman, III.
9. Regulation of Cardiac Performance in Clinical Heart Disease: Interactions Between Contractile State, Mechanical Abnormalities and Ventricular Compensatory Mechanisms — D.T. Mason.
10. Peripheral Circulatory Control Mechanisms in Congestive Heart Failure — R. Zelis, J. Longhurst, R.J. Capone, G. Lee and D.T. Mason.
11. Function of the Hypoxic Myocardium — Experimental and Clinical Aspects — E.A. Amsterdam.
12. Nature and Significance of Alterations in Myocardial Compliance — J.W. Covell
13. Renal Function and Edema Formation in Congestive Heart Failure — M.J. Tonkon, S.M. Rosen and D.T. Mason.

II. Evaluation

14. Physical Findings in Heart Failure and Their Physiologic Basis — R.A. O'Rourke and M.H. Crawford.
15. Echographic Evaluation of Cardiac Function — A.N. DeMaria, A.L. Neumann and D.T. Mason.
16. Cardiac Catheterization in the Clinical Assessment of Heart Disease and Ventricular Performance—D.T. Mason, R.F. Miller, D.S. Berman, L.A. Vismara, D.C. Williams, A.F. Salel, A.N. DeMaria, H.G. Bogren, G.L. DeNardo and E.A. Amsterdam.
17. Catheterization Evaluation of Cardiac Function in Acute and Chronic Coronary Artery Disease — C.E. Rackley, R.O. Russell, Jr., R.E. Moraski, J.A. Mantle, B.J. Feild and M. Smith.

III. Treatment

18. Management of Chronic Refractory Congestive Heart Failure—D.T. Mason, R.R. Miller, D.O. Williams, A.N. DeMaria, L.D. Segel and E.A. Amsterdam.
19. New Developments and Therapeutic Applications of Cardiac Stimulating Agents — J.F. Williams, Jr.
20. The Digitalis Glycosides: Clinical Pharmacology and Therapeutics — D.T. Mason, E.A. Amsterdam and G. Lee.
21. Ventricular Afterload Reducing Agents in Congestive Heart Failure Therapy — R.R. Miller, D.O. Williams, A.N. DeMaria, E.A. Amsterdam and D.T. Mason.
22. Myocardial Infarction Shock — Mechanisms and Therapy — E.A. Amsterdam, A.N. DeMaria, J.L. Hughes, E.J. Hurley, A.J. Lurie, D.O. Williams, R.F. Miller and D.T. Mason.
23. Antiarrhythmic Agents: Clinical Pharmacology and Therapeutics — D.T. Mason, A.M. DeMaria, E.A. Amsterdam, L.A. Vismara, R.R. Miller, Z. Vera and R.A. Massumi.

PROBLEM:

ECG STRESS TEST RESULTS

CHEST PAIN	NORMAL	EQUIVOCAL	ABNORMAL
ABSENT	NORMAL	?	?
ATYPICAL	?	?	?
ANGINA	?	?	ABNORMAL

It is now generally accepted that ECG Stress Testing, alone, is insufficiently sensitive and insufficiently specific to be diagnostic in many cases. (Ref. 1-8)

ANSWER: CKG™*
(CARDIOKYMOGRAPHY)

Recent investigations have shown that a second test such as CKG,™ Thallium Scintigraphy or Fluoroscopy can substantially increase diagnostic accuracy. (Ref. 2)

WHY CKG™?

The CKG™ provides an accurate, easy to interpret analog representation of left ventricular wall motion. (Ref. 9)

CKG™ is a non-invasive low cost test that can be done in the office right along with ECG Stress Testing.

You probably want to know a lot more about this important new technique. Call or write for additional information.

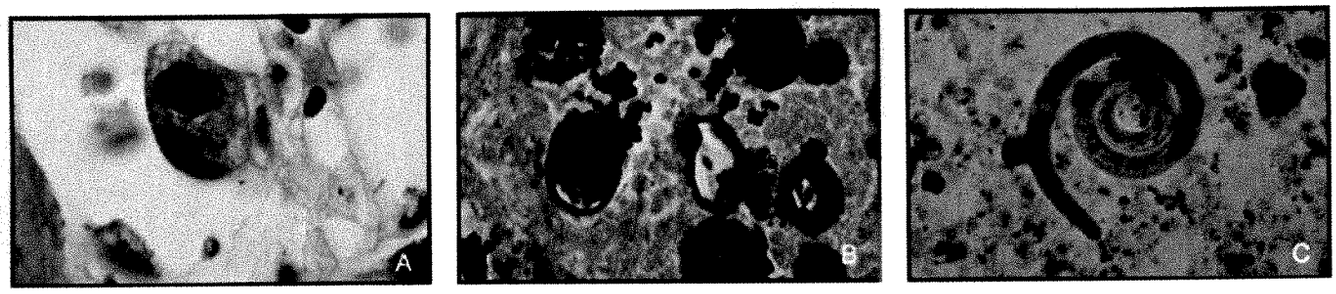
Paintings by Jackson Pollock?



Good guess for a layman. But *to you* these are the enemy. They are Cytomegalovirus gastritis (A) Disseminated coccidioidomycosis(B) and Strongyloides stercoralis filariform larva (C) . . . infections which demand special care when they strike patients with pre-existing illnesses and deficiencies. They are among the many discussed in . . .

INFECTIONS
IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color

Now at your fingertips . . . for instant reference . . . for rewarding study . . . the knowledge of world-renowned specialists to help you understand, diagnose, and manage infections which attack patients under treatment for

- Diabetes
- Alcoholism
- Cancer
- Drug Addiction
- Rheumatic Disease
- Uremia
- Pulmonary Disease
- Hepatic Insufficiency
- Allograft Transplantation, etc., etc.

Infections in the Abnormal Host brings together in one giant encyclopedic volume, over 1,000 pages, the guidance of a specialist team whose collaboration began in the 1960s. In 47 revealing chapters they review the mechanics of host defenses . . . the various underlying disorders and the infections associated with them . . . and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

A detailed indexing system gives you instant access to every diagnostic procedure, every treatment in the book. Study the entire book and you will gain priceless knowledge of an important and complex field. Consult it as the need arises, and it will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy

• Index

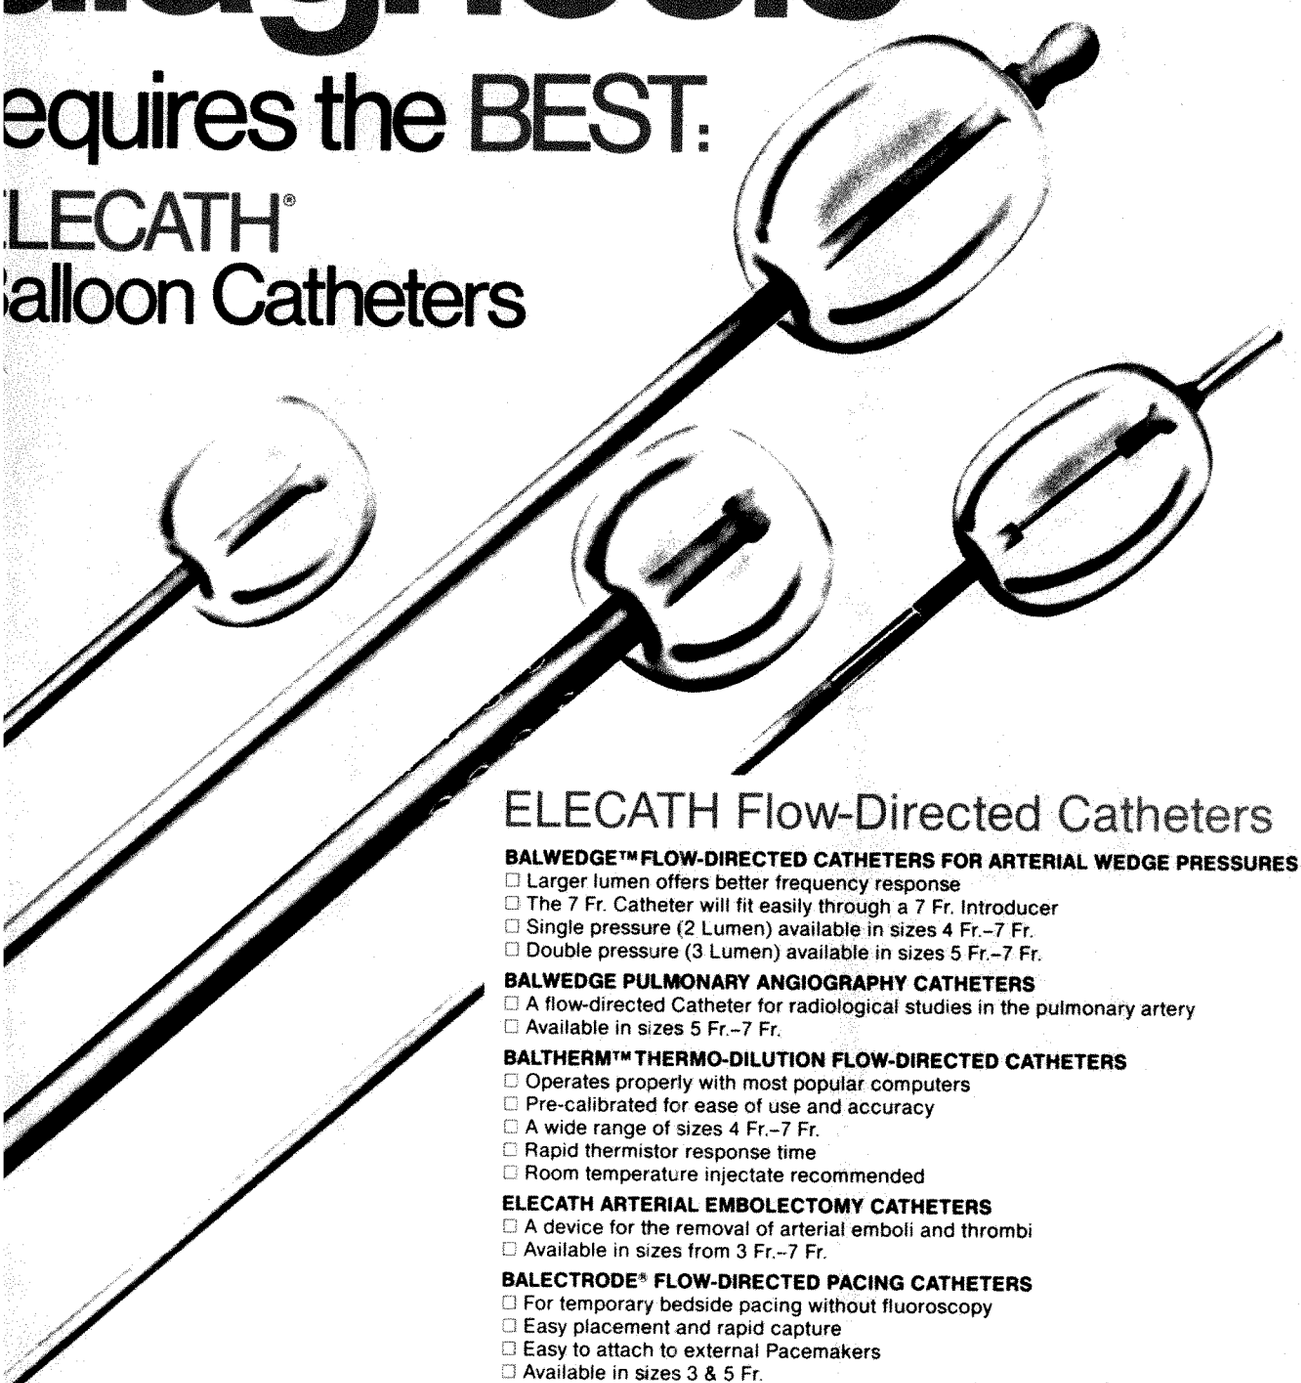
alloon Catheters



ELECATH Flow-Directed Catheters

BALWEDGE™ FLOW-DIRECTED CATHETERS FOR ARTERIAL WEDGE PRESSURES & C.V.P.
- ☐ Larger lumen offers better frequency response
- ☐ The 7 Fr. Catheter will fit easily through a 7 Fr. Introducer
- ☐ Single pressure (2 Lumen) available in sizes 4 Fr.–7 Fr.
- ☐ Double pressure (3 Lumen) available in sizes 5 Fr.–7 Fr.

BALWEDGE PULMONARY ANGIOGRAPHY CATHETERS
- ☐ A flow-directed Catheter for radiological studies in the pulmonary artery
- ☐ Available in sizes 5 Fr.–7 Fr.

BALTHERM™ THERMO-DILUTION FLOW-DIRECTED CATHETERS
- ☐ Operates properly with most popular computers
- ☐ Pre-calibrated for ease of use and accuracy
- ☐ A wide range of sizes 4 Fr.–7 Fr.
- ☐ Rapid thermistor response time
- ☐ Room temperature injectate recommended

ELECATH ARTERIAL EMBOLECTOMY CATHETERS
- ☐ A device for the removal of arterial emboli and thrombi
- ☐ Available in sizes from 3 Fr.–7 Fr.

BALECTRODE® FLOW-DIRECTED PACING CATHETERS
- ☐ For temporary bedside pacing without fluoroscopy
- ☐ Easy placement and rapid capture
- ☐ Easy to attach to external Pacemakers
- ☐ Available in sizes 3 & 5 Fr.

a **new** publication . . . for **every** professional with an interest in Exercise and the Heart

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

Just published, this comprehensive work covers every aspect of exercise and its role in **Diagnosis, Treatment,** and **Prevention** of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

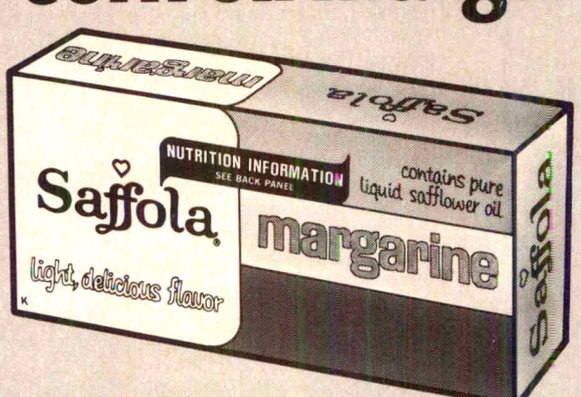
Saffola® fights cholesterol better than any corn oil margarine.



Higher in beneficial polyunsaturates. Contains no cholesterol. And tastes great.

Saffola is beneficial as part of a fat modified diet to help reduce serum cholesterol.

Nuclear Cardiology

ATTEND THE SYMPOSIUM LED BY THE NATION'S FOREMOST NUCLEAR CARDIOLOGISTS.

MARCH 7, 8 and 9, WHITEHALL HOTEL, HOUSTON, TEXAS

This is the first in a series* of symposia sponsored by Nuclear Cardiology Systems.

It immediately precedes the 29th Scientific Session of the American College of Cardiology.

The symposium is an opportunity for cardiologists to learn from the leading nuclear cardiologists the value of nuclear cardiology in patient management. Topics will guide the clinician in the selection of the appropriate nuclear procedure for specific clinical problems. The performance of basic imaging techniques will be illustrated by clinical example.

Las Vegas—April 18, 19 and 20
New York—May 16, 17 and 18

THE FACULTY*

George A. Beller, M.D.
Professor of Medicine
Head, Division of Cardiology,
University of Viriginia Medical
Center, Charlottesville, Virginia

Daniel S. Berman, M.D.
Assistant Clinical Professor of
Radiology, University of California
Los Angeles
Director, Department of Nuclear
Cardiology, Cedars-Sinai Medical
Center, Los Angeles, California

Jeffrey S. Borer, M.D.
Associate Professor of Medicine,
Cornell University
Chief, Cardiac and Catheterization
Laboratory, Director of Nuclear
Cardiology, New York Hospital,
New York, New York

Not all members of the faculty will be speaking at each symposium.

Richard Gorlin, M.D.
Murray M. Rosenberg Professor of Medicine
Chairman, Department of Medicine, Mount Sinai Hospital, New York, New York

Richard H. Helfant, M.D.
Professor of Clinical Medicine, University of Pennsylvania School of Medicine
Chief, Division of Cardiology, Presbyterian University of Pennsylvania Medical Center, Philadelphia, Pennsylvania

Melvin L. Marcus, M.D.
Associate Professor of Medicine, Cardiovascular Division, University of Iowa, Iowa City, Iowa

Richard W. Myers, M.D.
Chief, Department of Nuclear Medicine, Herrick Hospital, Berkeley, California

Bertram Pitt, M.D.
Professor of Internal Medicine
Director, Division of Cardiology, University of Michigan Medical Center, Ann Arbor, Michigan

Gerald M. Pohost, M.D.
Assistant Professor of Medicine, Harvard University School of Medicine
Assistant in Medicine, Cardiac Unit, Massachusetts General Hospital, Boston, Massachusetts

Robert A. Vogel, M.D.
Associate Professor of Medicine, University of Colorado
Director, Coronary Care and Medical Intensive Care Units, Veterans Administration Hospital

James T. Willerson, M.D.
Professor of Medicine
Director, Cardiology Division, University of Texas Southwestern Medical School
Director of Cardiology, Parkland Memorial Hospital, Dallas, Texas

Barry L. Zaret, M.D.
Associate Professor of Medicine
Chief, Cardiology Section, Yale University Medical School, New Haven, Connecticut

PROGRAM TOPICS

(First two days)

Clinical applications
Introduction to imaging techniques:
- Gated blood pool
- Thallium perfusion
- First transit
- Thallium and gated blood pool tomography
- Myocardial pyrophosphate infarct

Instrumentation
Data processors/software
Radiopharmaceuticals

OPTIONAL WORKSHOP*

(Third day)

Consultation on:
- Instrumentation
- Computer software
- Licensure
- Certificate of Need
- Third party reimbursement

*Workshop, conducted by Nuclear Cardiology Systems consultants, is designed solely for those physicians interested in establishing a nuclear cardiology laboratory within the next 12 months.

REGISTRATION

Registration fee is $750. This fee covers all lectures, symposium abstracts, coffee breaks and luncheons. A full refund will accompany cancellations made up to two weeks in advance of the meeting. No refunds will be made after that date. However, a substitute may be sent in place of the original applicant.

LIMITED REGISTRATION. HOUSTON, TEXAS, MARCH 7, 8 and 9.

FOR LATE REGISTRATION, CALL: (415) 928-0500

Applications to the symposium will be limited, so register early. Registration fee is $750 per person. Mail coupon or phone for reservations.

Two Volumes in the Clinical Cardiology Monograph Series

J. WILLIS HURST, M.D. and DEAN T. MASON, M.D.: Series Consultants

CARDIAC PACING *Second Edition*

Edited by PHILIP SAMET, M.D. and NABIL EL-SHERIF, M.D.

CONTENTS: Anatomy and Physiology of the Conduction System. Electrophysiology of the Specialized Conduction System. Engineering Aspects of Cardiac Pacing. Engineering Aspects of Implantable Cardiac Pacemakers. Physiologic Aspects of Cardiac Pacing. Pacemaker Electrocardiography. Indications for Cardiac Pacemaking. Pacemaker Followup Clinic System. Results of Cardiac Pacing. Electrophysiologic Basis of Programmed Electrical Stimulation of the Heart. Electrical Stimulation Techniques in the Diagnosis of Cardiac Arrhythmias. Cardiac Stimulation. Pacemaker Arrhythmias. Contribution of His Bundle Recordings to Cardiac Pacing. Pathophysiology of AV Block in Acute Myocardial Infarction. Acute Myocardial Infarction Conduction Disturbances: Clinical Aspects. Pacing in Ischemic Conduction Disturbances. Prognosis for Patients with Cogenital Heart Disease and Postoperative Conduction Defects. AV Sequential Pacing. Prognostic Value of the HV Interval in Conduction Disturbances. Clinical and Pharmacological Characteristics of Patients with Bundle Branch Block. Sensing in Demand Pacing. Cardiac Pacing in the Treatment of Cardiac Arrhythmias Following Open-Heart Surgery. Historical Aspects of Pacing. Techniques of Permanent Pacemaker Implantation.

1980, 640 pp., $47.50 ISBN: 0-8089-1211-9

CARDIAC ANESTHESIA

Edited by JOEL A. KAPLAN, M.D.

All aspects of patient care are presented in the belief that preoperative and postoperative management of the patient as a whole is as important as intraoperative management. Throughout, emphasis is on using sophisticated measurement techniques to determine proper therapeutic interventions and results.

1979, 530 pp., illus., $44.75 ISBN: 0-8089-1125-2

ELECTROCARDIOGRAPHY IN CLINICAL PRACTICE

By TE-CHUAN CHOU, M.D.

CONTENTS: NORMAL AND ABNORMAL ELECTROCARDIOGRAM. Normal Electrocardiogram. Atrial Abnormalities. Left Ventricular Hypertrophy. Right Ventricular Hypertrophy. Combined Ventricular Hypertrophy. Left Bundle Branch Block. Right Bundle Branch Block. The Hemiblocks, Bifascicular Block and Trifascicular Block. Myocardial Ischemia, Injury and Infarction. Stress Test. Pericarditis. Myocardial Diseases. Chronic Obstructive Lung Disease, Pneumothorax, Pulmonary Embolism. Congenital Heart Diseases in Adults. THE CARDIAC ARRHYTHMIAS. Sinus Rhythms. Atrial Arrhythmias. Atrioventricular Junctional Rhythms. Ventricular Arrhythmias. Atrioventricular Block and Concealed Conduction. The Wolff-Parkinson-White Syndrome and its Variants. DRUG EFFECTS, ELECTROLYTE IMBALANCE AND OTHER MISCELLANEOUS CONDITIONS. Effect of Drugs on the Electrocardiogram. Electrolyte Imbalance Diseases of the Central Nervous System. Hypothermia. The Mitral Valve Prolapsy Syndrome. Skeletal Deformities. Nonspecific S-T and T Wave Changes. Abnormal Q-T Interval. Abnormal U Wave. Artificial Electronic Pacemaker.

1979, 624 pp., 442 illus., $34.50 ISBN: 0-8089-1138-4

CLINICAL CARDIOLOGY

Edited by JAMES T. WILLERSON, M.D. and CHARLES A. SANDERS, M.D.

Volume 3 of THE SCIENCE AND PRACTICE OF CLINICAL MEDICINE Series

Clinical Cardiology is intended to provide a strong physiological basis for understanding clinical cardiology, and to describe recent advances in diagnostic and therapeutic techniques. The purpose is to present clinical cardiology in practical and relevant terms. Expert and detailed coverage is given to the advances in myocardial imaging, echocardiography, electrophysiology, diuretics, exercise testing, cardiac transplantation, and myocardial biopsy techniques. The scope of the topics ranges from Anatomy of the Cardiovascular System, Radionuclide Myocardial Imaging, to Obesity and the Cardiorespiratory System.

1977, 672 pp., illus., $39.50 ISBN: 0-8089-0992-4

PRIMARY AND SECONDARY ANGINA PECTORIS

Edited by ATTILIO MASERI, M.D., GERALD A. KLASSEN, M.D., F.R.C.P. (C), F.A.C.C., and MICHAEL LESCH, M.D.

CHAPTER HEADINGS: Experimental Coronary Obstruction and Determinants of Transmural Flow Distribution. Degree of Coronary Artery Obstruction in Patients with Symptomatic Myocardial Ischemia. Angina Secondary to Excessive Myocardial Metabolic Demands in Patients with Limited, Fixed Coronary Reserve. Angina Not Secondary to Limited, Fixed Coronary Reserve and Excessive Myocardial Metabolic Demands: "Primary" Angina. Physiological Basis of Coronary Vasoconstriction as a Cause of "Primary" Angina. Evidence of Acute-Myocardial Ischemia Caused by Vasoconstriction in Man. Physiological Basis of "Primary" Angina Not Caused by Vasoconstriction. Positive and Negative Feedback Mechanisms for Relieving or Sustaining Myocardial Ischemia and Determining Its Irreversibility. Rational Therapeutic Approaches to the Patient with Secondary and "Primary" Angina Pectoris. Outlook of the Anginal Patient—Arrhythmias and Sudden Death. Round Table: Perspectives and Guidelines in the Investigation and Treatment of Patients with Angina Pectoris.

1978, 464 pp., 150 illus., $22.50 ISBN: 0-8089-1112-0

PROGRESS IN CARDIOVASCULAR DISEASES

EDMUND H. SONNENBLICK, M.D., Editor/MICHAEL LESCH, M.D., Co-Editor

Each issue takes up a single major topic important to today's understanding and treatment of disorders of the heart and circulation. Invited experts approach the topic from various angles, using their own everyday experience and providing a complete review of the subject which represents the best in current knowledge and methodology.

Volume 22 (July 1979 to May 1980), Published Bimonthly, About 550 pages per volume. Subscriptions: $39.00 (outside U.S.A. $41.00).

While Others Are Reaching For This Technology

KB-Aerotech Puts It Within Reach

In keeping with its tradition of pioneering transducer technology, KB-AEROTECH brings the advantages of quarter wavelength matching layer design to echocardiography. With the introduction of two new QUIC*SCAN cardiac models, the QSA22DL and the QSA35CM, the echocardiographer now has available a set of three high sensitivity transducers which will accommodate the majority of adult and older pediatric patients.

The QSA22DL, a 2.25 MHz/13 mm/3-12 cm focal zone transducer, is a significant improvement over the standard 2.25 MHz transducers now used in echocardiography. This model was developed in response to the problems encountered in achieving adequate penetration for acceptable imaging when examining the obese, heavy chested, and/or emphasematous patient. In many cases the increased sensitivity of the QSA22DL will allow the sonographer to realize the resolution capabilities of a 2.25 MHz transducer while getting the penetration that was previously obtainable only with a 1.6 MHz or 1.9 MHz transducer. The broad 3-12 cm focal zone also makes the QSA22DL an excellent choice for the basic transducer in your M-Mode armamentarium.

The QSA35CM, a 3.5 MHz/10 mm/3-8 cm focal zone transducer, has a smaller patient contact surface than the 13 mm models, which allows easier access to the narrower intercostal spaces of some adults and older children. The increased sensitivity of this model often allows the sonographer to achieve the improved resolution of a 3.5 MHz transducer in examinations where a 2.25 MHz model was previously required to perform the study.

The QSA35DM, a 3.5 MHz/13 mm/4-10 cm focal zone transducer also has increased sensitivity which allows the resolution capabilities of 3.5 MHz to be effectively utilized in the more normal adult patient habitus.

These new products reaffirm KB-AEROTECH'S commitment to provide the diagnostic ultrasound community with state of the art transducer technology. However, this technology would have little value if it were not tailored to the clinical requirements of the physician and sonographer. It is this clinical relevance of our products that we at KB-AEROTECH emphasize. When it comes to meeting the needs of diagnostic ultrasound, we're on your wavelength.

Immediately following the Annual Meeting
of the American College of Cardiology, you are invited
to attend a timely and important symposium on

NITRATES, BETA-BLOCKERS AND BEYOND

MANAGEMENT OF THE SPECTRUM OF ANGINA PECTORIS

This symposium is designed to acquaint the physician
with various types of drugs used in the management of angina pectoris
and to indicate the specific roles of these agents.

Course Participants and Their Topics:

Course Chairman: **Thomas D. Giles, M.D.**

PHARMACOLOGIC PRINCIPLES IN
THE MANAGEMENT OF ANGINA PECTORIS I
Bertram Pitt, M.D.
Professor of Internal Medicine
Director, Cardiovascular Division
University of Michigan Medical Center
Ann Arbor, Michigan

PHYSIOLOGIC PRINCIPLES IN
THE MANAGEMENT OF ANGINA PECTORIS II
Goffredo G. Gensini, M.D.
Director, Monsignor Toomey Cardiovascular Laboratory
St. Joseph Hospital Health Center
Clinical Professor of Medicine
State University of New York
Syracuse, New York

NITRATES IN
THE MANAGEMENT OF ANGINA PECTORIS
Thomas D. Giles, M.D.
Professor of Medicine
Tulane University School of Medicine
Chief Medical Services
Veterans Administration Medical Center
New Orleans, Louisiana

BETA-ADRENORECEPTORS IN
THE MANAGEMENT OF ANGINA PECTORIS
William Shapiro, M.D.
Chief, Cardiovascular Section
Veterans Administration Medical Center
Professor, Internal Medicine
University of Texas Health Science Center
Southwestern Medical School
Dallas, Texas

Ca-ANTAGONISTS IN
THE MANAGEMENT OF ANGINA PECTORIS
Charles R. Conti, M.D.
Professor of Medicine
Chief, Division of Cardiology
J. Hillis Miller Health Center
University of Florida
Gainesville, Florida

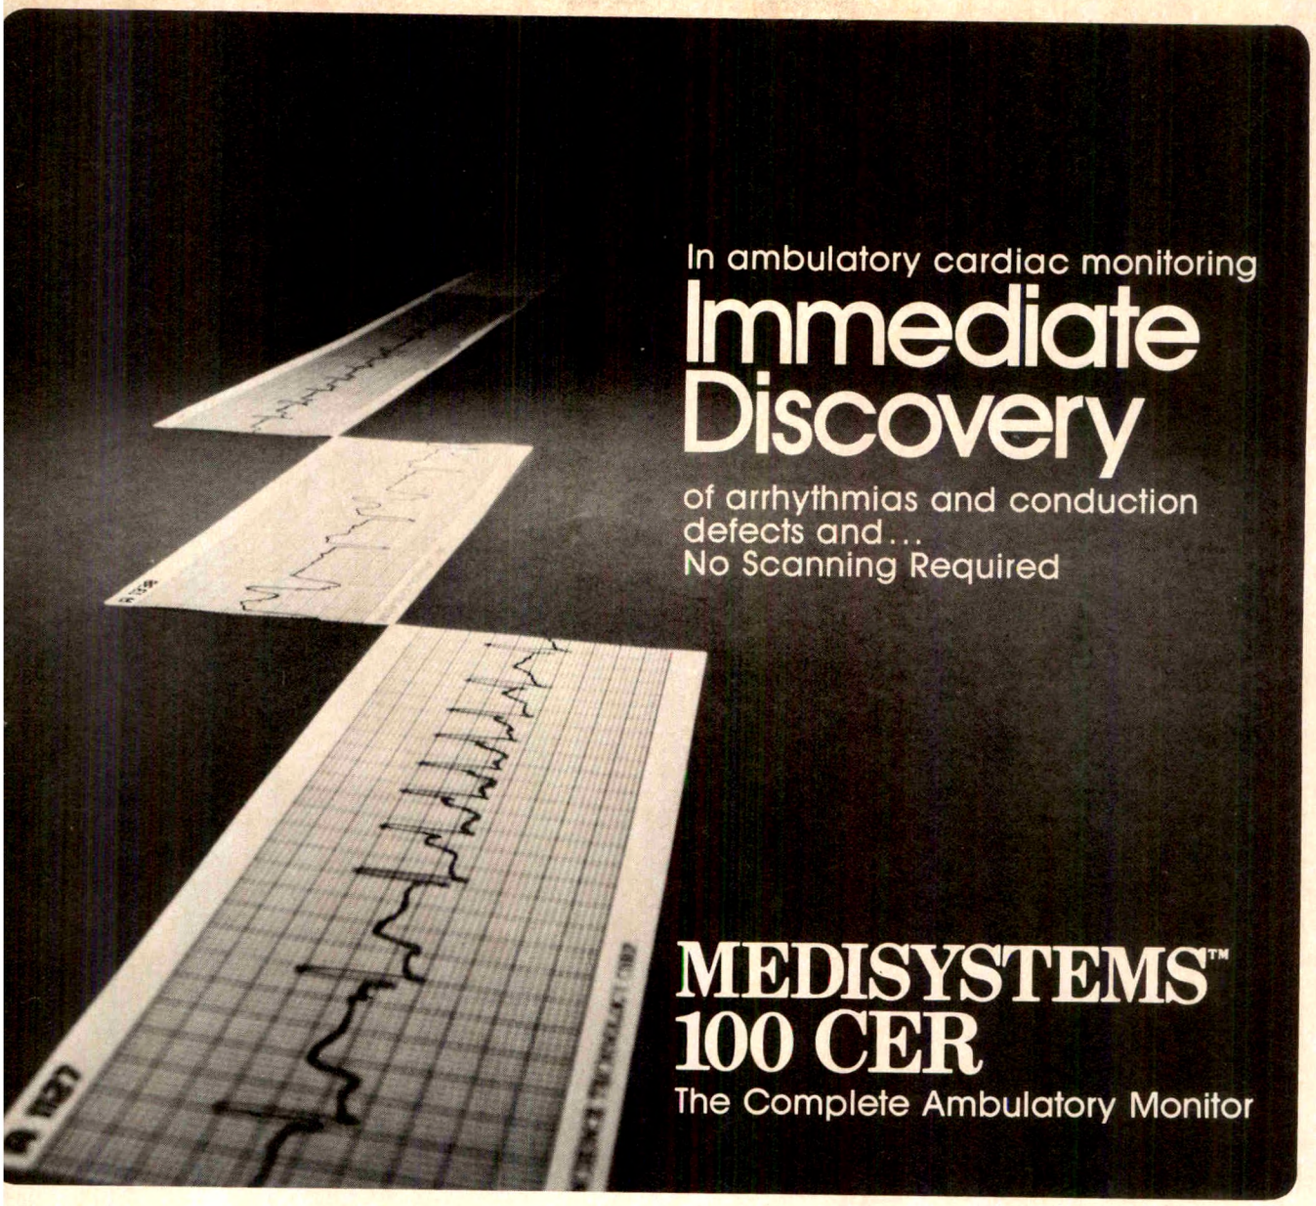
PANEL DISCUSSION:
THE FUTURE OF ANTIANGINAL AGENTS

As an organization accredited for continuing medical education, the Tulane University Medical Center designates this continuing medical activity as meeting the criteria for 3.5 credit hours in Category 1 of the Physician's Recognition Award of the American Medical Association.

Twelve Noon, Thursday, March 13, 1980
Imperial Ballroom, Hyatt Regency Houston

Buffet Luncheon.....12:00 Noon - 1:15 PM
Symposium .....1:15 PM - 4:45 PM
Wine and cheese reception will follow at the close of the symposium.

This symposium is made possible by an educational grant from **PARKE-DAVIS**
Div. of Warner-Lambert Co
Morris Plains, NJ 07950 USA



In ambulatory cardiac monitoring

Immediate Discovery

of arrhythmias and conduction defects and...
No Scanning Required

MEDISYSTEMS™ 100 CER

The Complete Ambulatory Monitor

Vaist-worn CER weighs less than vo pounds, **monitors patients ontinuously** and records only rrhythmias and conduction efects. Eliminates hours of review- ıg tapes and all the drawbacks f Holter monitoring.

ıstant printout for immediate nalysis in your office and **o scanning required.**

eliable. Easy to use. Inexpensive. etter for you...better for your patients.

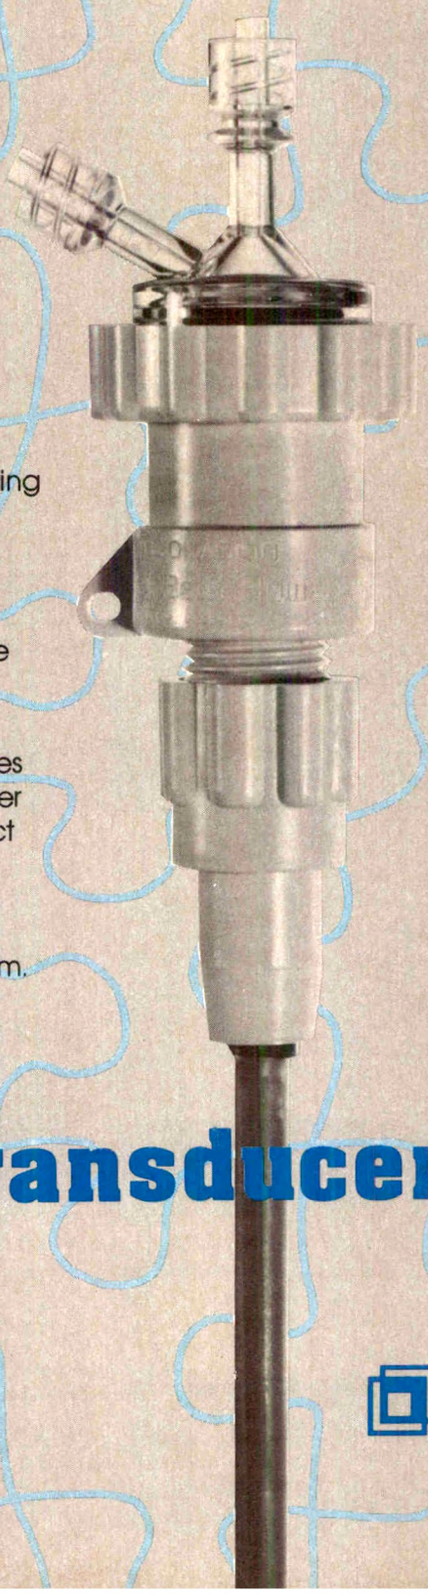
We Put The Pieces Together



No matter what patient monitoring equipment you now own — or plan to purchase — this Bell & Howell physiological pressure transducer will fit them all! Our inter-connecting cables provide complete compatibility.

We've put an end to the confusion of mismatching cables and connectors. When you order our 4-327I transducer, we select from our stock of 56 different cable-connector sets to custom-match precisely the monitor you specify. Any of them.

So all you need to know is the monitor make and model. We do the rest.

What if you replace your presen monitor with a different model later on? No problem. Not if you have our transducer. If necessary, you simply replace the cable-connector set. Not the valuable transducer. And the whole operation takes less than a minute.

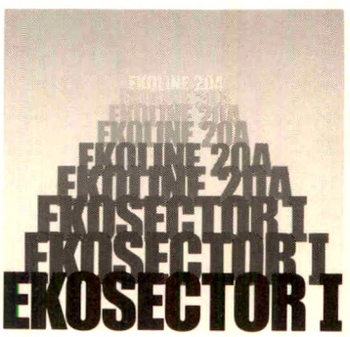
Now isn't that a piece of thoughtful engineering?

One Transducer Fits All

BELL & HOWELL
Information systems. For work, education and entertainment.

Announcing the SKI M-mode to Real-time Conversion Program.

A unique opportunity for owners of the Ekoline 20A®.



There'll never be a better time to expand your M-mode system to scanning.

Here's what we'll do to help.

We will exchange your Ekoline 20A M-mode system for a new factory assembled and calibrated EkoSector I® two-dimensional scanning system with a full one-year warranty at a price which is bound to match your needs and budget. And to make your procedures easier and faster, you get at no extra charge our M-mode Transducer Kit and 30° High Resolution Probe Head.

Take advantage of this special offer today.

For more details, call toll-free 800-538-1556. In California, call collect 408-732-6000. Or return this coupon.

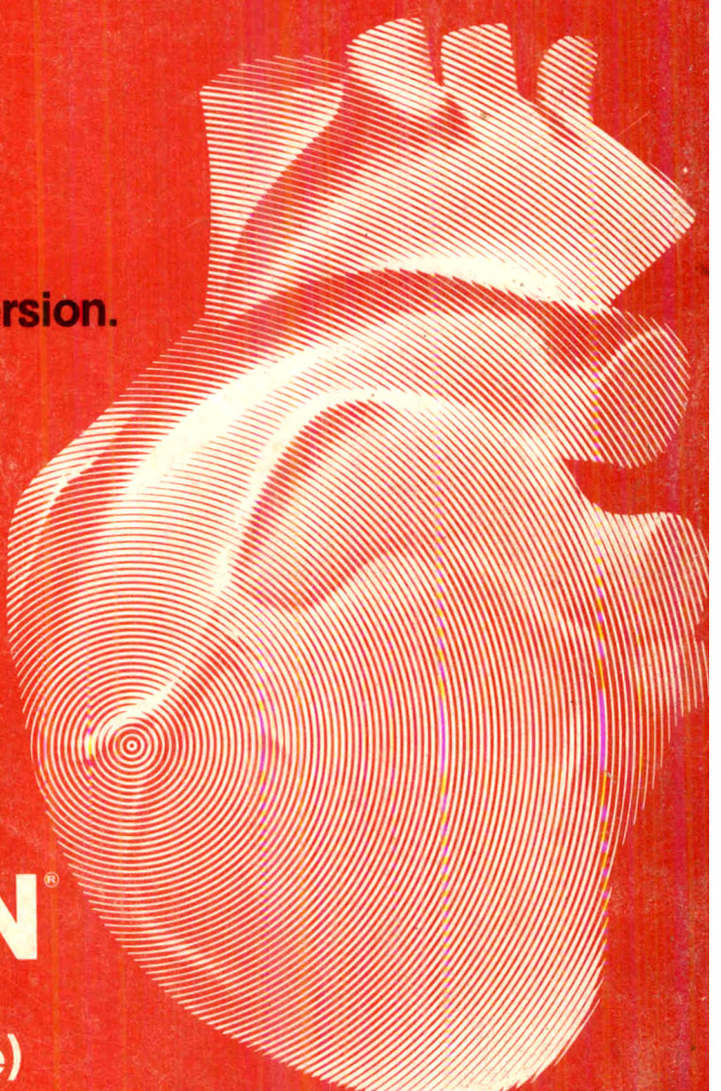
The Pacekeeper™



For ventricular arrhythmias.
For atrial arrhythmias.
For smooth, trouble-free conversion.
For steady maintenance.

CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

- ☐ Greater GI tolerance than with quinidine sulfate
- ☐ Full quinidine cardiodynamics
- ☐ Convenient b.i.d. or t.i.d. dosage for most patients

CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of a broad range of cardiac arrhythmias (see Brief Summary). After conversion to normal sinus rhythm—whether with CARDIOQUIN Tablets or electroconversion—only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required for maintenance in most cases. The polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*Aviado, D. M., Krantz and Carr's Pharmacologic Principles of Medical Practice, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heart-block; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 100.

Because ALDORIL® provides benefits day after day...
SPHYGMOMANOMETER
CERTIFIED
mmHg
Copyright © 1979 by Merck & Co., Inc.

many hypertensives have benefited year after year

cardiovascular benefits

cardiac output usually maintained

sodium and fluid retention generally controlled

two highly effective complementary agents

As a fixed combination, ALDORIL is not indicated for initial therapy since hypertension requires therapy titrated to the individual patient. If an available strength of ALDORIL meets the patient's titrated needs, the combination drug may be more convenient in patient management. Therapy should be reevaluated as necessary.

ALDORIL is contraindicated in active hepatic disease; anuria; hypersensitivity to methyldopa or to hydrochlorothiazide or other sulfonamide-derived drugs; if previous methyldopa therapy has been associated with liver disorders. In patients with renal disease, thiazides may precipitate azotemia. Use with caution in patients with severe renal disease or impaired hepatic function.

It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. For more details, see the brief summary of prescribing information.

For a brief summary of prescribing information, please see following page.

practical benefits

- **effects on daily activities usually minimal:** There is less frequent symptomatic postural hypotension with ALDORIL than with many other antihypertensive agents. Exercise hypotension and diurnal blood pressure variations rarely occur.
- **greater dosage convenience:** a b.i.d. regimen is possible for many patients
- **four dosage strengths:** offer the widest range of dosage strengths available in a combination antihypertensive

WARNING

This fixed combination drug is not indicated for initial therapy of hypertension. Hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see **Warnings**); anuria; hypersensitivity to methyldopa or to hydrochlorothiazide or other sulfonamide-derived drugs.

Warnings: METHYLDOPA—**It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions.**

With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood.

At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within the first three weeks of therapy, sometimes with eosinophilia or abnormalities in one or more liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually within the first two to three months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever, abnormalities in liver function tests, or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients.

Rarely, reversible reduction of white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Follow patients carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

HYDROCHLOROTHIAZIDE—Use with caution in severe renal disease. In patients with renal disease, thiazides may precipitate azotemia. Cumulative effects may develop in patients with impaired renal function. Use with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma. May add to or potentiate action of other antihypertensive drugs. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possibility of exacerbation or activation of systemic lupus erythematosus has been reported. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity; read circulars for lithium preparations before use of such concomitant therapy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant requires that anticipated benefits be weighed against possible risks.

Methyldopa and thiazides cross the placental barrier and appear in cord blood.

No unusual adverse reactions have been reported in association with the use of methyldopa during pregnancy. Although no obvious teratogenic effects have been reported, the possibility of fetal injury cannot be excluded.

The hazards of thiazides crossing the placental barrier include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in adults. Methyldopa and thiazides appear in breast milk. Patients taking ALDORIL should not nurse.

Precautions: METHYLDOPA—Should be used with caution in patients with history of previous liver disease or dysfunction (see **Warnings**). May interfere with measurement of urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites. Involuntary choreoathetotic movements have been observed in patients with severe bilateral cerebrovascular disease. If such movements occur, stop the drug. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

HYDROCHLOROTHIAZIDE—Perform periodic determination of serum electrolytes to detect possible electrolyte imbalance. Observe all patients for evidence of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when patient is vomiting excessively or receiving parenteral fluids. Warning signs or symptoms of fluid and electrolyte imbalance include dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting. Hypokalemia may develop, especially with brisk diuresis, in severe cirrhosis, with concomitant corticosteroids or ACTH, after prolonged therapy, or with inadequate oral electrolyte intake. Hypokalemia can sensitize or exaggerate response of heart to toxic effects of digitalis (e.g., increased ventricular irritability). Hypokalemia may be avoided or treated by use of potassium supplements, such as foods with a high potassium content. Although any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease), chloride replacement may be required in metabolic alkalosis. Dilutional hyponatremia may occur in edematous patients in hot weather; appropriate therapy is water restriction, rather than administration of salt, except in rare instances when the hyponatremia is life threatening. In actual salt depletion, appropriate replacement is the therapy of choice.

Hyperuricemia may occur or acute gout may be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged; latent diabetes mellitus may become manifest. Thiazides may increase responsiveness to tubocurarine. Antihypertensive effects of the drug may be enhanced in postsympathectomy patients. May decrease arterial responsiveness to norepinephrine; this diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. If progressive renal impairment becomes evident, consider withholding or discontinuing diuretic therapy. Thiazides may decrease serum PBI levels without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Pathological changes in the parathyroid glands with hypercalcemia and hypophosphatemia have been observed in a few patients on prolonged therapy; thiazides should be discontinued before testing for parathyroid function.

Adverse Reactions: METHYLDOPA—*Central nervous system:* Sedation, headache, asthenia or weakness; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression. *Cardiovascular:* Bradycardia, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.) *Gastrointestinal:* Nausea, vomiting, distention, constipation, flatus, diarrhea, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis. *Hepatic:* Abnormal liver function tests, jaundice, liver disorders. *Hematologic:* Positive Coombs test, hemolytic anemia. Leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells and rheumatoid factor. *Allergic:* Drug-related fever, lupus-like syndrome, myocarditis. *Other:* Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, impotence, decreased libido, dermatologic reactions including eczema and lichenoid eruptions, mild arthralgia, myalgia.

HYDROCHLOROTHIAZIDE—*Gastrointestinal system:* Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis, sialadenitis. *Central nervous system:* Dizziness, vertigo, paresthesias, headache, xanthopsia. *Hematologic:* Leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia, hemolytic anemia. *Cardiovascular:* Orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics). *Hypersensitivity:* Purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), fever, respiratory distress including pneumonitis, anaphylactic reactions. *Other:* Hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, transient blurred vision. Whenever adverse reactions are moderate or severe, thiazide dosage should be reduced or therapy withdrawn.

Note: Tolerance may occur, usually between the second and third month of therapy. Increasing dosage of either component separately or together frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

How Supplied: Tablets ALDORIL®-15, containing 250 mg methyldopa and 15 mg hydrochlorothiazide, bottles of 100 and 1000; Tablets ALDORIL®-25, containing 250 mg methyldopa and 25 mg hydrochlorothiazide, bottles of 100 and 1000; Tablets ALDORIL® D30, containing 500 mg methyldopa and 30 mg hydrochlorothiazide, bottles of 100; Tablets ALDORIL® D50, containing 500 mg methyldopa and 50 mg hydrochlorothiazide, bottles of 100.

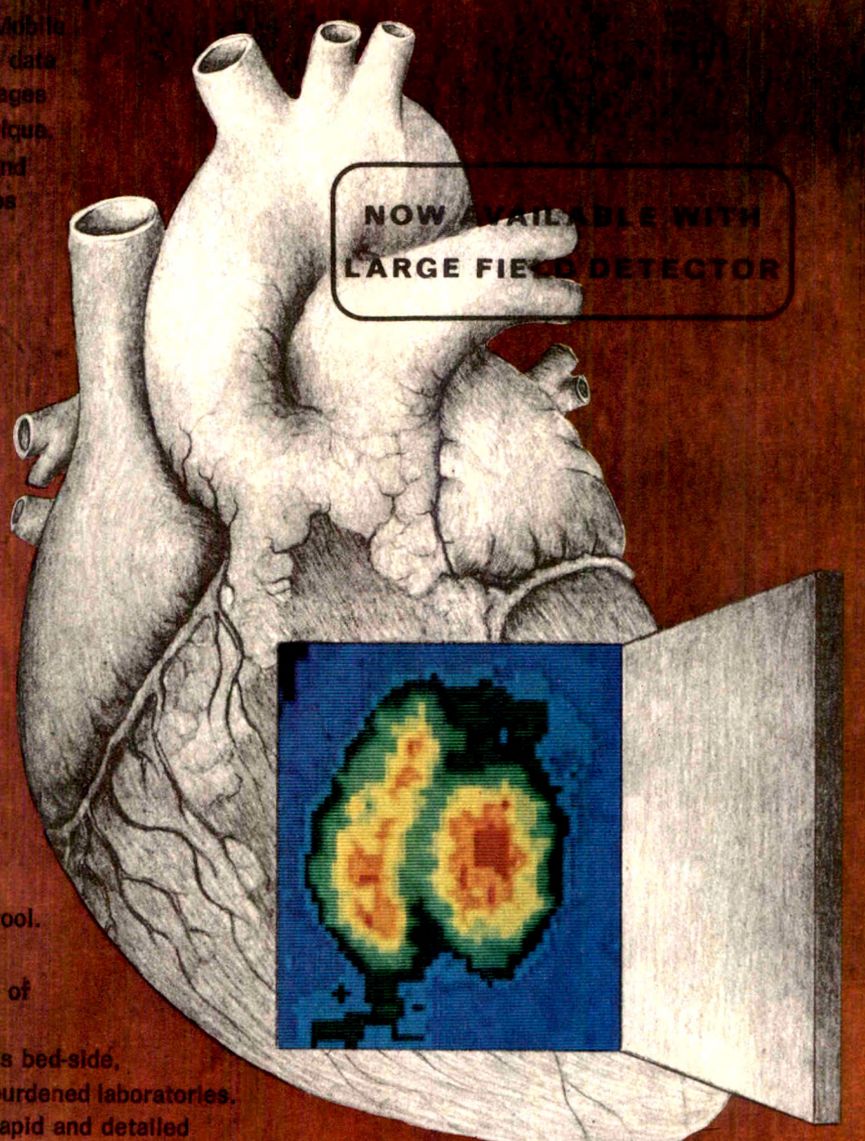
For Non-Invasive Dynamic Heart Studies

DYMAX-MB

A COMPUTERIZED MOBILE GAMMA CAMERA

Provides the Technique For Today – and Tomorrow

Results obtained using the DYMAX-MB Mobile Camera with its powerful minicomputer data processor, clearly demonstrate the advantages of radiocardiology as a diagnostic technique. DYMAX-MB is compact, fully mobile and simple to operate. The camera produces studies with excellent resolution and uniformity at both low and high countrates, while the self-contained processor provides instant clinical analysis of the data. Among the heart functions which can be studied "live" are wall motion, ejection fraction, cardiac output, interventricular shunts and other parameters of major importance.



Analytical procedures are speeded by automatic repeat of previously established protocols. On-the-spot analysis enables the attending physician to immediately evaluate results, eliminating the delays of batch processing at a central installation, thus maximising the efficacy of the DYMAX-MB.

Check for yourself the significant advantages of this highly efficient clinical tool.

You can :

- Spare your patient the trauma of catheterization.
- Complete the diagnosis at the patient's bed-side, sparing him exhausting movement to overburdened laboratories.
- Receive pre-processed data for more rapid and detailed interpretation than was possible with earlier techniques.

Until you examine the performance of this outstanding unit, you haven't heard the last word. Call us or write for more information or demonstration.

Dear Doctor:

SK&F Co. has traditionally responded to the needs of the patient and the physician. And the introduction of new 'Dyazide' 'PATIENT-PAK' 100's furthers that tradition.

The distinctive appearance of 'PATIENT-PAK' helps lower the risk of misidentification. That's particularly reassuring for elderly patients and those on multiple drug regimens. The bright red safety closure, the special label, and the distinctive red and white capsules all facilitate identification in cases of accidents, overdosage, drug incompatibility or unexpected drug reactions.

New 'PATIENT-PAK' 100's is one more way of helping you help your patients. They'll appreciate the added convenience, the economy, and the simplicity that 'PATIENT-PAK' 100's can bring to the therapeutic regimen.

For your patients' sake, specify 'PATIENT-PAK'.

Sincerely,

Wm S Pilling

Cardiocassette® II

advanced pocket size ambulatory ECG system.

Actual size

Small size and **long** duration (a week or more) makes this **ECG** recorder ideal for determination of causes of transient dyspnea, angina, cerebral ischemia, transient arrhythmias, and for cardiac rehabilitation programs.

Simple playback of programmed and patient activated recordings directly into office **ECG** units. No scanning or data processing equipment required.

Patient activated mode and **voice recordings** simplify detection of **ECG** abnormalities and accurate correlation with symptoms or activity being investigated.

For patients who need K^+Cl^- one sparkles bright:

KLORVESS® EFFERVESCENT GRANULES offer SPARKLING FAST DISSOLUTION

Each packet (2.8 g) provides 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, and L-lysine monohydrochloride 0.913 g.

- **ready in *seconds* instead of minutes —fast dissolution so unique it's patented***
- **pleasant citrus flavor**
- **each packet delivers 20 mEq of potassium and chloride**
- **easily carried in patient's pocket or purse**
- **can be mixed with water or other liquid for pleasant daily dosage**
- **sugar, sodium, carbohydrate and dye free**

Give your patients the KLORVESS sparkle

Give your patients the KLORVESS® sparkle

Klorvess® Effervescent Granules and Klorvess® (potassium chloride) 10% Liquid

Brief summary of prescribing information

DESCRIPTION: *Klorvess Effervescent Granules:* Each packet (2.8 g) contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g in a sodium-, sugar- and carbohydrate-free effervescent formulation. Dissolution of the packet contents in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

Klorvess (potassium chloride) 10% Liquid: Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

INDICATIONS: For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

CONTRAINDICATIONS: Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

PRECAUTIONS: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements. Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis. High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest. To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve the packet contents of *Klorvess Effervescent Granules* in 3 to 4 ounces of cold water, fruit juice or other liquid or dilute each tablespoonful of *Klorvess (potassium chloride) 10% Liquid* in 3 to 4 ounces of cold water. Both of these solutions should be ingested slowly with or immediately after meals.

ADVERSE REACTIONS: Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest. The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

DOSAGE AND ADMINISTRATION: *Klorvess Effervescent Granules:* Adults—One packet completely dissolved 2 to 4 times daily depending upon the requirements of the patient.

Klorvess (potassium chloride) 10% Liquid: Adults—One tablespoonful (15 ml) completely diluted in cold water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating.

OVERDOSAGE: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

HOW SUPPLIED: *Klorvess Effervescent Granules*—packages of 30 packets (2.8 g each). *Klorvess (potassium chloride) 10% Liquid* (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Effervescent Granules and Liquid are also available in institutional packaging as follows: *Klorvess Effervescent Granules*—packages of 1000 packets; *Klorvess Liquid*—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

ABC

Predictable angina*

...during episodes of emotional stress or physical exertion

SUMMARY OF PRESCRIBING INFORMATION

* **Indications:** Based on a review of this drug by The National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: The chewable dosage form of SORBITRATE is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety.

Precautions: Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: *Individual Dose:* To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an angina attack. CHEWABLE SORBITRATE® (isosorbide dinitrate) may be taken for prompt relief of angina pain three or four times daily. Although the onset and duration of effect of coronary nitrates may vary, following is the generally reported range of these values for CHEWABLE SORBITRATE.

Onset of Effect: Two to five minutes.
Duration of Effect: One to two hours.

Up to 2 hours of angina protection. At mealtime and any other time of stress.

CHEWABLE SORBITRATE®

(ISOSORBIDE DINITRATE) 5mg. and 10mg.

CLINICAL STUDIES

535 Detection of Coronary Artery Disease: Comparison of Exercise Stress Radionuclide Angiocardiography and Thallium Stress Perfusion Scanning

JAMES A. JENGO, RONALD FREEMAN, MARIANNE BRIZENDINE and ISMAEL MENA

In this study of 16 normal subjects and 42 patients with more than 75 percent coronary arterial obstruction, only 81 percent of the latter manifested significant S-T segment depression during exercise stress whereas 93 percent manifested thallium perfusion defects and 98 percent demonstrated abnormalities in segmental wall motion on radionuclide angiography. In patients with prior myocardial infarction who manifested new exercise abnormalities, 50 percent showed new thallium defects and 81 percent new wall motion defects. Radionuclide angiography may be more sensitive in detecting new ischemic disease in patients with prior myocardial infarction and offers previously unobtainable data on left ventricular function and anatomic site of disease.

542 Left Ventricular Ejection Fraction Determined by Radionuclide Ventriculography in Early Stages of First Transmural Myocardial Infarction. Relation to Short-Term Prognosis

PREDIMAN K. SHAH, MAX PICHLER, DANIEL S. BERMAN, BRAMAH N. SINGH and HAROLD J. C. SWAN

Multiple gated equilibrium cardiac blood pool scintigraphic studies (radionuclide ventriculography) within 24 hours of the onset of a first acute transmural myocardial infarction show that left ventricular ejection fraction is significantly reduced in acute anterior myocardial infarction but not in inferior infarction except in patients with associated precordial S-T segment depression. An ejection fraction of 0.30 or less has a poor prognosis and is associated with a high risk of hospital morbidity and mortality from pump failure. The ejection fraction is therefore a sensitive marker of ventricular dysfunction in the early stages of acute transmural infarction. It is possible that in some instances the reduced ejection fraction may partly be due to reversible but persisting ischemia that may be amenable to therapeutic interventions. The electrocardiographic site of myocardial infarction may also bear importantly on the severity and frequency of depressed ejection fraction.

547 Serial Ambulatory Electrocardiography and Treadmill Exercise Testing After Uncomplicated Myocardial Infarction

ROBERT F. DeBUSK, DENNIS M. DAVIDSON, NANCY HOUSTON and JOHN FITZGERALD

In this study of 90 men after clinically uncomplicated myocardial infarction the peak frequency of premature ventricular complexes recorded with ambulatory electrocardiography or treadmill exercise testing did not change significantly after the 3rd week. Ischemic S-T segment depression of 0.2 mV or greater or a peak work load of less than 4 multiples of resting energy expenditure (METS) on the 3rd week treadmill test was significantly associated with recurrent coronary events within 24 months. In patients without clinical heart failure treadmill testing as soon as 3 weeks after myocardial infarction may yield prognostic information not available with ambulatory electrocardiography or exercise testing later. There appears to be no apparent diagnostic advantage in performing additional ambulatory monitoring after the 3rd week. Ambulatory electrocardiographic monitoring and treadmill exercise testing find their optimal application in different patient subsets.

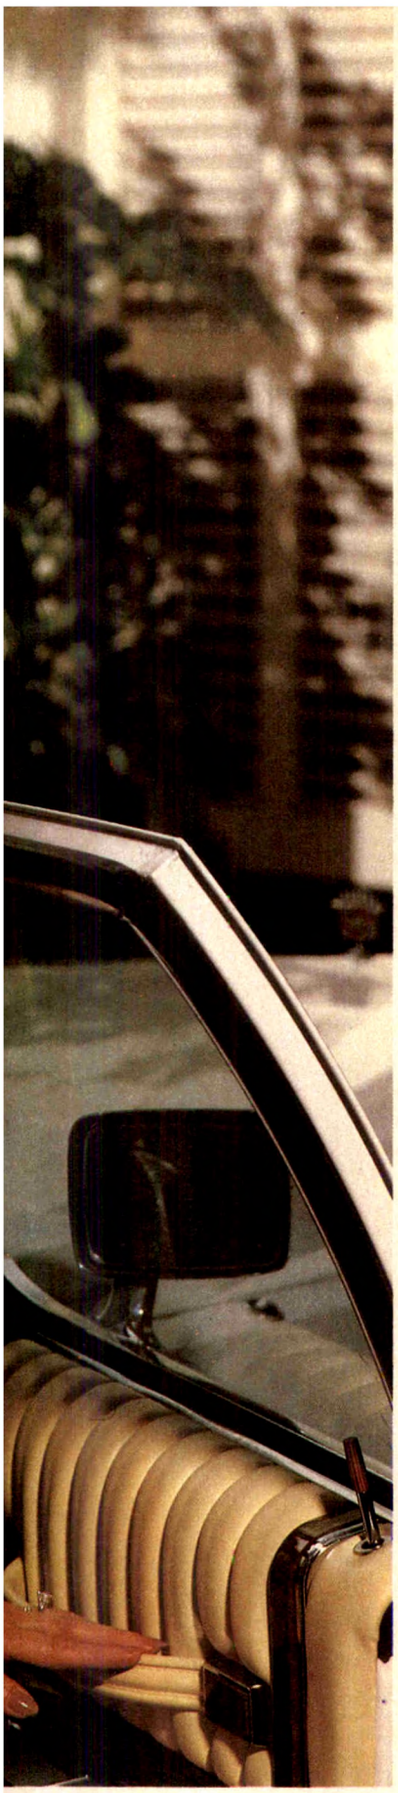
INTERMEDICS PULSE GENERATORS

INDICATIONS FOR USE Implantable cardiac pulse generators may be indicated for long-term treatment of impulse formation and conduction disorders resulting in symptomatic bradyarrhythmias, tachyarrhythmias, and heart block unresponsive to drug therapy.

PRECAUTIONS Implanted pacemakers have a finite and relatively wide variable service life as a result of factors such as the [illegible]ery of the battery and the shelf storage time of the manufactured pacemaker; variations in electrode system resistances, stimulation rate, and the percentage of time the implanted pacemaker is inhibited; and random electronic component failures.

Pacemaker operation can be influenced by electric, magnetic, or electromagnetic energy mimicking normal cardiac activity. In addition, certain environmental sources can couple sufficient energy into a pacemaker system to damage the pulse generator. Specifically, diathermy should not be used on pacemaker patients because of possible total inhibition of the pulse generator; electrocautery can inhibit and/or damage the pacemaker as well as cause burns or possible ventricular fibrillation; defibrillation can damage the pacemaker, and the presence of the pacemaker may cause increased cardiac muscle damage from defibrillation. Certain electrical and gasoline-powered appliances can cause inhibition of an implanted cardiac pacemaker system.

For complete precautions, see the Physician's Manual for



You want her pacemaker to be reliable,

and she wants to wear her designer originals.

Intermedics ThinLith.®

A thinner, lighter pacemaker for your patient's well being.

No one has to tell you that a pacemaker implant raises a number of concerns among your patients. One concern many of your patients may share is, very simply, "How much will it show?" At Intermedics, we are cognizant of this concern. We've designed a series of pacemakers to help minimize appearance anxiety among your patients while giving you outstanding pacemaker reliability in a trimmer, more compact size.

*Clinical experience with Intermedics unipolar ThinLiths demonstrates an average monthly failure rate of only 0.0105 per cent per month.** In addition, the lighter weight, reduced thickness and smoothly rounded corners reduce pocket bulge and add to the post-operative comfort of your patients.

Also, the ThinLith design helps to reduce skin pressure necrosis and the chances of pacemaker migration within the body.

ThinLith. The answer to your concerns about reliability. And your patients' concerns about appearance.

Examine the dimensions of our ThinLiths, and assure your patient that she can still wear those designer originals. Contact your Intermedics representative for more information on the reliability of our ThinLith series.

Typical dimensions of available ThinLiths

	Height (cm)	Width (cm)	Thickness (cm)	Weight (g)	Volume (cm3)
ThinLith II	6.0	4.6	1.1	68	27.5
ThinLith III	5.1	4.6	1.1	55	22

the Intermedics cardiac pulse generator to be used. CONTRAINDICATIONS AND SIDE EFFECTS There are no known contraindications to the use of pacemakers as a medical method for control of heart rate. Body rejection phenomena, local tissue reaction or skin necrosis, muscle and nerve stimulation, embolism, and cardiac tamponade have been reported.

Neither of the models pictured are cardiac pacemaker patients.

New

Persantine®-75
(dipyridamole)

BI

75mg

Important savings for your patients
• Fewer tablets per day • Convenient dosage

Persantine® (dipyridamole) Tablets of 25mg and 75mg

INDICATIONS—Based on a review of this drug by the National Academy of Science-National Research Council and /or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension. Persantine tablets, 25 mg, contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. The incidence of sensitivity is generally low, but frequently seen in patients with aspirin hypersensitivity.

ADVERSE REACTIONS— Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION— The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

Tablets of 25 mg and 75 mg

CONTENTS

555 Ventricular Compliance in Ischemic Right Ventricular Dysfunction

ISABEL COMA-CANELLA and JOSE LOPEZ-SENDON

This hemodynamic study found ischemic right ventricular dysfunction in 54 patients with acute myocardial infarction and a right atrial pressure disproportionately increased in relation to the pulmonary capillary pressure. The right atrial pressure curve in 74 percent of the patients showed a noncompliant M- or W-shaped pattern similar to that found in constrictive pericarditis. The severe noncompliant pattern was significantly related to the presence of a low output syndrome and mortality from this cause. The simple noninvasive jugular venous pulse tracing had a pattern quite similar to that of the right atrial pressure in this study and, in a large proportion of cases, could assist in diagnosing right ventricular dysfunction and in estimating prognosis of these patients.

562 Negative Intraventricular Diastolic Pressure in Patients With Mitral Stenosis: Evidence of Left Ventricular Diastolic Suction

HANI N. SABBAH, DANIEL T. ANBE and PAUL D. STEIN

Hemodynamic measurements in 15 patients with mitral stenosis and in 16 patients with no significant heart disease revealed a negative ventricular diastolic pressure during left ventricular filling in the first group but not in the second. The negative diastolic pressure in the patients with severe mitral stenosis appeared related to the maintenance of a vigorous contraction that exerted a strong sucking action to draw blood through the reduced inflow orifice. The presence of a negative diastolic intraventricular pressure in these patients suggests that the dynamics of the ventricle during diastole may participate in its filling process.

567 Echocardiography in Assessing Acute Pulmonary Hypertension Due to Pulmonary Embolism

WOLFGANG KASPER, THOMAS MEINERTZ, FRIEDRICH KERSTING, HERBERT LÖLLGEN, PETER LIMBOURG and HANJÖRG JUST

This study in 18 patients with acute pulmonary embolism demonstrates that a dilated pulmonary artery delineated by suprasternal echocardiography indicates an increase in pulmonary arterial pressure. Precordial echocardiography revealed that right ventricular dimension was increased in 13 of 16 patients and left ventricular dimension decreased in 10 of 15 patients. The ratio of right to left ventricular end-diastolic diameter correlated well with the angiographic index of severity of embolic obstruction in the patients with acute pulmonary embolism. These results indicate that combined suprasternal and precordial echocardiography appears to be a valuable noninvasive technique in the assessment of acute pulmonary hypertension in patients with acute pulmonary embolism and no known prior cardiopulmonary disorder.

573 Hemodynamic Observations in Patients With Left Ventricle to Aorta Conduit

MICHAEL R. NIHILL, DENTON A. COOLEY, JOHN C. NORMAN, GRADY L. HALLMAN, and DAN G. McNAMARA

The implantation of a composite conduit between the left ventricular apex and abdominal aorta appeared effective in relieving severe and otherwise inoperable left ventricular outflow tract obstruction and in preserving or improving left ventricular function and aortic hemodynamics in 14 patients ranging from 9 to 72 years of age. An average of 36 percent of the left ventricular output was ejected through the conduit. Postoperatively, the left ventricle to aorta pressure gradients were reduced from an average preoperative value of 100.6 mm Hg to 22.1; left ventricular end-diastolic volume averaged 87.5 percent of normal and cardiac index and ejection fraction were normal in all but one patient. Follow-up of some patients up to 48 months postoperatively indicates that this operation is tolerated well and permits normal exercise, growth and development in children.

EXPERIMENTAL STUDIES

583 Electrophysiologic and Anatomic Correlates of Sustained Ventricular Tachyarrhythmias in a Model of Chronic Myocardial Infarction

ERIC L. MICHELSON, JOSEPH F. SPEAR and E. NEIL MOORE

Liquid K...
It's no picnic.

The tasteless Slow-K tablet that doesn't insult food

Slow-K®
(potassium chloride) slow-release tablets 8 mEq

The right taste

The right taste in potassium supplementation is no taste or aftertaste. That's the taste of Slow-K. Tasteless. Even when taken with meals, it allows patients to enjoy the flavor of food. Compare this with liquid K's unpleasant taste. It's easy to see why Slow-K was the overwhelming choice of patients in taste comparisons with liquid KCl and potassium gluconate preparations.[1,2]

The right salt

Potassium chloride, the active ingredient of Slow-K, "...is the salt of choice to correct the hypokalaemic alkalosis resulting from thiazides and related diuretics...."[3]

The right delivery

Slow-K delivers KCl slowly, through controlled, gradual release within the gastrointestinal tract. Patients encounter much less nausea, heartburn and diarrhea than with liquid KCl, as demonstrated by comparative studies.[1] (Occurrence of abdominal cramping was comparable.)

Patients also appreciate the convenience of a small, easy-to-carry Slow-K tablet.

Slow-K...When compliance with liquid K supplements is a problem*

*Slow-release potassium chloride tablets should be reserved for patients who cannot tolerate, refuse to take, or have compliance problems with liquid K preparations because of reports of GI ulceration and bleeding with slow-release KCl tablets (total number of GI lesions in both foreign countries and the United States remains less than one per 100,000 patient-years). The incidence of lesions with enteric-coated KCl tablets is 40-50 per 100,000 patient-years.

Please turn page for prescribing information.

CIBA

SLOW-K®
(potassium chloride)
slow-release tablets

DESCRIPTION

Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS

BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.

2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy; and certain diarrheal states.

3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS

In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS

Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS

Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion, particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram, and clinical status of patient.

ADVERSE REACTIONS

Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE

Usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for prevention of hypokalemia to 40-100 mEq per day or more for treatment of potassium depletion.

Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

C I B A

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability and insomnia associated with anxiety neuroses and transient situational disturbances; anxiety associated with depressive symptoms and as a treatment of symptoms of anxiety if such symptoms are a significant feature of functional or organic disorders, particularly gastrointestinal or cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatric patients requires caution and frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring of vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® (IV) for (lorazepam) Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

The anxious heart. Since anxiety so often accompanies cardiovascular disease, you may wish to institute adjunctive therapy to help bring this complicating factor under control.

Seven benzodiazepines are now at your disposal. All of them are anxiolytics. One of them—Ativan (lorazepam)—has been specifically evaluated in seven double-blind, controlled studies involving 423 patients (211 on Ativan) and found significantly effective in the relief of anxiety associated with organic and functional cardiovascular disorders. The cardiovascular component has not, of course, been shown to be significantly benefited by such therapy.

In addition to this outstanding record of clinical usefulness, Ativan offers you a unique pharmacokinetic profile. Unlike older benzodiazepines, it does not generate multiple active metabolites; steady-state serum levels are rapidly achieved and disappear rapidly once you decide to discontinue therapy. (The pharmacokinetic profile of a drug can define such characteristics as absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Compatible with cardiotonics, antihypertensives, diuretics, anticoagulants and nonnarcotic analgesics*...usually well tolerated...simple to use on a b.i.d. schedule...a preferred prescription to control anxiety in cardiovascular disease.

*No evidence of any clinically significant interaction between Ativan and any other medication given concomitantly was observed in clinical studies. All benzodiazepines, however, including Ativan, produce added CNS depressant effects when administered with alcohol and other CNS depressants.

See important information on preceding page.

Ativan® (lorazepam) for Anxiety

and electrophysiologic heterogeneity sufficient to predispose to the initiation of sustained reentrant ventricular tachyarrhythmias by programmed electric stimulation. Nine of the 10 animals had reproducibly sustained ventricular tachyarrhythmias after the use of routine methods of programmed electric stimulation. This model also produces small infarctions so that the animals remain in clinically stable condition and may tolerate ventricular tachyarrhythmias without rapid hemodynamic deterioration. It appears suitable for the further evaluation of both the mechanisms of arrhythmias and the effects of potential therapeutic regimens.

591 Scanning Electron Microscopy After Coronary Transluminal Angioplasty of Normal Canine Coronary Arteries

RICHARD C. PASTERNAK, KENNETH L. BAUGHMAN, JOHN T. FALLON and PETER C. BLOCK

Scanning electron microscopy to assess morphologic changes caused by the angioplasty balloon catheter in the normal coronary arteries of 11 dogs showed loss of epithelium and stimulated platelet adhesion and thrombus formation. The intima was severely damaged in the dogs pretreated with aspirin, but the administration of low molecular weight dextran helped prevent the immediate layering of platelets. The long-range effects of endothelial damage induced by angioplasty remain unclear. However, the model used in these experiments offers a good method for conducting long-range observations on the possible consequences of coronary transluminal angioplasty and the effects of antiplatelet interventions.

PEDIATRIC CARDIOLOGY

599 Collateral Vessels Between the Coronary and Bronchial Arteries in Patients With Cyanotic Congenital Heart Disease

HARRAN Y. ZUREIKAT

This prospective study using selective coronary arteriography found collateral vessels between the coronary and bronchial arteries in 5 of 23 patients with cyanotic congenital heart disease but none in 214 subjects with noncyanotic congenital heart disease. Such collateral vessels from the coronary arteries provide an increment to pulmonary blood flow in patients with cyanosis and diminished pulmonary flow. The presence of collateral vessels could not be detected clinically by auscultatory bruits, characteristic X-ray findings or electrocardiographic evidence of ischemia.

604 Electrocardiogram in Double Chamber Right Ventricle

KALMAN J. GOITEIN, WILLIAM H. NECHES, SANG C. PARK, ROBERT A. MATHEWS, CORA C. LENOX and JAMES R. ZUBERBUHLER

Examination of the electrocardiograms in 30 patients with a double chamber right ventricle as a result of obstruction by an anomalous muscle bundle revealed that 40 percent had upright T waves in lead V_3R as the only electrocardiographic finding suspicious of right ventricular hypertrophy. This abnormality in the absence of other electrocardiographic evidence of right ventricular hypertrophy in patients with the clinical diagnosis of ventricular septal defect alone or in association with other anomalies should alert the clinician to the possibility of double chamber right ventricle prior to cardiac catheterization.

STUDIES IN HYPERTENSION

609 Saralasin Infusion in Screening Patients for Renovascular Hypertension

LAWRENCE R. KRAKOFF, ARTUR B. RIBEIRO, JANET U. GORKIN and KATHERINE R. FELTON

These results of screening 19 patients with and 34 without proved renovascular hypertension by infusion of saralasin, a competitive antagonist of angiotensin II, indicate that only 25 percent of positive saralasin tests will cor-

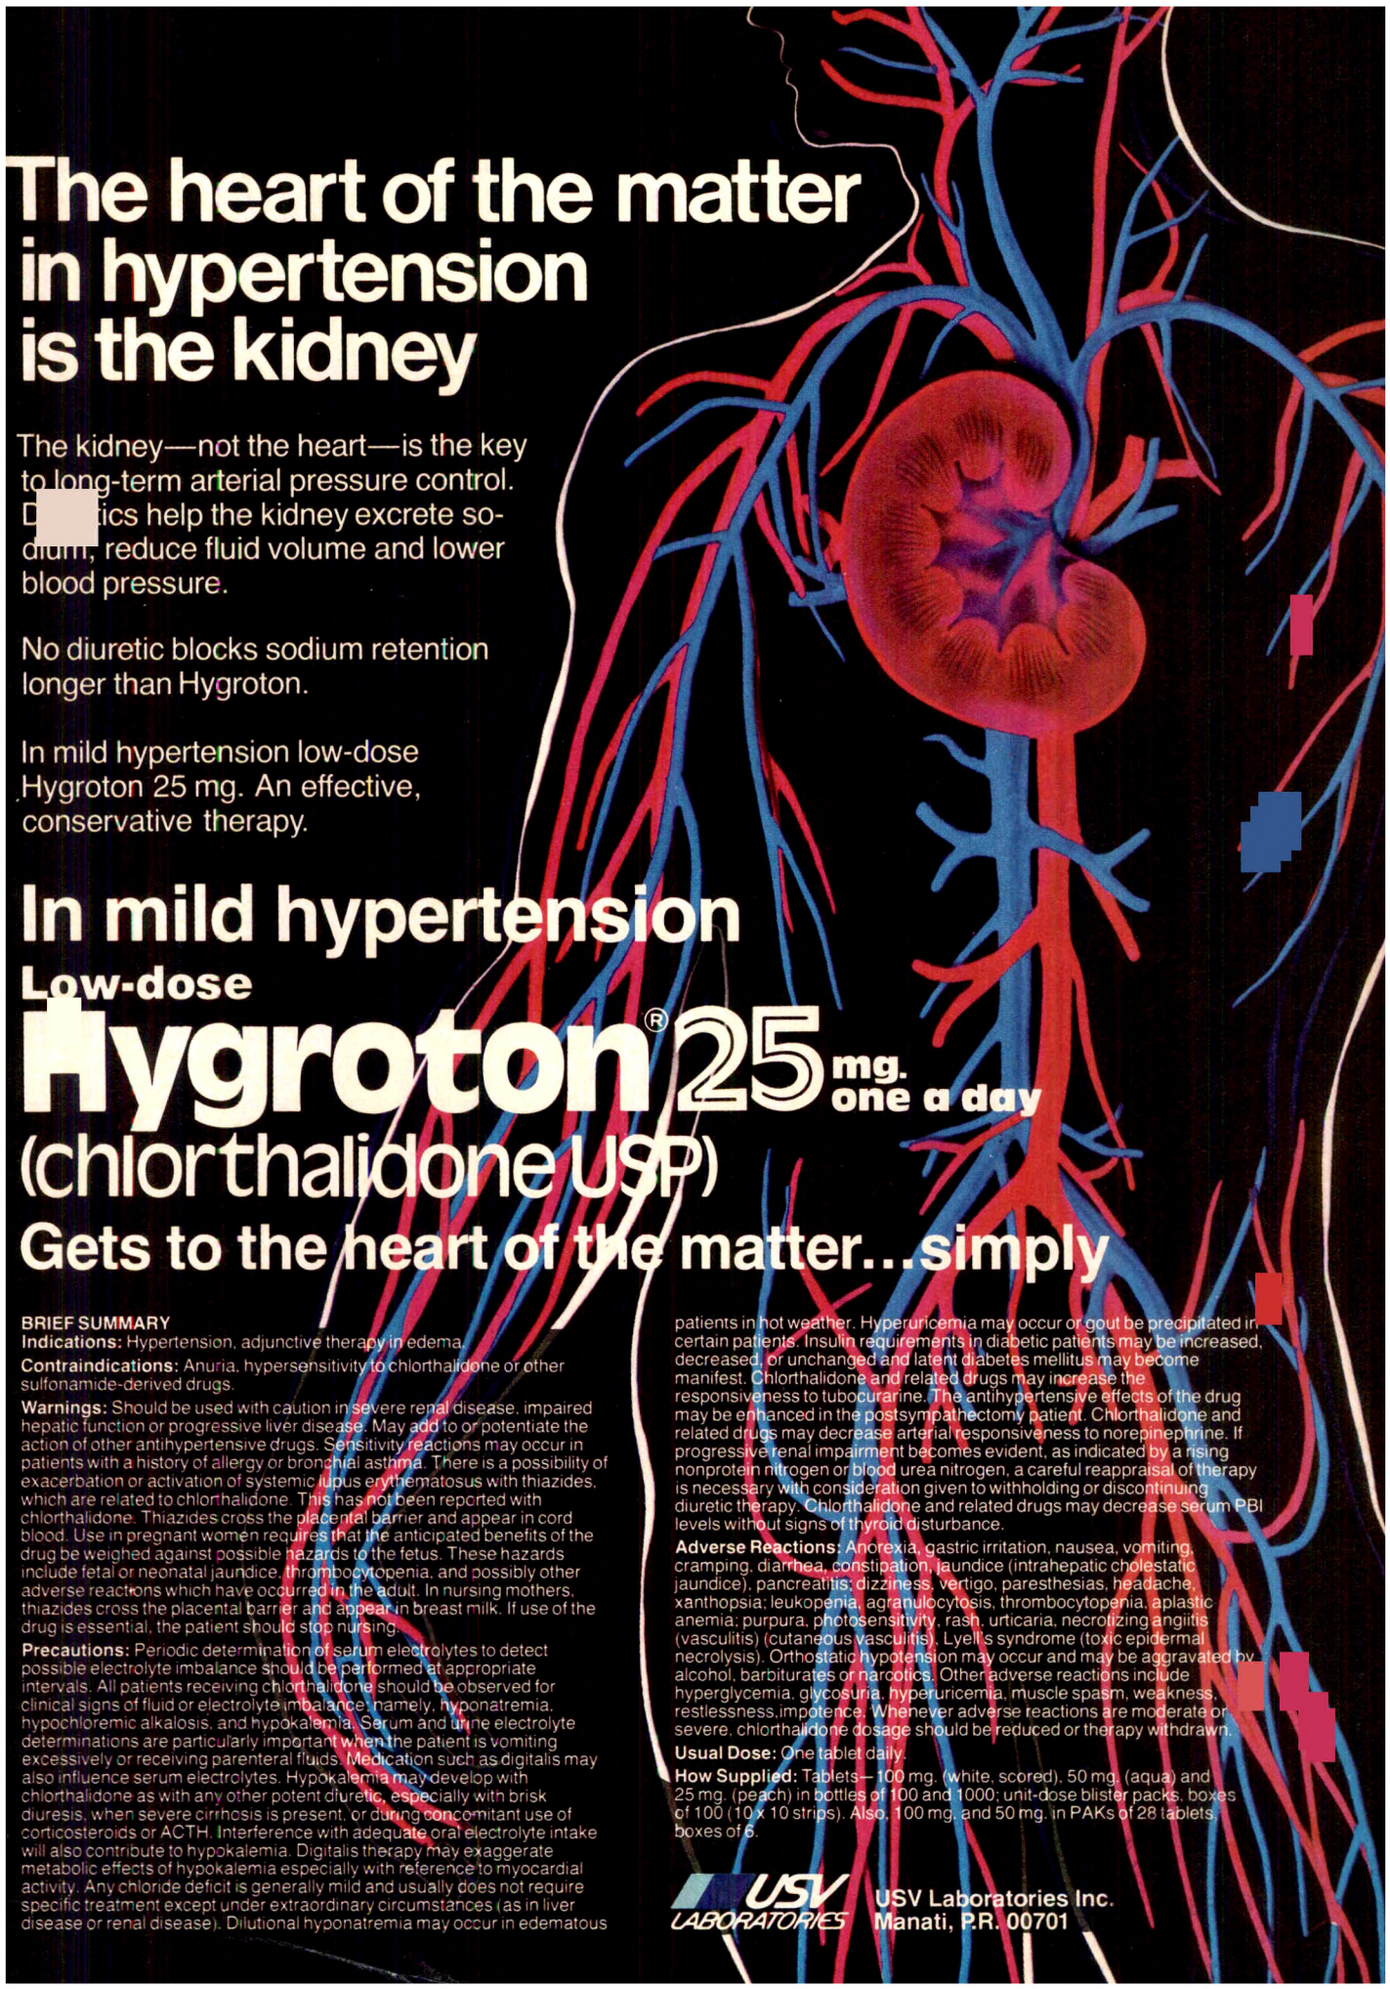
UNIVERSITY LIBRARY



The heart of the matter in hypertension is the kidney

The kidney—not the heart—is the key to long-term arterial pressure control. Diuretics help the kidney excrete sodium, reduce fluid volume and lower blood pressure.

No diuretic blocks sodium retention longer than Hygroton.

In mild hypertension low-dose Hygroton 25 mg. An effective, conservative therapy.

In mild hypertension

Low-dose

Hygroton® 25 mg. one a day

(chlorthalidone USP)

Gets to the heart of the matter...simply

BRIEF SUMMARY

Indications: Hypertension, adjunctive therapy in edema.

Contraindications: Anuria, hypersensitivity to chlorthalidone or other sulfonamide-derived drugs.

Warnings: Should be used with caution in severe renal disease, impaired hepatic function or progressive liver disease. May add to or potentiate the action of other antihypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. There is a possibility of exacerbation or activation of systemic lupus erythematosus with thiazides, which are related to chlorthalidone. This has not been reported with chlorthalidone. Thiazides cross the placental barrier and appear in cord blood. Use in pregnant women requires that the anticipated benefits of the drug be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier and appear in breast milk. If use of the drug is essential, the patient should stop nursing.

Precautions: Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather. Hyperuricemia may occur or gout be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes mellitus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy. Chlorthalidone and related drugs may decrease serum PBI levels without signs of thyroid disturbance.

Adverse Reactions: Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis; dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn.

Usual Dose: One tablet daily.

How Supplied: Tablets—100 mg. (white, scored), 50 mg. (aqua) and 25 mg. (peach) in bottles of 100 and 1000; unit-dose blister packs, boxes of 100 (10 x 10 strips). Also, 100 mg. and 50 mg. in PAKs of 28 tablets, boxes of 6.

USV LABORATORIES

USV Laboratories Inc.
Manati, P.R. 00701

Announcing the formation of

Berlex Laboratories Inc.

a new pharmaceutical company that will offer the best of two worlds

Dear Doctor:

You are familiar with the product that appears on the opposite page, but you are not familiar with the company name that now appears on that product, Berlex Laboratories Inc.

Berlex Laboratories Inc. is the new American subsidiary of Schering AG, Berlin, West Germany, one of the world's most respected research-oriented pharmaceutical manufacturers, with a history of innovation and excellence dating back to 1851. Schering AG is not connected with Schering-Plough Corporation, Kenilworth, New Jersey.

Berlex Laboratories was formed through the acquisition of certain products and manufacturing and research facilities of Cooper Laboratories, Inc. The more familiar preparations in the specialties of cardiology, internal medicine, allergy and general medicine include:

Aminodur® Dura-Tabs® (aminophylline)
Deconamine® (chlorpheniramine maleate/d-pseudoephedrine hydrochloride)
Elixophyllin® (theophylline)
Elixicon® Suspension (theophylline)
Kay Ciel® (potassium chloride)
Pyocidin-Otic® (polymyxin-hydrocortisone)
Quinaglute® Dura-Tabs® (quinidine gluconate)
Sus-Phrine® (epinephrine)
Therapav® (papaverine hydrochloride)

In the future, Berlex Laboratories plans to augment these well-established products with others not currently available in the United States but which have gained high acceptance by physicians around the world. Berlex Laboratories' parent company manufactures and distributes over 100 ethical products through 120 plants and subsidiaries in 140 countries.

Although you are unfamiliar with our name now, you will soon know us as physicians in other countries know and respect our parent company.

Berlex Laboratories looks forward to serving you with products developed by our worldwide research resources. Products to meet the challenges of tomorrow will come from commitment to research today. Berlex Laboratories Inc. is making that commitment now to meet the challenges of tomorrow.

BERLEX Laboratories Inc.

When the compromised arrhyth patient needs round-the-cloc year-after-year protection

Quinaglu 324 mg DURA-T

(quinidine gluconat

CONTRAINDICATIONS:
Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.
Partial A-V or complete heart block, o intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening.
Renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defect ventricular premature beats, ventricul tachycardia or flutter while on the dru
Marked cardiac enlargement, particu larly with congestive failure, poor ren function, and especially renal tubular acidosis.
Idiosyncrasy or hypersensitivity to quinidine.

WARNINGS:
In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degr of A-V block to a 1:1 ratio resulting in extremely rapid ventricular rate.

PRECAUTIONS:
The precautions to be observed includ all those applicable to quinidine. A pr liminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has a idiosyncrasy to quinidine. Hypersensi tivity to quinidine, although rare, should constantly be considered, espe cially during the first weeks of therapy
Quinidine in large doses may reduce contractile force of the heart, therefore extreme caution should be exercised i using the drug in patients with severe heart disease, hypotension or digitalis intoxication. The potential disadvantages and benefits must be weighed.
It should be administered cautiously, if at all, to senile patients.
Hospitalization for close clinical obse tion, electrocardiographic monitoring, possibly plasma quinidine levels is in cated when large doses are used or wi patients who present an increased ris

ADVERSE REACTIONS:
Symptoms of cinchonism, ringing in ears, headache, nausea, disturbed vision may appear in sensitive patient after a single dose of the drug.
Cardiovascular: Widening of QRS co plex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism, hypotension.
Gastrointestinal: Nausea, vomiting, abdominal pain, diarrhea.
Hematologic: Acute hemolytic anemia hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, exciteme confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision fields photophobia, diplopia, night blindnes scotomata), optic neuritis.
Dermatologic: Cutaneous flushing wi intense pruritus.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vasc lar collapse, respiratory arrest.
See package insert for full informatio

DURA-TABS®
(quinidine gluconate)
when the arrhythmic patient
requires long-term

rectly predict the presence of renovascular hypertension when its prevalence rate among hypertensive patients is 5 percent. In this series the saralasin test was positive in 75 percent of patients with proved renovascular hypertension but 12 percent of those proved not to have renovascular hypertension had a false positive test. At present this test appears as useful as the intravenous pyelogram in screening patients for renovascular hypertension.

614 Pindolol in the Treatment of Hypertension: Systolic Time Intervals as a Predictor of Response to Beta Receptor Blockade

GARY D. PLOTNICK, MICHAEL L. FISHER, JENNIFER H. HAMILTON, MICHAEL ROBINSON, NATHAN H. CARLINER, ALPHONSO H. JANOWSKI and BRUCE P. HAMILTON

Using serial systolic time intervals to assess cardiac function, this study of 22 hypertensive patients treated with pindolol, a beta adrenergic blocking drug with intrinsic sympathomimetic activity, shows that patients with a normal pretreatment preejection period/left ventricular ejection time (PEP/LVET) ratio were more likely to respond than those with an abnormal pretreatment ratio. Pindolol's dual action as a beta blocking agent with intrinsic sympathomimetic activity may be responsible for this difference. Beta blockade effects appear to dominate in those with normal cardiac function while sympathomimetic activity balances the beta blocking effect in those with abnormal cardiac function. When patients with high renin hypertension were excluded, the systolic time intervals were a better predictor of response than the renin classification.

REPORTS ON THERAPY

621 Episodic Drug Treatment in the Management of Paroxysmal Arrhythmias

BASIL MARGOLIS, REGIS A. DeSILVA and BERNARD LOWN

Intermittent oral antiarrhythmic drug "cocktail" therapy taken only at the onset of an episode of arrhythmia proved effective and safe in terminating episodic supraventricular and ventricular arrhythmias in 24 of 32 patients. This method obviated the need for hospitalization and at last year's costs at a Boston hospital (emergency room visit plus 8 to 16 hours' observation, $120; 24 hours in intensive care unit, $595; electrical cardioversion, $77) produced significant financial savings. Other advantages include the participation of the patient as an integral agent in the management process and the reduction of his psychologic stress as a provoker of arrhythmias.

627 Mexiletine Therapy in 15 Patients With Drug-Resistant Ventricular Tachycardia

JAMES J. HEGER, STANLEY NATTEL, ROBERT L. RINKENBERGER and DOUGLAS P. ZIPES

Mexiletine in these studies exhibited limited antiarrhythmic efficacy in 15 patients with chronic and recurrent episodes of ventricular tachycardia or ventricular fibrillation already refractory to other antiarrhythmic agents and was associated with frequent adverse side effects. Considerable interpatient variability in dose-response and a narrow toxic-therapeutic ratio were observed. The elimination half-life was 12.6 ± 1.6 hours.

633 Ventricular Ectopic Activity After Medical and Surgical Treatment for Recurrent Sustained Ventricular Tachycardia

IRVING M. HERLING, LEONARD N. HOROWITZ and MARK E. JOSEPHSON

These results in 23 patients with recurrent sustained ventricular tachycardia who underwent Holter electrocardiographic monitoring indicate the response of ventricular ectopic activity on Holter monitoring to antiarrhythmic or surgical therapy does not predict therapeutic success in the treatment of recurrent sustained ventricular tachycardia. Eleven patients in whom drug therapy failed underwent aneurysmectomy and endocardial resection; in these, sustained ventricular tachycardia could not be induced postoperatively by programmed electric stimulation nor has it occurred spontaneously in any patient. Nevertheless, eight of these continued to show per-

continued on page A29

Hal Fisher is out for his morning ECG.

ırdick's ambulatory ECG stem for patients on the go.

Jogging, cycling, tennis. Working out or work routine. Most patient activities can be continued while you monitor his ECG. This compact ambulatory monitor tells you what you need to know, detects ırdiac events in the patient ıo has known or suspected cardiac ɔnormalities, wherever he is. Yet is miniaturized monitor/recorder weighs st 15 ounces and can be worn in a pocket, 'er the shoulder or on the hip, giving e patient complete freedom of activity.

Makes sense for the physician, too. ırdick's ambulatory monitor offers many adntages for the physician. For example, you n choose from a broad range of automatic ration-and-interval settings to achieve ECG ɔnitoring programs from 15 hours to a week in al length. And if the patient feels unusual symms, he can verbally record on tape his own feelings *on the spot* and activate a recording of his electrocardiogram. This is selective monitoring at its best.

Simple playback. Burdick's ambulatory monitor enables you to play back the recorded ECG directly into any standard office ECG unit. No expensive scanning or data processing equipment is needed.

Use for monitoring transient cardiac abnormalities or rehabilitation progress. Ideally suited for determining the causes of transient cardiac abnormalities such as angina, dyspnea, dizziness, cerebral ischemia, and for monitoring cardiac rehabilitation progress.

Seeing is believing. For more information or a demonstration, call us toll-free at 800-356-0701. In Wisconsin call 608-868-7631. Or write **The Burdick Corporation, Milton, Wisconsin 53563.**

tion please see the following page.

Lopressor®
metoprolol tartrate

Geigy

the only relatively selective beta blocker for hypertension

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities, arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

667292 (8/79) C79-22

sistent complex ventricular ectopic activity on Holter monitoring, suggesting that the mechanism for successful surgery was an alteration of the reentrant circuit. It appears that alterations of the reentrant circuit are probably the method by which surgery or pharmacologic therapy, or both, successfully ablates long-term ventricular arrhythmias.

640 Study of Moxaprindine With Programmed Electric Stimulation of the Heart in Patients With Reentrant Tachyarrhythmias

ANDRÉ WALEFFE, LUC MARY-RABINE and HENRI E. KULBERTUS

Programmed electric stimulation of the heart in 19 patients with recurrent tachyarrhythmias shows that moxaprindine, a new derivative of aprindine, is a potent effective antiarrhythmic agent whose long-term efficacy and toxicity in patients deserve further investigation. No side effects were observed in this acute study. Moxaprindine lengthened conduction time along the His-Purkinje system, prolonged the refractory periods of the right atrial and ventricular muscle and depressed the atrioventricular node. These results were comparable with those reported for aprindine. It also produced a marked effect on accessory pathways used in an anterograde direction. Perfused intravenously during episodes of tachycardia in 17 patients, it interrupted the rhythm disorder in all instances. No tachycardia could be elicited after drug administration in 11 of 19 subjects.

648 Sustained Hemodynamic Effects Without Tolerance During Long-Term Isosorbide Dinitrate Treatment of Chronic Left Ventricular Failure

JOSEPH A. FRANCIOSA and JAY N. COHN

Hemodynamic measurements in 19 patients with chronic left heart failure before and 90 minutes after oral administration of 40 mg of isosorbide dinitrate and similar measurements 3 months after the daily administration of isosorbide dinitrate in 9 patients and placebo in 10 patients confirm that such long-term administration of isosorbide dinitrate is associated with sustained hemodynamic effects and responsiveness in patients with congestive heart failure. However, nitrate treatment had no significant effect on morbidity or mortality in this group of patients. It is possible that the combination of hydralazine and nitrate may be preferable to prazosin in the long-term therapy of congestive heart failure because patients taking these agents do not manifest drug tolerance as they do with prazosin.

655 Dose Requirements of Hydralazine in Patients With Severe Chronic Congestive Heart Failure

MILTON PACKER, JOSE MELLER, NORMA MEDINA, RICHARD GORLIN and MICHAEL V. HERMAN

The doses of hydralazine required to obtain significant hemodynamic responses in patients with severe chronic refractory heart failure are variable and appear to be related to varying degrees of vascular hyporesponsiveness or drug malabsorption, or both, observed in states of high venous pressure. These doses are generally higher than those needed in hypertensive patients. Whereas hypertensive patients usually respond to doses of 50 mg or less, patients with heart failure rarely demonstrated hemodynamic effects with single doses smaller than 75 mg. In this study of 40 patients, more than 40 percent required single doses of hydralazine substantially larger than 100 mg to reduce significantly systemic vascular resistance. Effective doses ranged as high as 800 mg orally as a single dose and up to 2,400 mg daily. Occasionally a patient responded only to intravenous administration. Failure of hydralazine to produce clinical improvement in an individual patient may be due to the administration of subtherapeutic quantities of the drug.

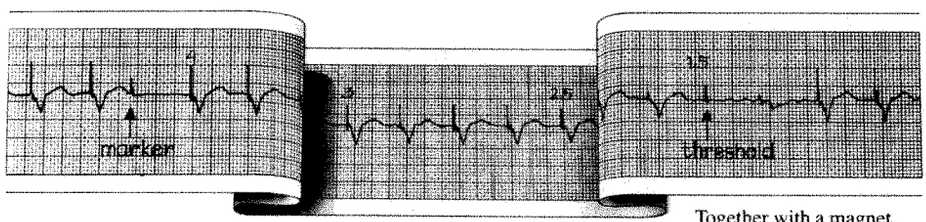
Vitatron's C1000 and C4000

A new standard in threshold measurement.



Together with a magnet, this is all you need.

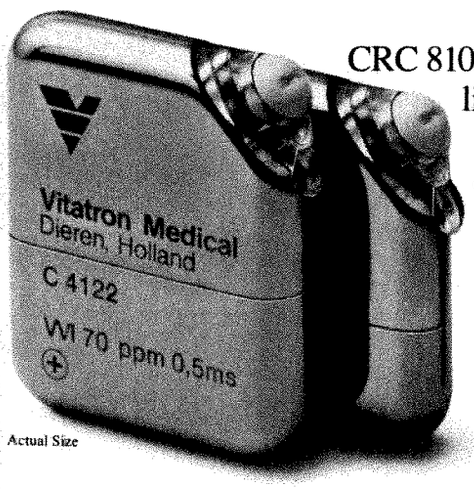
Introducing our C1000 and C4000 pacemakers.

They offer a safer method of *non-invasive* stimulation threshold analysis. One in which all you need is a simple magnet, and a standard ECG recorder.

The magnet starts an output amplitude step-down mode. After completion or at interruption of the step-down cycle, the pacemaker automatically reverts to full output.

How has Vitatron achieved such an important advance? New monolithic integrated injection logic (I^2L) is one reason. Here, all analogue and digital circuitry is contained on a single chip that measures 2.8x2.8 mm.

Overall size of the C1000, incidentally, is mere 50x47x12 mm, with a weight of just 46 grams. The C4000 measures 57x47x12 mm, and weighs 56 grams. Units come in an all-titanium can that's been hermetically sealed by laser welding.



Actual Size

Finally, thanks to our patented dc-dc converter and the CRC 810B lithiode battery, the C1000 has a projected service life of over 9 years*; the C4000, over 15 years.**

Our C1000 and C4000 pacemakers. *Think of them as a new standard in patient safety.*

For specifications write to Vitatron Medical B.V., P.O. Box 76, 6950 AB Dieren, The Netherlands. In the United States: Vitatron Medical Inc., One Gateway Center, Newton, MA 02158.

*Over 6 years service life expected under worst case conditions, 70 ppm, 510 Ohm load, 1.0 millisecond pulse duration; over 9 years, 0.5 ms duration.
**Over 10 years service life expected under worst case conditions, 70 ppm, 510 Ohm load, 1.0 millisecond pulse duration; over 15 years, 0.5 ms duration.

LITHIODE TM
Lithium/Iodine Cell
MODEL 810

For the special needs of patients with hard, dry stools

SENOKOT®-S

(standardized senna concentrate and dioctyl sodium sulfosuccinate) **Tablets**

the "S" stands for softener

For patients with hard, dry stools
Hard, dry stools hurt, and may be hazardous by causing straining. SENOKOT-S Tablets offer comfortable relief by softening the stool *and* stimulating its movement.

Provides standardized senna concentrate, a clinically established laxative of choice
Standardized senna concentrate is a gentle, effective neuroperistaltic stimulant with documented effectiveness in thousands of patients. Its virtually colon-specific, gentle, predictable action is generally free of side effects at proper dosage levels.

Provides DSS, the classic stool softener
DSS in SENOKOT-S Tablets complements the laxative effect of standardized senna concentrate by "moistening" and softening the stool for smoother and easier passage.

Comfortable overnight action
With DSS and standardized senna concentrate, SENOKOT-S Tablets provide *both* softness and stimulation for constipated patients with hard, dry stools. Taken at bedtime, SENOKOT-S Tablets usually induce predictable, comfortable evacuation the next morning.

CONTENTS

technique is clinically valuable for evaluating left ventricular contraction, detecting the presence and severity of regional asynergy and eliciting ejection fraction abnormalities at rest and during exercise stress. It may prove useful in assessing the size and course of an acute myocardial infarction, the natural history of cardiac diseases and the effects of different therapies. Its future role will be shaped by the development of improved technology to increase its accuracy as compared with other available noninvasive measures as detailed in this excellent review.

674 Nuclear Cardiology II. The Role of Myocardial Perfusion Imaging Using Thallium-201 in Diagnosis of Coronary Heart Disease

MONTY M. BODENHEIMER, VIDYA S. BANKA and RICHARD H. HELFANT

This review assesses the uses and limitations of thallium-201 perfusion imaging in the diagnosis of acute and chronic manifestations of coronary heart disease. It is the agent of choice in the clinical assessment of relative myocardial perfusion and is of particular value in the diagnosis of coronary heart disease. However, in the setting of acute myocardial ischemia the role of thallium-201 is less clear. Concentration of thallium in the myocardium is determined by the amount of isotope delivered by coronary flow, myocardial uptake and the rate of myocardial isotope efflux. The thallium uptake depends on the integrity of myocardial cell function (in particular, that of membrane adenosine triphosphatase). The size of the involved area of myocardium (ischemic tissue or scar, or both) determines the presence or absence of a defect in the thallium image. A minimum of 5 g of myocardium must be involved in abnormal thallium uptake for a defect to be visualized in a thallium image. Thallium imaging during exercise is generally somewhat more accurate than a stress electrocardiogram in the diagnosis of coronary heart disease.

CASE REPORTS

685 Calcification in Porcine Xenograft Valves in Children

MEREDITH M. SILVER, JAMES POLLOCK, MALCOLM D. SILVER, WILLIAM G. WILLIAMS and GEORGE A. TRUSLER

Calcification of porcine xenografts seems to occur more frequently and earlier after insertion in children than in adults, as suggested by these three examples in a series of 93 children at the same institution. Such deposition may be at the sites of maximal stress as determined by in vitro testing of tissue valves. A host factor in children may possibly override the apparent protection against calcification conferred by glutaraldehyde pretreatment of tissue in adults. Because calcification occurs so prematurely in children with the xenograft valve, these prostheses may not be appropriate in this age group. However, their use permits the avoidance of anticoagulation in active children.

690 Severe Calcification of Glutaraldehyde-Preserved Porcine Xenografts in Children

FRANCIS T. THANDROYEN, IAN N. WHITTON, DUNCAN PIRIE, MICHAEL A. ROGERS and ABDUL S. MITHA

Severe calcification of glutaraldehyde-preserved porcine xenografts in the mitral valve position occurred in four children aged 13 to 15 years within 17 to 25 months of implantation. Such calcification produced critical obstruction with rapid cardiac deterioration necessitating valve replacement. Auscultation alone may be unhelpful and difficult in diagnosing stenotic xenografts in the mitral valve position. Electrocardiographic evidence of rightward shift of the mean frontal QRS axis, radiologic signs of increasing left atrial and pulmonary arterial segments on the chest X-ray film and echocardiography may provide valuable early information on stenotic prosthetic valve dysfunction. Such calcification occurred in the presence of normal serum calcium levels and was not related to infective endocarditis.

Duraquin®
(QUINIDINE GLUCONATE TABLETS) SUSTAINED-RELEASE TABLETS, 330 mg

BRIEF SUMMARY OF PRESCRIBING INFORMATION
DURAQUIN® (quinidine gluconate tablets) Sustained Release
AHFS Category 24:04

CLINICAL PHARMACOLOGY. In clinical studies, single doses of Duraquin produced a mean maximum plasma level at 2 hours which was maintained for 12 hours. This broad plateau indicates slow, continuous absorption from the gastrointestinal tract.

In multiple dose studies, administration of Duraquin tablets, 660 mg every 12 hours, produced steady state (equilibrium) plasma levels shortly after 24 hours. The average quinidine plasma levels (Cramer and Isaksson assay[1]) were 0.81 mcg/ml and the mean peak levels were 1.16 mcg/ml in a group of normal male subjects weighing 75 Kg. Following the last dose at steady state, quinidine plasma levels decreased at an approximate rate of 50% in 10 hours. This compares to the expected plasma half-life of 6.3 hours for quinidine sulfate tablets, USP.

Therapeutic and toxic effects coordinate better with plasma levels than with dosage. While therapeutic levels of 3 to 6 mcg/ml with a range of 1.5 to 9 mcg/ml have been reported, these values are based on peak plasma levels determined by the less specific Edgar and Sokolow assay.[2] This procedure yields quinidine levels averaging 22% higher than the Cramer and Isaksson assay. Plasma levels vary considerably in patients receiving identical doses. Therefore, it is advisable to adjust the dosage by monitoring plasma quinidine levels.

INDICATION. Duraquin tablets are indicated for the prevention of premature atrial, nodal, or ventricular contractions. They are also indicated for the maintenance of normal sinus rhythm following spontaneous reversion or electrical conversion of atrial, nodal, or ventricular tachycardia, atrial flutter and fibrillation (either paroxysmal or chronic).

CONTRAINDICATIONS. 1. History of hypersensitivity to quinidine manifested by thrombocytopenia, skin eruption, febrile reactions, etc.
2. Complete A-V block
3. Complete bundle branch block or other severe intraventricular conduction defects exhibiting marked QRS widening or bizarre complexes
4. Myasthenia gravis
5. Arrhythmias associated with digitalis toxicity

WARNINGS. 1. (a) In the treatment of atrial fibrillation with rapid ventricular response, ventricular rate should be controlled with digitalis glycosides *prior* to administration of quinidine.

(b) In the treatment of atrial flutter with quinidine, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine.

Recent reports have described increased, potentially toxic, digoxin plasma levels when quinidine is administered concurrently. When concurrent use is necessary, digoxin dosage should be reduced and plasma concentration should be monitored and patients observed closely for digitalis intoxication.

2. Quinidine cardiotoxicity may be manifested by increased PR and QT intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia. Appearance of these toxic signs during quinidine administration mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. Note: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia.

3. "Quinidine Syncope" may occur as a complication of long-term therapy. It is manifested by sudden loss of consciousness and ventricular arrhythmias with bizarre QRS complexes. This syndrome does not appear to be related to dose or plasma levels but occurs more often with prolonged QT intervals.

4. Because quinidine antagonizes the effect of vagal excitation upon the atrium and the A-V node, the administration of parasympathomimetic drugs (choline esters) or the use of any other procedure to enhance vagal activity may fail to terminate paroxysmal supraventricular tachycardia in patients receiving quinidine.

5. Quinidine should be used with extreme caution in:

a) the presence of incomplete A-V block, since a complete block and asystole may result. Quinidine may cause unpredictable abnormalities of rhythm in digitalized hearts. Therefore, it should be used with caution in the presence of digitalis intoxication (see 1.(b) above).

b) Partial bundle branch block.

c) Severe congestive heart failure and hypotensive states due to the depressant effects of quinidine on myocardial contractility and arterial pressure.

d) Poor renal function, especially renal tubular acidosis, because of the potential accumulation of quinidine in plasma leading to toxic concentrations.

PRECAUTIONS. 1. Test Dose—A preliminary test dose of a single tablet of quinidine *sulfate* should be administered prior to the initiation of the sustained release gluconate to determine whether the patient has an idiosyncrasy to the Quinidine molecule.

2. Hypersensitivity—During the first weeks of therapy, hypersensitivity to quinidine, although rare, should be considered (eg, angioedema, purpura, acute asthmatic episode, vascular collapse).

3. Long-Term Therapy—Periodic blood counts and liver and kidney function tests should be performed during long-term therapy and the drug should be discontinued if blood dyscrasias or signs of hepatic or renal disorders occur.

4. Large Doses—ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered.

5. Usage in Pregnancy—The use of quinidine, in pregnancy, should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus.

6. Nursing Mothers—The drug should be used with extreme caution in nursing mothers because the drug is excreted in breast milk.

7. General—In patients exhibiting asthma, muscle weakness, and infection with fever *prior* to quinidine administration, hypersensitivity reactions to the drug may be masked.

DRUG INTERACTIONS. 1. Caution should be used when quinidine and its analogs are administered concurrently with coumarin anticoagulants. This combination may reduce prothrombin levels and cause bleeding.

2. Quinidine, a weak base, may have its half-life prolonged in patients who are concurrently taking drugs that can alkalize the urine, such as thiazide diuretics, sodium bicarbonate, and carbonic anhydrase inhibitors. Quinidine and drugs which alkalize the urine should be used together cautiously.

3. Quinidine exhibits a distinct anticholinergic activity in the myocardial tissues. An additive vagolytic effect may be seen when quinidine and drugs having anticholinergic blocking activity are used together. Drugs having cholinergic activity may be antagonized by quinidine.

4. Quinidine and other antiarrhythmic agents may produce additive cardiac depressant effects when administered together.

5. Quinidine interaction with cardiac glycosides (digoxin); See WARNINGS.

6. Antacids may delay absorption of quinidine but appear unlikely to cause incomplete absorption.

7. Phenobarbital and phenytoin may reduce plasma $T_{1/2}$ of quinidine by 50%.

8. Quinidine may potentiate the neuromuscular blocking effect in ventilatory depression of patients receiving decamethonium, tubocurare, or succinylcholine.

ADVERSE REACTIONS. Symptoms of cinchonism (ringing in the ears, headache, disturbed vision) may appear in sensitive patients after a single dose of the drug.

Gastrointestinal: The most common side effects encountered with quinidine are referable to this system. Diarrhea frequently occurs, but it rarely necessitates withdrawal of the drug. Nausea, vomiting, and abdominal pain also occur. Some of these effects may be minimized by administering the drug with meals.

Cardiovascular: widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardias and fibrillation; paradoxical tachycardia, arterial embolism and hypotension.

Hematologic: acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis.

CNS: headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, photophobia, diplopia, night blindness, scotomata); optic neuritis.

Dermatologic: cutaneous flushing with intense pruritus.

Hypersensitivity reactions: angioedema, acute asthmatic episode, vascular collapse, respiratory arrest.

DOSAGE AND ADMINISTRATION. Dosage should be titrated to give the desired clinical effect, eg, elimination of paroxysmal rhythm or reduction in premature contractions (See CLINICAL PHARMACOLOGY). This will often require prolonged ambulatory ECG monitoring, as hour-to-hour variability renders brief ECG recordings unreliable. When doses larger than 2.5 g/day are used, quinidine blood levels should be monitored, if possible, and serial ECGs should be followed (See WARNINGS and PRECAUTIONS).

For prevention of premature contractions and maintenance of normal sinus rhythm following electrical conversion, the usual dosage is from 330 mg to 660 mg every eight hours, most patients requiring the higher dose.

In elderly patients, and in patients in the lower end of the normal weight range, plasma quinidine determinations should be considered. Dosage adjustments may be required.

OVERDOSAGE. Cardiotoxic effects of quinidine may be reversed in part by molar sodium lactate; the hypotension may be reversed by vasoconstrictors and b catecholamines (since the vasodilation is partly due to alpha-adrenergic blockade).

HOW SUPPLIED. N 0071-0850 (P-D 850) Duraquin (quinidine gluconate tablets) 330-mg tablets are supplied in bottles of 100 tablets and in unit-dose packages of 100 (10 strips of 10 tablets each).

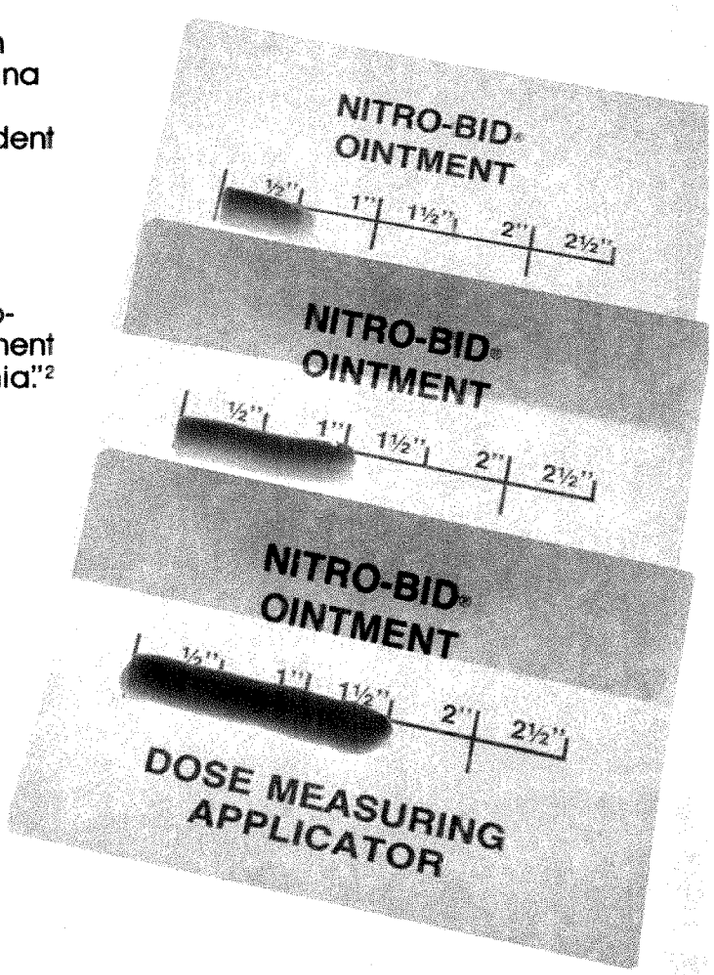
In angina pectoris...

NITRO-BID®
(2% nitroglycerin)
Transdermal Ointment

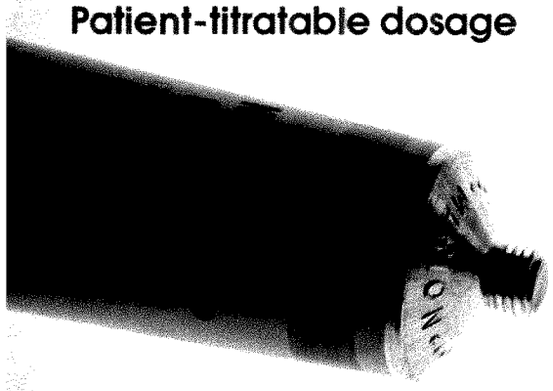
For prolonged prophylactic action, with improved left ventricular function

"Cutaneous administration of Nitroglycerin ointment (NITRO-BID®) in patients with angina pectoris exhibits prolonged action with evidence of pharmacological activity evident up to eight hours after application."[1]

"data indicate that nitroglycerin ointment (NITRO-BID®) exerts profound reduction of peripheral arteriolar and venous tone with resultant alterations in left ventricular hemodynamic variables which afford enhancement of exercise tolerance and reduced ischemia."[2]



Patient-titratable dosage



Brief Summary:

Description: Nitroglycerin 2% (glyceryl trinitrate) and lactose in a special absorptive lanolin and white petrolatum base.

Action: Nitroglycerin is continuously absorbed through the skin into the circulation, thus exerting prolonged vasodilator effects.

Indications: For the prevention and treatment of angina pectoris due to coronary artery disease.

Contraindications: In patients known to be intolerant of the organic nitrate drugs.

Warnings: In acute myocardial infarction or congestive heart failure, nitroglycerin ointment should be used under careful clinical and/or hemodynamic monitoring.

Precautions: Symptoms of hypotension, particularly when suddenly arising from the recumbent position, are signs of overdosage. When they occur, dosage should be reduced.

Adverse Reactions: Transient headaches are the most common side effect, especially at higher dosages. Headaches should be treated with mild analgesics, and nitroglycerin ointment continued. Only with untreatable headaches should the dosage be reduced. Although uncommon, hypotension, an increase in heart rate, faintness, flushing, dizziness, and nausea may occur. These all are attributable to the pharmacologic effects of nitroglycerin on the cardiovascular system, but are symptoms of overdosage. When they occur and persist, the dosage should be reduced.

Dosage: Usual dose is 2 inches (50 mm), as squeezed from the tube, every eight hours. Some patients may need 4 to 5 inches (100 to 125 mm) and/or application every four hours. Optimal dosage should be based upon clinical response, side effects, and effects of therapy upon blood pressure. Consult full product disclosure before prescribing.

Caution: Federal law prohibits dispensing without prescription.

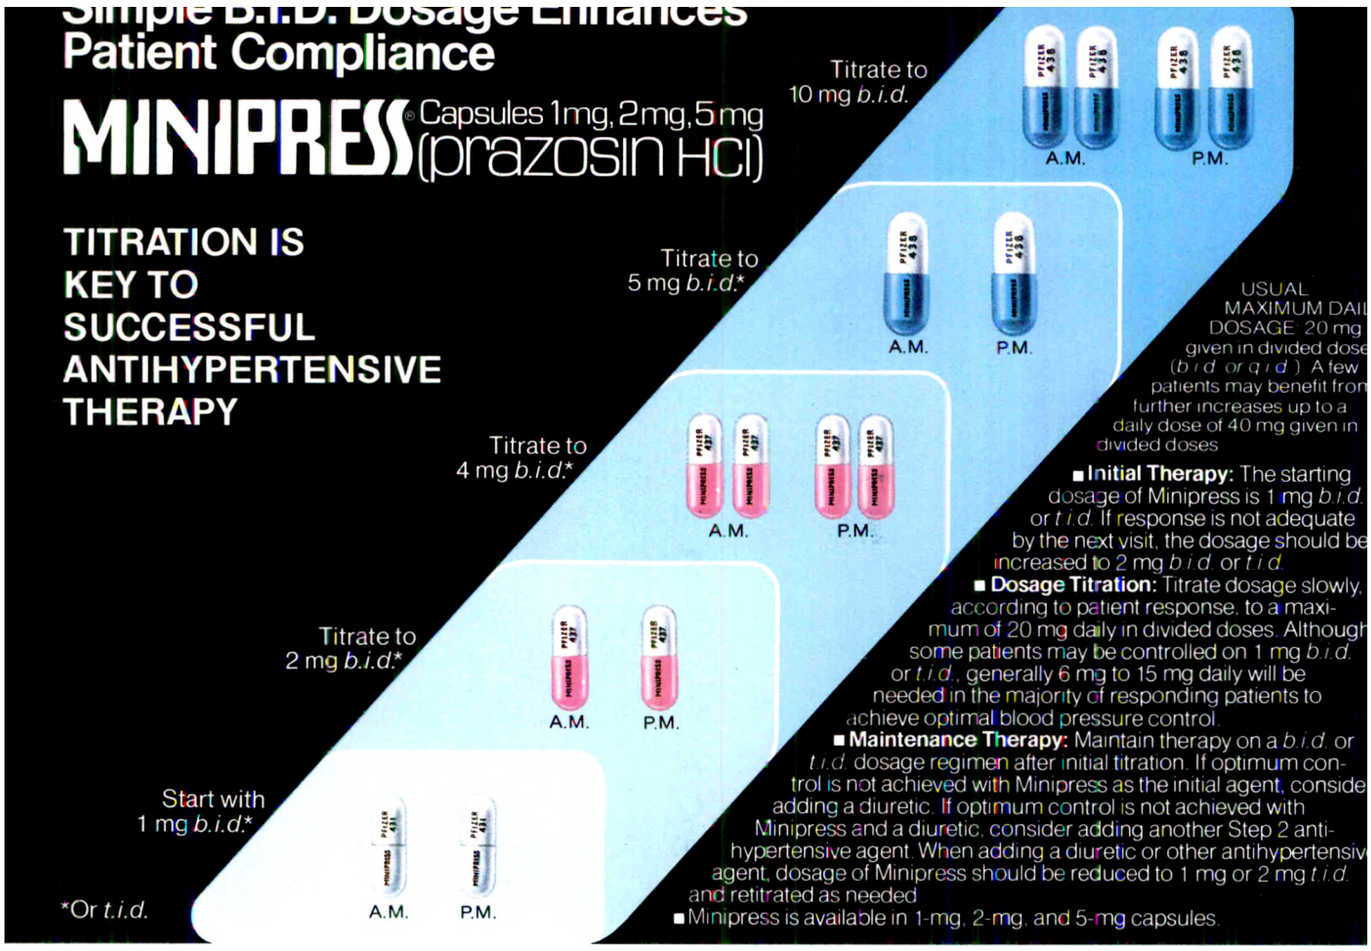
Before prescribing Minipress, WARNINGS
and DOSAGE AND ADMINISTRATION
MINIPRESS® Capsules 1mg, 2mg, 5mg
(prazosin HCl)

Simple B.I.D. Dosage Enhances Patient Compliance

MINIPRESS® Capsules 1mg, 2mg, 5mg (prazosin HCl)

TITRATION IS KEY TO SUCCESSFUL ANTIHYPERTENSIVE THERAPY



*Or *t.i.d.*

USUAL MAXIMUM DAILY DOSAGE: 20 mg given in divided doses (*b.i.d.* or *q.i.d.*). A few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses.

■ **Initial Therapy:** The starting dosage of Minipress is 1 mg *b.i.d.* or *t.i.d.* If response is not adequate by the next visit, the dosage should be increased to 2 mg *b.i.d.* or *t.i.d.*

■ **Dosage Titration:** Titrate dosage slowly, according to patient response, to a maximum of 20 mg daily in divided doses. Although some patients may be controlled on 1 mg *b.i.d.* or *t.i.d.*, generally 6 mg to 15 mg daily will be needed in the majority of responding patients to achieve optimal blood pressure control.

■ **Maintenance Therapy:** Maintain therapy on a *b.i.d.* or *t.i.d.* dosage regimen after initial titration. If optimum control is not achieved with Minipress as the initial agent, consider adding a diuretic. If optimum control is not achieved with Minipress and a diuretic, consider adding another Step 2 antihypertensive agent. When adding a diuretic or other antihypertensive agent, dosage of Minipress should be reduced to 1 mg or 2 mg *t.i.d.* and retitrated as needed.

■ Minipress is available in 1-mg, 2-mg, and 5-mg capsules.

BRIEF SUMMARY

MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*

INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3% and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established).

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus.

Genitourinary: urinary frequency, incontinence, impotence.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings).

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy, however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

Pfizer **LABORATORIES DIVISION**
PFIZER INC.

For The Cardiologist Who Wants The Ultimate In Ultrasound Controls.

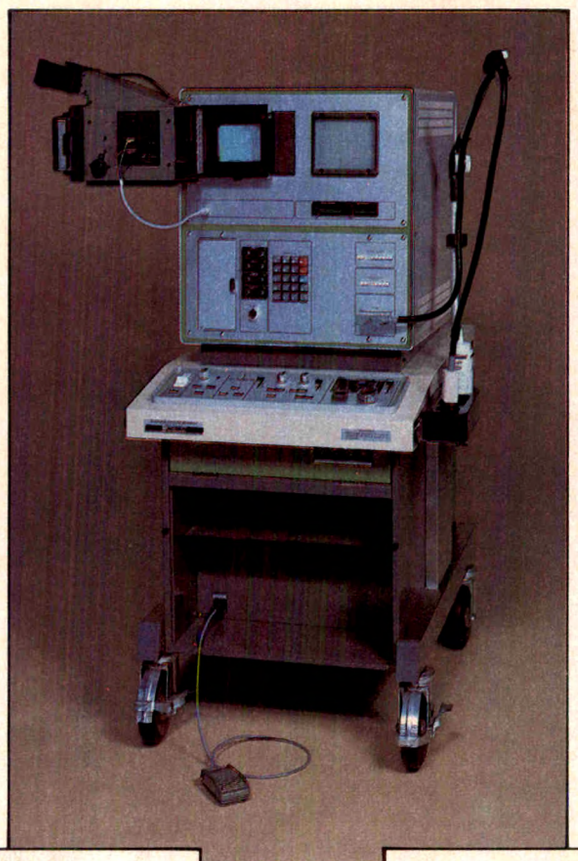
Toshiba's high speed SSH-10A ultrasound electronic sector scanner produces an ultra fine diagnostic image.

Over 16 different parameters can be modified by the cardiologist to maximize image quality in relation to specific patient characteristics.

Valve movement, chamber size and details of the internal structure of the heart can all be clearly observed, measured and diagnosed. Wide range sector angle is a full 78°.

A clear real time, cross sectional B mode image of the heart structure is obtained by simply positioning the probe on the chest wall.

Displayed on the C.R.T. with the B mode image are nonfade ECG and patient I.D. Two angles of the M mode image can also be displayed simultaneously on a second C.R.T. and/or a strip recorder.



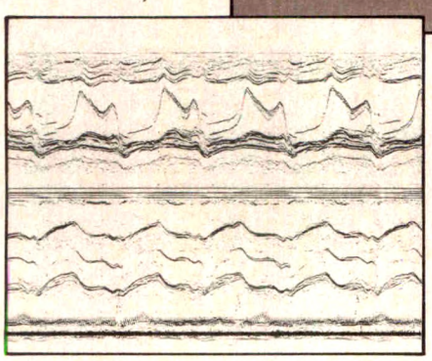
Two UCG traces, M mode tracing and Kymograph studies are additional capabilities.

In short, the SSH-10A gives you the maximum ultrasound information from one mobile unit. So get full information on it now. Contact your local Toshiba representative.

Toshiba Medical Systems,
1154 Dominguez,
Carson, CA 90745

SSH-10A Features:

- Complete Mobility
- Superior Resolution of Electronic Sector Scanning
- Dual M Mode
- 4 Channels of Physiological Monitoring
- Real Time B Mode Cross Sectional Image with ECG and Patient I.D.
- Flexibility for All General Pediatric and Adult Applications



Left: Dual channel M mode showing simultaneously aorta and mitral function.

Right: Long axis left heart.

HEART...

INDERAL®
(PROPRANOLOL HCl)
BETTER SOONER THAN LATER

ALONE Excessive exertions. Emotional upheavals. Anxieties. Stress. Catecholamines rise—atrial pacemakers overrespond. And the ECG reads PAT. Or persistent sinus tachycardia. Or persistent atrial extrasystoles. Consider INDERAL (propranolol HCl) alone. When conventional measures fail, a low 10 to 30 mg dose, given t.i.d. or q.i.d., will block cardiac beta-receptors from excessive catecholamine stimulation. Suppress ectopic pacemakers. And permit resumption of normal sinus rhythm. Even when normal sinus rhythm has not been restored, INDERAL slows conduction in the AV node and prolongs its refractory time. Slowed AV conduction will often block reentry circuits, to help restore sinus rhythm.

WITH The ECG reads atrial flutter. Or atrial fibrillation. You have digitalized your patient, but the arrhythmia is not yet controlled. Consider adding INDERAL (propranolol HCl). Combined with digitalis, it obviates increasing digitalis dosage to toxic levels—while slowing the ventricular rate sufficiently to achieve control. INDERAL also complements the action of other agents. Combined with quinidine, it allows lower doses of quinidine—reducing the need for toxic levels. And often, with INDERAL added, atrial arrhythmias respond when no single agent works alone.

INSTEAD The arrhythmia is induced by an antiarrhythmic drug such as digitalis or quinidine. Persists after discontinuance of the drug and correction of electrolyte imbalance. Consider INDERAL instead. Often the drug of choice, except in the presence of serious congestive heart failure. Often, too, INDERAL (propranolol HCl) abolishes supraventricular arrhythmias when either digitalis or quinidine has failed.

With proper patient selection—in the absence of contraindications such as bradycardia, greater than first degree heart block, asthma, and congestive heart failure unless failure is secondary to tachyarrhythmias treatable with INDERAL—serious cardiovascular and respiratory side effects are seldom encountered.* Rely on it: INDERAL. Alone. With. Or Instead.

*Please turn the page for brief summary of prescribing information on contraindications, adverse reactions, and warnings, including avoidance of abrupt withdrawal.

A PRIME CONSIDERATION FOR SUPRAVENTRICULAR ARRHYTHMIAS

INDERAL®
(PROPRANOLOL HCl)
10mg and 20mg tablets

Ayerst

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR)
Inderal® BRAND OF propranolol hydrochloride **A beta-adrenergic blocking agent**

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

ACTIONS: INDERAL is a beta-adrenergic receptor blocking drug, possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available beta receptor sites. When access to beta receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

Propranolol is almost completely absorbed from the gastrointestinal tract, but a portion is immediately bound by the liver. Peak effect occurs in one to one and one-half hours. The biologic half-life is approximately two to three hours. Propranolol is not significantly dialyzable. There is no simple correlation between dose or plasma level and therapeutic effect, and the dose-sensitivity range as observed in clinical practice is wide. The principal reason for this is that sympathetic tone varies widely between individuals. Since there is no reliable test to estimate sympathetic tone or to determine whether total beta blockade has been achieved, proper dosage requires titration.

Beta receptor blockade is useful in conditions in which, because of pathologic or functional changes, sympathetic activity is excessive or inappropriate and detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

The proper objective of beta blockade therapy is to decrease adverse sympathetic stimulation but not to the degree that may impair necessary sympathetic support.

Propranolol exerts its antiarrhythmic effects in concentrations associated with beta-adrenergic blockade and this appears to be its principal antiarrhythmic mechanism of action. The membrane effect also plays a role, particularly, some authorities believe, in digitalis-induced arrhythmias.

Beta-adrenergic blockade is of unique importance in the management of arrhythmias due to increased levels of circulating catecholamines or enhanced sensitivity of the heart to catecholamines (arrhythmias associated with pheochromocytoma, thyrotoxicosis, exercise).

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential and depresses cardiac function.

Propranolol may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta-adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to decreased oxygen requirement.

INDICATIONS: Cardiac Arrhythmias: *1.) Supraventricular arrhythmias.* a) Paroxysmal atrial tachycardias, particularly those arrhythmias induced by catecholamines or digitalis or associated with the Wolff-Parkinson-White syndrome. (See W-P-W under WARNINGS.) b) Persistent sinus tachycardia which is noncompensatory and impairs the well-being of the patient. c) Tachycardias and arrhythmias due to thyrotoxicosis when causing distress or increased hazard and when immediate effect is necessary as adjunctive, short term (2-4 weeks) therapy. May be used with, but not in place of, specific therapy. (See Thyrotoxicosis under WARNINGS.) d) Persistent atrial extrasystoles which impair the well-being of the patient and do not respond to conventional measures. e) Atrial flutter and fibrillation when ventricular rate cannot be controlled by digitalis alone, or when digitalis is contraindicated.

2.) Ventricular tachycardias. Ventricular arrhythmias do not respond to propranolol as predictably as do the supraventricular arrhythmias. a) Ventricular tachycardias: With the exception of those induced by catecholamines or digitalis, INDERAL is not the drug of first choice. In critical situations when cardioversion technics or other drugs are not indicated or are not effective, INDERAL may be considered. If, after consideration of the risks involved, INDERAL is used, it should be given intravenously in low dosage and very slowly. (See DOSAGE AND ADMINISTRATION.) *Care in the administration of* INDERAL *with constant electrocardiographic monitoring is essential as the failing heart requires some sympathetic drive for maintenance of myocardial tone.* b) Persistent premature ventricular extrasystoles which do not respond to conventional measures and impair the well-being of the patient.

3.) Tachyarrhythmias of digitalis intoxication. If digitalis-induced tachyarrhythmias persist following discontinuance of digitalis and correction of electrolyte abnormalities, they are usually reversible with *oral* INDERAL. Severe bradycardia may occur. (See OVERDOSAGE OR EXAGGERATED RESPONSE.)

Intravenous propranolol hydrochloride is reserved for life-threatening arrhythmias. Temporary maintenance with oral therapy may be indicated. (See DOSAGE AND ADMINISTRATION.)

4.) Resistant tachyarrhythmias due to excessive catecholamine action during anesthesia. Tachyarrhythmias due to excessive catecholamine action during anesthesia may sometimes arise because of release of endogenous catecholamines or administration of catecholamines. When usual measures fail in such arrhythmias, INDERAL may be given intravenously to abolish them. All general inhalation anesthetics produce some degree of myocardial depression. Therefore, when INDERAL is used to treat arrhythmias during anesthesia, it should be used with extreme caution and constant ECG and central venous pressure monitoring. (See WARNINGS.)

Hypertrophic Subaortic Stenosis: INDERAL is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL also improves exercise performance. The effectiveness of INDERAL in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta receptor stimulation. Clinical improvement may be temporary.

Pheochromocytoma: After primary treatment with an alpha-adrenergic blocking agent has been instituted, INDERAL may be useful as *adjunctive* therapy if the control of tachycardia becomes necessary before or during surgery.

It is hazardous to use INDERAL unless alpha-adrenergic blocking drugs are already in use, since this would predispose to serious blood pressure elevation. Blocking only the peripheral dilator (beta) action of epinephrine leaves its constrictor (alpha) action unopposed.

In the event of hemorrhage or shock, there is a disadvantage in having both beta and alpha blockade since the combination prevents the increase in heart rate and peripheral vasoconstriction needed to maintain blood pressure.

With inoperable or metastatic pheochromocytoma, INDERAL may be useful as an adjunct to the management of symptoms due to excessive beta receptor stimulation.

CONTRAINDICATIONS: INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS: CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (i.e., that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by INDERAL's negative inotropic effect. The effects of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely. a) If cardiac failure continues, despite adequate digitalization and diuretic therapy, INDERAL therapy should be immediately withdrawn. b) If tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.*, isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to keep in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. Embryotoxic effects have been seen in animal studies at doses about 10 times the maximum recommended human dose.

PRECAUTIONS: Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS: *Cardiovascular:* bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura.

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Miscellaneous: reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been conclusively associated with propranolol.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DOSAGE AND ADMINISTRATION: The dosage range for INDERAL is different for each indication.

ORAL

ARRHYTHMIAS—10-30 mg three or four times daily, before meals and at bedtime.

HYPERTROPHIC SUBAORTIC STENOSIS—20-40 mg three or four times daily, before meals and at bedtime.

PHEOCHROMOCYTOMA—*Preoperatively*—60 mg daily in divided doses for three days prior to surgery, concomitantly with an alpha-adrenergic blocking agent.—*Management of inoperable tumor*—30 mg daily in divided doses.

PEDIATRIC DOSAGE: At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

INTRAVENOUS: Intravenous administration is reserved for life-threatening arrhythmias or those occurring under anesthesia. The usual dose is from 1 to 3 mg administered under careful monitoring, *e.g.* electrocardiographic, central venous pressure. The rate of administration should not exceed 1 mg (1 ml) per minute to diminish the possibility of lowering blood pressure and causing cardiac standstill. Sufficient time should be allowed for the drug to reach the site of action even when a slow circulation is present. If necessary, a second dose may be given after two minutes. Thereafter, additional drug should not be given in less than four hours. Addition of INDERAL should not be given when the desired alteration in rate and/or rhythm is achieved.

Transference to oral therapy should be made as soon as possible.

The intravenous administration of INDERAL has not been evaluated adequately in the management of hypertensive emergencies.

OVERDOSAGE OR EXAGGERATED RESPONSE: IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg). IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY.

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS.

HYPOTENSION—VASOPRESSORS, *e.g.* LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE.)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE.

HOW SUPPLIED: INDERAL (propranolol hycrochloride)

TABLETS: *No. 461*—Each scored tablet contains 10 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100. *No. 462*—Each scored tablet contains 20 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100. *No. 464*—Each scored tablet contains 40 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100. *No. 468*—Each scored tablet contains 80 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

INJECTABLE: *No. 3255*—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 ml ampuls in boxes of 10.

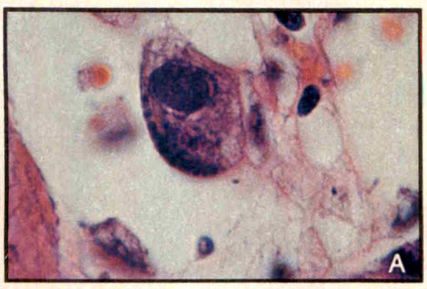
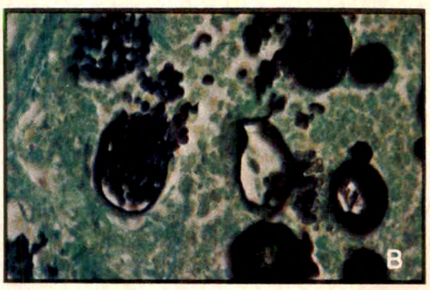
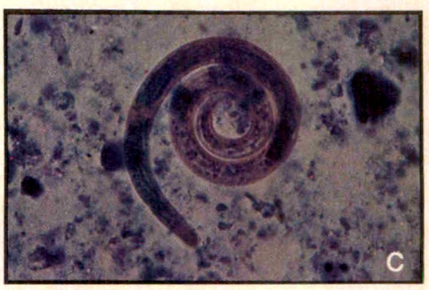
Paintings by Jackson Pollock?







Good guess for a layman. But *to you* these are the enemy. They are Cytomegalovirus gastritis (A) Disseminated coccidioidomycosis (B) and Strongyloides stercoralis filariform larva (C) . . . infections which demand special care when they strike patients with pre-existing illnesses and deficiencies. They are among the many discussed in . . .

INFECTIONS
IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color

Now at your fingertips . . . for instant reference . . . for rewarding study . . . the knowledge of world-renowned specialists to help you understand, diagnose, and manage infections which attack patients under treatment for

- Diabetes
- Alcoholism
- Cancer
- Drug Addiction
- Rheumatic Disease
- Uremia
- Pulmonary Disease
- Hepatic Insufficiency
- Allograft Transplantation, etc., etc.

Infections in the Abnormal Host brings together in one giant encyclopedic volume, over 1,000 pages, the guidance of a specialist team whose collaboration began in the 1960s. In 39 revealing chapters they review the mechanics of host defenses . . . the various underlying disorders and the infections associated with them . . . and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

A detailed indexing system gives you instant access to every diagnostic procedure, every treatment in the book. Study the entire book and you will gain priceless knowledge of an important and complex field. Consult it as the need arises, and it will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

MICROTHIN-D1
MODEL 0520
UNIPOLAR
NEG
MICROTHIN-D1
MODEL 0620
BIPOLAR
MICROTHIN-P1
MODEL 0622
BIPOLAR

We're proud to introduce MICROTHIN™-1 to you as the first phase in our pacing program for the future.

MICROTHIN-1 affords you traditional CPI® reliability plus important patient benefits, including:

- Slim 11 mm Profile
- Light Weight
- Predictable, Precise Replacement Indicator
- Improved Defibrillation Protection

MICROTHIN-D1 gives you the best features available in ventricular demand pacing . . . unexcelled reliability after seven years of lithium pacing experience, plus carefully engineered product refinements developed through CPI's dedication to pacing perfection.

Available in Models 0520 Unipolar and 0620 Bipolar.

MICROTHIN-P1 is the programmable ventricular demand pacemaker that sets the standard for easy programming and follow-up.

EASY TO PROGRAM. It's a challenge to design a programming system that's easy to use. But CPI turns challenge into precedent-setting products and thus MICROTHIN-P1 is unequalled in programming ease. A programming sequence is completed in just 2.5 seconds.

EASY TO FOLLOW-UP. We've simplified your follow-up routine by taking the inaccuracy out of the replacement indicator. You don't need to trust calculations based on last programmed rate, length of implant, or output voltage. For all your patients, simply replace MICROTHIN-P1 at a magnet rate of 85 ppm.

PATIENT-ORIENTED OPTIONS. MICROTHIN-P1 provides 90 rates between 30 and 119. . .20 output choices from low diagnostic to high output. . .so your care for each patient can be individualized.

Available in Models 0522 Unipolar and 0622 Bipolar.

There's more to come! Contact your sales representative for details. And keep in contact — the future with MICROTHIN has just begun.

CLINICAL STUDIES

Detection of Coronary Artery Disease: Comparison of Exercise Stress Radionuclide Angiocardiography and Thallium Stress Perfusion Scanning

JAMES A. JENGO, MD, FACC
RONALD FREEMAN, MD
MARIANNE BRIZENDINE, RN
ISMAEL MENA, MD

Torrance and Long Beach, California

Exercise thallium scanning and stress radionuclide angiography were compared in 16 normal subjects and 42 patients with more than 75 percent coronary arterial obstruction in studies using upright exercise on a bicycle ergometer. Studies at rest were subsequently obtained. Exercise thallium scans in the control group were normal in 15 and showed a defect in 1; ejection fraction increased in all 16 (from 0.61 ± 0.03 to 0.80 ± 0.03; $p < 0.0005$). During exercise, regional wall motion increased uniformly. In the group with coronary artery disease, thallium scanning revealed a new defect in the distribution of the involved arteries in 24 patients (57 percent). In 15 who had a defect at rest, no new defect developed, but in 9 (60 percent) of the 15 new segmental wall motion defects were evident on radionuclide angiography. With exercise, ejection fraction decreased slightly (from 0.52 ± 0.04 to 0.45 ± 0.03; $p < 0.005$). Regional wall motion abnormalities developed in the areas corresponding to thallium defects in all. Thallium scanning had a 93 percent and radionuclide angiography a 98 percent sensitivity value in detecting coronary artery disease; the respective specificity values were 94 and 100 percent (not statistically significant; $p < 0.02$). In patients with prior myocardial infarction who manifested new exercise abnormalities, 50 percent showed new thallium defects and 81 percent new wall motion defects.

Thus, both exercise thallium scanning and radionuclide angiography are useful in detecting coronary artery disease. The latter study may be more sensitive in detecting new disease in patients with prior myocardial infarction. It also offers previously unobtainable data on left ventricular function and anatomic site of disease.

Assessment of myocardial perfusion using thallium-201 during exercise-induced stress has been shown to be a sensitive and valuable diagnostic aid in the detection of coronary artery disease.[1–4] However, even when this procedure is coupled with continuous electrocardiographic monitoring up to 11 percent of patients with angiographically significant coronary artery disease are not detected.[1] In fact, in some patients with double or triple vessel disease uniformly diminished perfusion throughout the myocardium is frequently undetected because of the lack

of a normal reference for comparison.[2,3] In addition, thallium perfusion scans give no information on the physiologic significance of demonstrated hypoperfusion.

Recently, the technique of intravenous radionuclide angiocardiography has been used to evaluate the effects of exercise stress on global and regional left ventricular function.[5–9] Patients without angiographically significant coronary artery disease uniformly have an increased ejection fraction and demonstrate increased segmental wall motion during exercise stress. However, patients with significant coronary arterial obstruction manifest segmental wall motion abnormalities during exercise stress and demonstrate either a decrease or a lack of increase in left ventricular ejection fraction.[6]

In this study we compared the sensitivity and specificity of thallium-201 stress testing and first pass radionuclide stress angiography in detecting coronary artery disease (1) in patients without prior myocardial infarction, and (2) in patients with prior myocardial infarction who might have disease in areas other than the original infarct site.

Methods

Patient selection: All patients were referred for coronary arteriography because of chest pain refractory to conventional antianginal therapy. All coronary arteriograms were performed within 6 months of the radionuclide procedures. No change in the patients' clinical status occurred between studies.

The patients were classified into two groups on the basis of angiographic evidence of coronary artery disease. Group 1, the control group, comprised 16 patients (10 male) with an average age of 41 years (range 28 to 64). None of these patients had greater than 50 percent obstruction of any coronary artery. Group 2 consisted of 42 randomly selected patients (33 male) with an average age of 57 years (range 45 to 68). Each of these patients had at least 75 percent obstruction of at least one coronary artery. Twenty-one of the patients had electrocardiographic and documented enzyme evidence of a prior myocardial infarction.

Exercise protocol: Before the start of exercise a no. 20 gauge Jelco polyethylene catheter was placed into an antecubital vein and connected to a slow infusion of a solution of 5 percent dextrose in water. Standard electrocardiographic electrodes were then attached so that the six limb leads could be recorded before and during each stage of the exercise protocol.

Exercise was performed using a bicycle ergometer with the patient seated in the upright position. The starting work load was 75 kilopond-meters (kpm) and was increased at 1 minute intervals in increments of 75 kpm. Blood pressure, heart rate and an electrocardiogram were recorded just before the work load was increased at each level. The end point was the attainment of (1) maximal predicted heart rate, (2) flat S-T segment depression of at least 2 mm, (3) frequent ventricular ectopic activity, or (4) severe chest pain or fatigue causing the patient to refuse further exercise. At this point, 1.5 mCi of thallium-201 was injected intravenously and exercise continued for 1 more minute. Within 10 minutes after the cessation of exercise, imaging was begun and 300,000 count images were obtained in the anterior, left anterior oblique and left lateral projections. A flexible lead shield with an opening 10 cm in diameter was used to mask out extracardiac activity. If a defect was noted in any of the exercise thallium images, the patient was scheduled to return in 4 to 7 days for a second study at rest.

Radionuclide angiography: The subjects exercised again to the same work load 1 hour after the thallium exercise study. To perform studies at the time of maximal upright stress required overcoming the problem of patient motion relative to the scintillation camera detector. To accomplish this the exercise was performed with the subject facing the camera detector in the 30° right anterior oblique projection while seated on the bicycle ergometer. A foam rubber wedge attached to the high resolution collimator was used to maintain this projection. The subject was then held to the detector and the wedge by a strap placed around his back and connected at its ends to the camera's detector. In addition, the subject's arms grasped the detector gantry. The mobile camera detector gantry had a small amount of free movement so that it moved with the patient while he pedaled the bicycle. In this way the patient remained motionless relative to the detector because his motion was transferred to the camera gantry itself.

At the time of the subject's maximal stress, a 20 second list mode acquisition was made either onto magnetic tape or directly onto the disk of a minicomputer during the injection of a 15 mCi bolus dose of technetium-99m DTPA into an an-

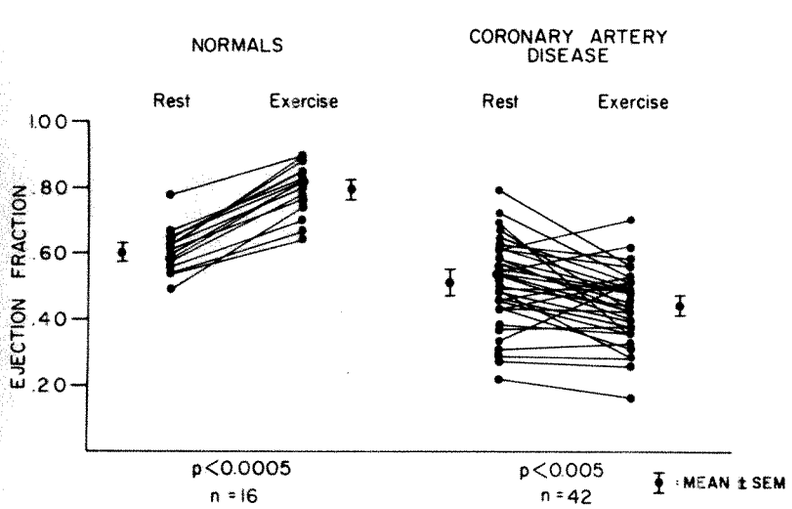

FIGURE 1. Changes in ejection fraction from rest to exercise in the 16 normal subjects (**left**) and the group of 42 patients with coronary artery disease (**right**). SEM = standard error of the mean.

tecubital vein. The exercise was continued while the acquisition was completed. An upright first pass radionuclide angiocardiogram was obtained at rest 4 hours later using 20 mCi of technetium-99m pertechnetate.

At the time of study all patients were in the fasting state and were continuing to take all prescribed medications. No study was performed within 4 hours of the last dose of nitrates.

Data processing: The list mode data were recorded either on the camera's high speed (75 inches/s [190.5 cm]) magnetic tape drive or directly onto the disk of a minicomputer system (Informatek Simis 3) for calculation of ejection fraction and determination of segmental wall motion as described previously.[6] The outlines of the end-diastolic and end-systolic images were obtained and superimposed on a color video display. For evaluation of regional wall motion, the left ventricular outline was divided into four segments: anterobasal, anteroapical, inferoapical and posterobasal. Each segment was assessed by three different observers and judged to be either dyskinetic, akinetic, hypokinetic, normal or hyperkinetic. All studies were interpreted without knowledge of the results of angiograms, and vice versa. In addition, the edge outlines of the 16 sequential frames composing one composite cardiac cycle were repetitively and sequentially displayed on the color television monitor; the end-diastolic outline was continuously present to serve as a reference. This dynamic display of the "beating edge" of the ventricle with the diastolic edge as reference enabled the observer to visualize the dynamic sequence of cardiac contraction.

Statistical analysis: Sensitivity was defined as True positive studies/True positive plus False negative studies. Specificity was defined as True negative studies/False positive plus True negative studies. Comparisons of two studies in individual patients were made using the paired Student's *t* test. The sensitivity and specificity of the two techniques was compared using the McNemar test.

Results

Control Group

Thallium studies: All 16 patients with normal coronary arteriograms had normal resting thallium perfusion scans. Fifteen of the 16 patients also had normal exercise perfusion studies; 1 had a defect associated with exercise.

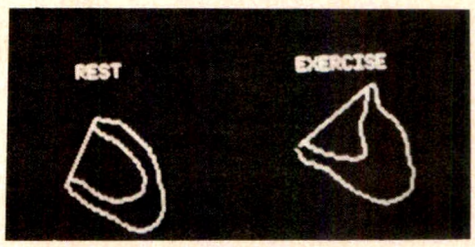

FIGURE 2. Superimposition of the diastolic and systolic outlines of the left ventricle in the right anterior oblique projection during rest (**left**) and during exercise (**right**) in a control subject. Note the uniform improvement in wall motion during exercise.

Ejection fraction and segmental wall motion: The ejection fraction (Fig. 1) uniformly increased from rest to exercise: 0.61 ± 0.03 to 0.80 ± 0.03 (mean ± standard error of the mean) ($p < 0.0005$). All patients had an increase of at least 0.10 in ejection fraction during exercise. Segmental wall motion evaluated over the two anterior and two inferoposterior segments was normal at rest in 15 of the 16 patients, but was uniformly increased during exercise in all 16 patients (Fig. 2). Fifteen of the 16 patients had a negative electrocardiographic response to exercise stress (Table I).

Group With Coronary Artery Disease

Thallium studies: Among the 42 patients with angiographically significant coronary artery disease, the thallium perfusion study at rest was normal in 20 and showed some defect in the remaining 22 patients. A new perfusion defect developed during exercise in 24 (57 percent) of the 42 patients. Eighteen (86 percent) of the 21 patients with prior myocardial infarction had a perfusion defect at rest. In five (28 percent) of these patients a new defect developed during stress. A perfusion defect was either present at rest or developed

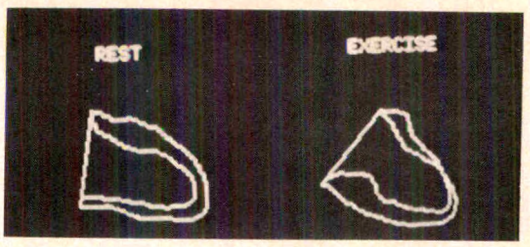

FIGURE 4. Superimposition of the diastolic and systolic outlines of the left ventricle in a patient with coronary artery disease whose ejection fraction increased during exercise. Note the development of regional anterior wall hypokinesia during exercise, but with associated hyperkinesia of the inferobasal wall of the ventricle.

during stress in 39 patients (93 percent). Thus, the overall sensitivity of the thallium study in the detection of coronary artery disease was 93 percent and specificity was 94 percent. In two patients (5 percent) no perfusion defect was present either at rest or during exercise. In the subgroup of 16 patients with prior myocardial infarction who manifested a second perfusion or wall motion defect with exercise, only 8 patients (50 percent) manifested the new defect in the thallium perfusion study during stress.

Ejection fraction and segmental wall motion: The ejection fraction (Fig. 1) decreased in response to exercise stress (from 0.52 ± 0.04 to 0.45 ± 0.03; $p < 0.005$). These data include the values from six patients (14 percent) whose ejection fraction increased. In five of the six patients whose ejection fraction increased, segmental wall motion defects developed in the distribution of the stenosed coronary artery; however, hyperkinesia developed in the other regions (see Fig. 4). In the sixth patient, no segmental wall motion (or thallium) defects developed.

Sixteen of the 42 patients had no segmental wall motion defect at rest, but 40 patients (95 percent) (Fig. 3 and 4) either manifested a new wall motion defect (28 of 42 [67 percent]) or showed no improvement in a preexisting defect in the distribution of the diseased coronary artery or arteries during exercise (consistent with an area of prior infarction) (12 patients).

All 21 patients with a documented prior myocardial infarction had segmental wall motion abnormalities at rest. Of these patients, 13 (62 percent) manifested new wall motion defects during exercise stress corresponding to areas supplied by one or more additional significantly stenosed coronary arteries. Two patients (5 percent) showed no wall motion abnormality (or thallium defect), but their exercise tests had to be stopped early because of symptoms of leg claudication. A wall motion defect at rest or during stress, or both, or a lack of change or decrease in stress ejection fraction was present in 41 patients (98 percent). In the remaining patient the ejection fraction increased by only 6 percent. Thus, the overall sensitivity for the detection of coronary artery disease was 98 percent with a 100 percent specificity. Among the patients with prior myocardial infarction who had a second perfusion or wall motion defect with exercise, 13 (81 percent) demonstrated the new defect as a segmental wall motion defect during stress.

The electrocardiographic stress test was positive in 34 patients (81 percent) and negative in the remaining 8 (Table II).

Comparison of sensitivity and specificity: Thallium scanning had a 50 percent and radionuclide angiography an 81 percent sensitivity in detecting significant additional coronary arterial lesions in the presence of prior myocardial infarction. This difference was only significant to the 0.2 level. The specificity of the methods was 94 and 100 percent, respectively.

Discussion

The significance of coronary arterial obstruction depends on whether the relation between myocardial oxygen supply and demand results in impairment of myocardial function. There are many reports[10,11] of patients with relatively severe coronary artery disease without symptoms of angina. It has also been shown[11] that the severity and frequency of anginal episodes do not correlate with degree of coronary obstruction.

Potential limitations of thallium perfusion study: During exercise stress, coronary arterial blood flow normally increases. When an obstructed coronary artery prevents this normal increase, the relative difference in flow occurs in the distribution of this artery in relation to that of neighboring coronary arteries that are able to transport the increased flow and results in the difference in perfusion imaged with this technique. However, because thallium perfusion imaging enables assessment of coronary perfusion only in reference to the areas with better perfusion, it may not detect perfusion defects in patients who have diffuse coronary artery disease. These patients may have a uniform homogenous distribution of thallium uptake because blood flow is uniformly and globally decreased; thus the thallium study may find no relative difference in uptake, and yield a false negative result.[2,3] In addition, the timing of imaging after the thallium injection is crucial because redistribution of the agent is detectable as early as 10 minutes[12] after the cessation of exercise.

The thallium method also cannot be used to quantitate a change in perfusion in an area already displaying a perfusion defect at rest. This was exemplified in our study by the 15 patients (36 percent) of the 42 patients with coronary artery disease who had no new defect in perfusion during exercise stress. However, 9 (60 percent)

of these 15 patients did manifest a new segmental wall motion defect during exercise stress.

Radionuclide angiography to study segmental wall motion: Abnormalities in left ventricular segmental wall motion are sensitive indicators of regional ischemia secondary to stenoses of the coronary arteries supplying those areas.[13–19] When myocardial oxygen demand is increased by exercise stress, regional abnormalities in left ventricular function become manifest in those patients with true ischemic heart disease.[5,20]

The technique of first pass radionuclide angiocardiography has been found to be an accurate and reproducible method of quantitatively evaluating both global left ventricular function[21] and segmental wall motion.[22] Left ventricular function improves both regionally and globally during maximal exercise stress in normal subjects and patients without significant coronary arterial obstruction. However, in patients with angiographically significant coronary artery disease, both regional and global abnormalities in left ventricular function became apparent during exercise stress.

In six patients with significant coronary artery disease global ejection fraction increased during exercise stress. In five of these patients regional contractility improved in areas supplied by nonsignificantly stenosed coronary arteries (Fig. 4), thus offsetting the effects of the decrease in contractility of the ischemic areas. In the sixth patient, exercise was stopped because of leg claudication before the predicted maximal heart rate could be achieved.

Radionuclide angiography versus thallium perfusion scanning: Of the 15 patients whose thallium perfusion defect at rest was unchanged during exercise, 9 had no new segmental wall motion defects. In all patients with significant coronary artery disease who exercised to their previously defined end point, either a

new wall motion defect developed or segmental wall motion did not improve during exercise stress. These segmental wall motion defects corresponded to the areas of myocardium supplied by the stenosed coronary arteries, thus confirming the importance of evaluating regional as well as global left ventricular function during exercise stress.

Of patients with prior myocardial infarctions 86 percent had a thallium defect at rest, but all had wall motion abnormalities at rest. Of the 16 patients with prior myocardial infarction who manifested a second defect during exercise, the defect was demonstrated as a new perfusion defect in only 8 (sensitivity 50 percent) but appeared as a wall motion abnormality in 13 (sensitivity 81 percent). Although these data suggest that radionuclide stress angiography is more sensitive in detecting additional coronary artery disease in patients with prior myocardial infarction, the differences in sensitivity were not statistically significant ($p < 0.2$).

Comparison with electrocardiographic stress testing: Only 34 (81 percent) of the 42 patients with coronary artery disease manifested significant S-T segment depression during the exercise stress, whereas 93 percent manifested thallium defects and 98 percent demonstrated abnormalities in segmental wall motion. Electrocardiographic stress testing is a valuable tool, but has a relatively large incidence of false positive results when applied as a screening procedure[23–25] in an asymptomatic population. Thus, the physician must ask: Should an asymptomatic patient with abnormal treadmill test results be subjected to coronary arteriography with its attendant risks and costs or be left to wonder whether he has a high risk of having a heart attack? The noninvasive procedures described here with their high sensitivity (93 percent for thallium, 97 percent for radionuclide angiography) and specificity (94 and 100 percent, respectively) may be helpful in clarifying this complex problem.

Implications: Our results are in agreement with data from prior studies indicating the sensitivity of both thallium perfusion stress testing and radionuclide angiographic stress testing in detecting the presence of coronary artery disease. In patients with a preexisting infarction both thallium and radionuclide angiography are useful in detecting additional coronary artery disease and may serve complementary roles. However, radionuclide angiography may be a more sensitive and specific indicator of both the presence and the location of significant associated coronary artery disease. In addition, thallium stress testing offers no information on left ventricular function and only indirect evidence of the nature of coronary obstructive disease.

Left Ventricular Ejection Fraction Determined by Radionuclide Ventriculography in Early Stages of First Transmural Myocardial Infarction

Relation to Short-Term Prognosis

Los Angeles, California

Left ventricular ejection fraction was determined with multiple gated equilibrium cardiac blood pool scintigraphy within 24 hours of the onset of symptoms of a first acute transmural myocardial infarction in 56 patients (23 with anterior and 33 with inferior infarction). A depressed ejection fraction (less than 0.54) was more frequent in patients with anterior (96 percent) than in those with inferior (61 percent) infarction ($p < 0.001$); the mean ejection fraction was lower in patients with anterior (0.34 ± 0.09 standard deviation) than in those with inferior (0.50 ± 0.14) infarction ($p < 0.001$). Of the 33 patients with inferior infarction, 19 had concomitant S-T segment depression in the precordial leads; the mean ejection fraction was lower in this subgroup than in the remaining 14 without such S-T depression (0.41 ± 0.11 versus 0.61 ± 0.08, $p < 0.05$). During the subsequent hospital course, one or more complications (congestive failure, hypotension, shock, postinfarction angina, death) developed in 27 patients. The mean ejection fraction was lower in this group (0.34 ± 0.10) than in the remaining 29 patients whose hospital course was uncomplicated (0.52 ± 0.13) ($p < 0.001$). Seven patients (12 percent) died (six from pump failure and one from ventricular arrhythmias) 2 to 14 days after the onset of infarction. The initial ejection fraction was lower in nonsurvivors (0.27 ± 0.11) than in survivors (0.46 ± 0.13) ($p < 0.001$). Death due to pump failure occurred in 6 of 11 patients (55 percent) with an ejection fraction of 0.30 or less; in contrast, only 1 of the 45 patients with a higher ejection fraction died in the hospital ($p < 0.001$).

The overall data thus indicate that left ventricular ejection fraction is significantly reduced in acute anterior myocardial infarction but not in inferior infarction except in patients with associated precordial S-T segment depression. An ejection fraction of 0.30 or less is of prognostic value in predicting a high risk of hospital morbidity and mortality from pump failure in patients with a first acute transmural infarction.

A reduction in the overall mortality from acute myocardial infarction in recent years[1] has resulted primarily from the development of coronary care units[2] and resuscitative resources for reversal of out-of-hospital ventricular fibrillation[3] as well as from the prophylactic use of antiarrhythmic drugs.[4] The average mortality rate of hospitalized patients with acute myocardial infarction remains between 10 and 15 percent and is caused almost exclusively by "pump failure" consequent upon the loss of a substantial volume of functioning myocardium.[5] The long-term prognosis of survivors of acute myocardial infarction also appears to be determined essentially by the extent of the potentially viable cardiac muscle responsible for residual ventricular function.[6]

Several studies[7,8] have shown that hemodynamic indexes of ventricular function are the major determinants of mortality and morbidity in

acute infarction, and the subsets of patients with high and low mortality rates may be defined on the basis of early hemodynamic assessment. Although the availability of bedside right heart catheterization with the Swan-Ganz catheter has facilitated hemodynamic evaluation of critically ill patients, hemodynamic variables such as cardiac output and ventricular pressures do not completely characterize the overall alterations in ventricular function.[9]

Recently developed radionuclide techniques have made it possible to assess ventricular function in terms of changes in left ventricular volumes and ejection fraction as well as in segmental wall motion.[10–12] These techniques are noninvasive and may therefore be applied to critically ill patients at the bedside without appreciable extra risk or discomfort. In this study, multiple cardiac blood pool scintigraphy (radionuclide ventriculography[13,14]) was used to determine the ejection fraction as an index of ventricular function in patients in the early stages of a first acute transmural infarction to define the relation between the alterations in ejection fraction and the location of the infarct as well as the prognostic significance of such changes with respect to hospital morbidity and mortality.

Methods

Patients: Fifty-six patients (45 men and 11 women, mean age 61 years) were studied within 4 to 24 hours (mean 15 ± 7 [standard deviation]) of onset of their first acute transmural myocardial infarction. The diagnosis of acute transmural myocardial infarction was based on the presence of all of the following criteria: (1) prolonged chest pain lasting longer than 30 minutes; (b) development of pathologic Q waves (0.04 second in duration) in at least two electrocardiographic leads; (3) characteristic elevations of serum creatine kinase (CK) including its MB isoenzyme fraction, glutamic oxaloacetic transaminase and lactic dehydrogenase. Patients with a history or electrocardiographic evidence, or both, of previous myocardial infarction or significant valve disease were excluded. No patient was receiving digitalis, propranolol, vasodilators or sympathomimetic agents at the time of the scintigraphic study.

The location of the acute infarct was characterized according to established electrocardiographic criteria as anterior (including anteroseptal and anterolateral) or inferior.[15] Patients with inferior infarction were further characterized into two subgroups, namely, those with concomitant precordial lead S-T segment depression (greater than 1 mm in at least two of six precordial leads) and those without S-T depression. None of the patients in the subgroup with precordial S-T segment depression had electrocardiographic evidence of left ventricular hypertrophy or bundle branch block. Twenty-three patients had anterior infarction and 33 had inferior infarction (19 with concomitant precordial S-T segment depression and 14 without). The mean age was not significantly different among the three groups of patients: 58 ± 11 years (range 34 to 77); 65 ± 10 (range 41 to 83); and 61 ± 13 (32–82), respectively.

Measurement of left ventricular ejection fraction: Radionuclide ventriculography in the 45° left anterior oblique and anterior views was performed within 24 hours of the onset of symptoms in all patients after intravenous injection of 20 to 25 mCi of in vitro labeled technetium-99m autologous red blood cells,[13,14] using a mobile gamma camera (Ohio Nuclear 420) equipped with a low energy all purpose collimator and a mobile computer (Medical Data Systems). Two-hundred thousand count images were obtained in each of 14 frames distributed over the initial two thirds of the cardiac cycle. The total imaging time for the two views ranged from 12 to 20 minutes. A background-corrected left ventricular activity-time curve was generated from the counts within each of 14 computer-defined frames in the left anterior oblique view.

Ejection fraction (EF was calculated as follows: EF = (End-diastolic counts − End-systolic counts)/End-diastolic counts.

Validation of radionuclide ventriculography and normal study: The technique of multiple gated equilibrium cardiac blood pool scintigraphy as used in this study and referred to as radionuclide ventriculography has been validated as a highly reproducible and accurate technique for determination of left ventricular ejection fraction.[14] Ejection fraction determined with this technique correlated well (r = 0.93) with ejection fraction determined with contrast cineangiography.[14] On the basis of data obtained in 20 normal subjects, the lower limit of normal left ventricular ejection fraction obtained with this radionuclide technique was 0.54 (range 0.54 to 0.79; mean 0.63 ± 0.08). *A depressed ejection fraction in this study is defined as a value of less than 0.54.*

Statistical analysis: The data are expressed as mean ± standard deviation. The significance of difference in ejection fraction between groups was assessed using one-way analysis of variance and Scheffe's test.[16] Chi-square analysis was used to assess the significance of difference in mortality between the patients with an initial ejection fraction of 0.30 or less and those with a value of 0.30 or higher.

Results

Left ventricular ejection fraction: The alterations in left ventricular ejection fraction in relation to the electrocardiographic location of the infarct in the 56 patients are presented in Figure 1. Ejection fraction was depressed (less than 0.54) in 42 (75 percent) of the 56 patients (mean 0.43 ± 0.15; range 0.17 to 0.74). Of the 23 patients with anterior infarction, 22 (96 percent) had

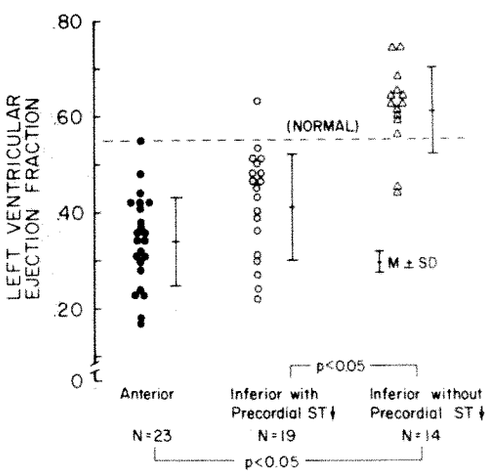

FIGURE 1. Left ventricular ejection fraction within 24 hours of a first acute transmural myocardial infarction in 56 patients in relation to the electrocardiographic location of the infarct. **Closed circles** represent anterior infarction, **open circles** inferior infarction with precordial S-T depression (↓), and **open triangles** represent inferior infarction without precordial S-T depression. The **horizontal dashed line** shows the lower limit of the normal ejection fraction (0.54). M = mean; N = number of patients; p = probability; SD = standard deviation.

a depressed ejection fraction (mean 0.34 ± 0.09; range 0.17 to 0.55). In contrast, the ejection fraction was depressed in 20 (61 percent) of 33 patients with inferior infarction (mean 0.50 ± 0.14; range 0.22 to 0.74). The mean ejection fraction was significantly lower in patients with anterior infarction than in those with inferior infarction ($p < 0.001$).

Of the 33 patients with inferior infarction, ejection fraction was depressed in 18 (95 percent) of 19 patients who had concomitant precordial S-T depression (mean 0.41 ± 0.11; range 0.22 to 0.63) but in only 2 (14 percent) of 14 who did not have precordial S-T depression (mean 0.61 ± 0.08; range 0.44 to 0.74). The difference in mean ejection fractions between the two subgroups of patients with inferior infarction was significant ($p < 0.05$). In 3 of 19 patients with inferior infarction and concomitant precordial S-T depression, electrocardiographic signs of true posterior infarction developed (R/S ratio) 1 or greater in lead V_1 and in V_2 in the absence of right bundle branch block). The mean ejection fraction of these 3 patients (0.39) was not significantly different from that of the remaining 16 patients (0.42). Patients with anterior infarction had a significantly lower ejection fraction than that of the subgroup of patients with inferior infarction without precordial S-T depression ($p < 0.05$).

Hospital course: One or more of the following complications developed in 27 of 56 patients within the first 2 weeks of their hospital course: (1) congestive heart failure (post-tussive rales with a ventricular gallop, sound or radiologic signs of pulmonary venous hypertension, or both); (2) hypotension (systolic pressure less than 90 mm Hg) with or without shock syndrome in association with congestive heart failure; (3) recurrence or continuation of ischemic chest pain after the first 24 hours of onset of myocardial infarction; and (4) death. In anterior myocardial infarction, one or more of these complications developed in 15 of the 23 patients; congestive heart failure in 10, hypotension in 4, recurrent or continual ischemic chest pain in 8 and death in 3. In inferior myocardial infarction, one or more of these complications were found in 12 of the 23 patients, all of whom had precordial S-T depression; congestive heart failure developed in 10, hypotension in 5, recurrent or continual ischemic pain in 9 and death in 4.

The left ventricular ejection fraction was significantly lower in the group with, than in the group without complications (0.34 ± 0.10 versus 0.52 ± 0.13, $p < 0.001$) (Fig. 2). None of the listed complications occurred in patients with a normal ejection fraction (0.54 or greater); however, a depressed ejection fraction (less than 0.54) was found in 15 (51 percent) of 29 patients without clinical complications. Among 11 patients with an initial ejection fraction of 0.30 or less, 6 did not exhibit hypotension, shock, or congestive heart failure at the time of initial evaluation, indicating a low degree of sensitivity of clinical assessment in detecting severely depressed ventricular function.

Ejection fraction and mortality: All 14 patients with a normal ejection fraction survived the initial hospital course. Seven (12.5 percent) of 56 patients died within 2 to 14 days of the onset of acute myocardial infarction. Six of these seven patients died of progressive pump failure in spite of therapy with one or more of the following supportive measures—inotropic agents, vasodilators and intraaortic balloon counter pulsation. The remaining patient died of refractory ventricular arrhythmias. The mean ejection fraction was significantly lower in the 7 nonsurvivors than in the 49 survivors (0.27 ± 0.11 versus 0.46 ± 0.13, $p < 0.001$) (Fig. 3). When the patient who died of ventricular arrhythmias was excluded (ejection fraction 0.50), all remaing six nonsurvivors had an ejection fraction of 0.30 or less. Only 5 (10 percent) of 49 survivors had a similar degree of depression in the ejection fraction. Therefore, death related to pump failure occurred in 6 (55 percent) of 11 patients with an initial ejection fraction of 0.30 or less and in none in 44 patients who had an ejection fraction exceeding 0.30 ($p < 0.001$). In the five survivors with a

severely depressed (0.30 or less) initial ejection fraction, the value increased by 21 and 42 percent, respectively, in two patients during the early hospital course and remained unchanged in two patients. In the fifth patient severe mitral regurgitation developed within 2 weeks of the onset of infarction and mitral valve replacement was required.

Discussion

Ejection fraction in acute myocardial infarction: Our data indicate that left ventricular ejection fraction, when determined in the early stages of a first transmural myocardial infarction, is significantly reduced in patients with anteriorly located infarction. In contrast, it is not reduced in patients with inferior infarction except in the subset whose inferior damage is associated with prominent S-T segment depression in the precordial leads of the electrocardiogram. The ejection fraction, used as an index of ventricular function, was determined by a noninvasive radionuclide technique utilizing multiple gated equilibrium cardiac blood pool scintigraphy, which permits accurate and reproducible measurements.[14] Unlike techniques that utilize area-length methods for computing ejection fraction, the technique we used is not fundamentally dependent on assumptions regarding chamber geometry, an important consideration in view of abnormalities of segmental wall motion often present in patients with acute ischemic heart disease.[17] Additional advantages of the technique include the relatively low cost of the radionuclide tracer used and the easy applicability of the procedure to critically ill patients at the bedside with the availability of mobile equipment.

In our study, only patients with transmural myocardial infarction who had no historic or electrocardiographic evidence of prior myocardial infarction, were included. Thus, the observed alterations in ventricular function could be related to a single discrete episode of acute infarction, as indicated by the electrocardiographic abnormalities. In the 56 patients studied in the very early phases of acute myocardial infarction, the left ventricular ejection fraction was depressed in 42 (75 percent). These results thus confirm and extend the data of other investigators,[18–21] who reported a reduced ventricular ejection fraction in their patients studied at various times after the onset of acute myocardial infarction.

Correlation of ejection fraction and site of infarction and ischemia: Our results, although obtained in a relatively small group patients, demonstrate that the electrocardiographic site of myocardial infarction may bear importantly on the severity and frequency of depression of the ventricular ejection fraction. For example, the ejection fraction was depressed in 22 (96 percent) of 23 patients with anterior myocardial infarction and in only 20 (61 percent) of 33 patients with inferior infarction, a difference also reported by Reduto et al.,[20] who used the first pass radionuclide technique. Other workers[18,19,21] did not analyze their data on depressed ejection fraction in acute infarction with respect to the possible differences in relation to electrocardiographic site of ischemic damage.

In our series, patients with inferior infarction appeared to form two discrete subsets in relation to the presence or absence of concomitant S-T segment depression in precordial leads. Ejection fraction was depressed in 18 (95 percent) of 19 patients in the subgroup precordial S-T segment depression, but in only 2 (14 percent) of 14 patients in the subgroup without associated S-T segment depression. The greater depression of ejection fraction in anterior than in inferior infarction demonstrated in our study is consistent with the known hemodynamic evidence of greater left ventricular dysfunction in anterior than in inferior infarction.[22] However, our patients with inferior infarction who had associated S-T segment depression also had a significant depression of ventricular function, presumably related to concomitant anterior myocardial wall ischemia.[23] It is unlikely that true posterior infarction was the principal cause of the precordial S-T depression because only 3 of the 19 patients with inferior infarction and concomitant precordial S-T depression had electrocardiographic evidence of true posterior infarction. The nature of this association between S-T depression and inferior infarction is not clear because coronary angiography was not performed in most of the survivors or in those who died in the hospital. However, if the depressed ejection fraction in this subset of patients with inferior infarction is related to substantial anterior wall myocardial *ischemia rather than infarction,* it is possible that the large incidence of hospital morbidity and mortality may be altered favorably by interventions that have a salutory effect on the ischemic or jeopardized myocardium.[24] Thus our finding that a subset of high risk patients with inferior myocardial infarction may be identified with electrocardiographic and radionuclide ventriculographic criteria may have important therapeutic implications.

Ejection fraction correlated with morbidity and mortality: Our overall data with respect to the depressed ejection fraction in the early phases of acute infarction is also significant in relation to the short-term or hospital morbidity and mortality. The ejection fraction determined early was depressed in all 27 patients who later manifested congestive heart failure, hypotension and shock as well as in those who continued to experience recurrent ischemic chest pain or those who died in the hospital. Seven (12 percent) of 56 patients died within 2 weeks of the onset of acute myocardial infarction, an incidence that is in general agreement with the average mortality figures in patients with transmural myocardial infarction in our unit during the past 3 years. Six of the seven deaths occurred as a secondary consequence of myocardial pump failure (the remaining death was due to refractory ventricular arrhythmias), all in patients with ejection fraction of 0.30 or less. Furthermore, these deaths as well as virtually all the serious complications occurring during the hospital stay developed only in patients who had either anterior infarction or inferior infarction associated with precordial S-T segment depression. Conversely, no deaths occurred in patients with a normal ejection fraction, and there were no hospital deaths related to pump failure in those who had an initial ejection frac-

tion in excess of 0.30. These data therefore emphasize the prognostic significance of the alteration in left ventricular ejection fraction in the early phases of transmural myocardial infarction.

Depressed ejection fraction in the absence of clinical complications: Although the average ejection fraction in the group without clinical complications was higher than that of the group with complications, the ejection fraction was moderately depressed in 15 (51 percent) of the 29 patients in the former group. However, this degree of ventricular dysfunction was not clinically apparent. Similarly, among the 11 patients with severely depressed ejection fraction (0.30 or less) congestive cardiac failure or hypotension, or both, was absent in 5 at the time of the initial determination of the ejection fraction. These data, therefore, confirm the relative insensitivity of clinical variables alone in detecting the presence of depressed ventricular function in the early stages of acute myocardial infarction.

Implications: Our data indicate that left ventricular ejection fraction, determined with radionuclide ventriculography, is a sensitive marker of ventricular dysfunction in the early stages of acute transmural infarction. Depressed ejection fraction is commonly present in patients with anterior infarction and in a subset of patients with inferior infarction even in the absence of clinically detectable complications. Severe depression of the ejection fraction is associated with substantial hospital morbidity and mortality, and it is possible that in some instances the reduced ejection fraction may partly be due to reversible but persisting ischemia that may be amenable to therapeutic interventions. The prognostic significance of a depressed ejection fraction early in the course of acute myocardial infarction should be confirmed in a larger series of patients with anterior and inferior infarction. With such confirmation, our data may be of potential value in the noninvasive detection of high risk subsets of patients for controlled clinical trials designed to decrease mortality in acute infarction by reducing associated myocardial ischemia or limiting infarct size.

Serial Ambulatory Electrocardiography and Treadmill Exercise Testing After Uncomplicated Myocardial Infarction

ROBERT F. DeBUSK, MD, FACC
DENNIS M. DAVIDSON, MD
NANCY HOUSTON, RN
JOHN FITZGERALD, MD

Stanford, California

To compare the diagnostic and prognostic utility of ambulatory electrocardiography and treadmill exercise testing after clinically uncomplicated myocardial infarction, 90 men (mean age 52 years) were evaluated 3 weeks after the acute event and a variable number were evaluated 11, 26 and 52 weeks after the acute event. The prevalence of "any" premature ventricular complex and of "complex" ventricular ectopic activity was greater with ambulatory electrocardiography than with treadmill testing (78 versus 49 percent; $p < 0.01$ and 42 versus 27 percent; $p < 0.05$), respectively. Whereas the prevalence of any premature ventricular complex on treadmill testing was stable only at 11 weeks and thereafter, the prevalence of any premature ventricular complex on ambulatory electrocardiography was stable throughout the year. The peak frequency of premature ventricular complexes recorded with either method did not change significantly after the 3rd week. Ischemic S-T segment depression of 0.2 mV or greater or a peak work load of less than 4 multiples of resting energy expenditure on the 3 week treadmill test was significantly ($p < 0.05$) associated with coronary events within 24 months. In contrast, premature ventricular complexes recorded during treadmill testing or ambulatory electrocardiography at any time were not predictive of subsequent coronary events. In patients without clinical heart failure treadmill testing soon after myocardial infarction may yield prognostic information not available with ambulatory electrocardiography.

Complex ventricular ectopic activity recorded 2 to 3 weeks after acute myocardial infarction is associated with an increased rate of subsequent coronary events.[1–3] Because ambulatory electrocardiography poses no risks to the patient, most clinicians have utilized this method to record ventricular ectopic activity soon after myocardial infarction. More recently, treadmill exercise testing has been found to elicit prognostically important ventricular ectopic activity in selected patients soon after infarction.[4–6] Because of the potential risks of exercise testing early after infarction, this method has generally been withheld from patients with clinically significant left ventricular dysfunction. This selection factor affects the relation previously noted between ventricular ectopic activity recorded with ambulatory electrocardiography and exercise testing.[7,8] Moreover, characteristics of the study population, especially the extent of left ventricular dysfunction, greatly influence the prognostic significance of ventricular ectopic activity recorded soon after infarction.[9]

We performed serial ambulatory electrocardiography and treadmill exercise testing in patients without clinically significant left ventricular dysfunction 3 weeks after myocardial infarction. Our objectives were (1) to determine the optimal timing and frequency of ambulatory electrocardiograms or treadmill exercise tests required for the diagnosis of

ventricular ectopic activity in the year after clinically uncomplicated infarction, (2) to compare the detection rate of ventricular ectopic activity with serial ambulatory electrocardiography and serial treadmill exercise testing, and (3) to contrast the prognostic value of premature ventricular activity recorded with either technique with selected clinical and exercise test characteristics.

Methods

Ninety consecutive men aged 70 years or less who had been treated for acute myocardial infarction at the Stanford Medical Center between January 1974 and April 1976 were selected for study. Their mean age (± standard deviation) was 52 ± 7 years. These 90 patients demonstrated none of the following characteristics 3 weeks after hospital admission: (1) angina at rest or unstable angina, (2) clinically significant left ventricular dysfunction manifested as breathlessness, edema, pulmonary rales or a ventricular gallop sound, (3) associated medical conditions such as significant valvular heart disease, blood pressure greater than 180/110 mm Hg or limiting pulmonary disease or musculoskeletal abnormalities. Infarction was documented by a history of prolonged chest pain and the appearance of new Q waves or evolutionary ST-T changes and characteristic elevation of serum cardiac enzymes during hospitalization. The clinical characteristics of the patients studied (Table I) are similar to those of approximately two thirds of all men aged 70 or less with myocardial infarction who are discharged from our institution.

Thirty-four percent of patients took antiarrhythmic medication at some point during the study: propranolol in 20 cases (average daily dose 80 mg), quinidine in 8 cases (average daily dose 800 mg) and procainamide in 3 cases (average daily dose 1,000 mg). Six patients took a combination of at least two of these drugs. Three patients took digitalis. During the 16 to 24 hours before exercise testing and ambulatory electrocardiography, all medications except digitalis were withheld. Administration of the medications was restarted after testing. Patients did not undergo formal excercise training, modification of coronary risk factors or psychologic counseling during this study.

Treadmill exercise testing: This test was performed between 1:00 and 5:00 p.m. at 3, 11, 26 and 52 weeks after infarction. Before exercise testing, the patients were interviewed and examined by a physician and informed consent was obtained. A physician and a specially trained nurse conducted the tests. Twelve-lead electrocardiograms were recorded at rest, at the end of each 3 minute stage of exercise and at 1, 3, 5, 7 and 10 minutes of recovery. In addition, leads V_4 to V_6 were continuously displayed on a three channel oscilloscopic monitor and were recorded on magnetic tape for 3 minutes before exercise and during the entire period of exercise and recovery. Exercise was performed on a motor-driven treadmill using protocols described by Naughton et al.[10] (Table II). Exercise commenced at a work load equivalent to 3 multiples of resting energy expenditure and work loads were added every 3 minutes. Tests at 3 weeks were terminated on the appearance of any of the following end points: (1) limiting symptoms of chest pain, dyspnea, fatigue, leg cramps or dizziness; (2) exertional hypotension, defined as a decrease in systolic blood pressure of 10 mm Hg or more from the peak value attained earlier during exercise; (3) ventricular tachycardia, defined as three or more consecutive premature ventricular complexes; or (4) a heart rate of 130 beats/min in the absence of prior end points. Tests performed at 11 weeks or later were symptom-limited, that is, terminated without respect to maximal heart rate.

Ventricular premature complexes were characterized by the peak frequency per minute occurring at rest *or* during treadmill exercise *or* during recovery. Premature ventricular complexes were also characterized by configuration, that is, bigeminy or couplets (two consecutive complexes) or ventricular tachycardia (three or more consecutive complexes). These configurations were termed "complex" independent of the frequency of premature ventricular complexes. Multifocal configuration of exercise-induced premature ventricular complexes was not classified because of the difficulty of its detection at the relatively high heart rates encountered with exercise testing and the difficulty in distinguishing such complexes from aberrantly conducted complexes of supraventricular origin.

Flat or downsloping S-T segments displaced 0.1 mV or more below the P-Q baseline measured 0.08 second after the J point were defined as "ischemic." In the presence of resting S-T segment depression, an additional 0.1 mV of flat or downsloping depression was required for the diagnosis of ischemia.

Ambulatory electrocardiography: At the conclusion of exercise testing, 12 hour ambulatory electrocardiographic recorders were attached. A bipolar MCL_5 lead was used. Our methods for computer-processing of tape-recorded electrocardiograms have previously been described.[11,12] As opposed to the frequency of premature ventricular complexes on treadmill exercise testing, which was expressed as the peak frequency/min, their peak frequency on ambulatory electrocardiography was expressed as the peak frequency/15 min. Premature ventricular complexes were also classified by configuration, that is, bigeminy, couplets, multifocal or ven-

TABLE I

Clinical Characteristics of Patients

	Patients (n)	% of Total Group of 90 Patients
Anterior transmural MI	23	25
Inferior transmural MI	58	64
Nontransmural MI	9	10
Angina pectoris prior to MI	14	16
Prior MI	10	11
Cardiomegaly by X-ray examination in hospital	11	12
Ventricular fibrillation (hospital days 1 to 5)	1	1
Ventricular tachycardia (hospital days 1 to 5)	24	27

MI = myocardial infarction.

TABLE II

Treadmill Test Protocol

Speed (mph)	Incline (%)	Work Load (METs)
2.0	3.5	3
2.0	7.0	4
2.0	10.5	5
2.0	14.0	6
2.0	17.5	7
3.0	12.5	8
3.0	15.0	9
3.0	17.5	10
3.0	20.0	11
3.0	22.5	12

METs = multiples of resting energy expenditure.

tricular tachycardia. These configurations were termed "complex" independent of the frequency of the complexes.

Follow-up tests and clinical course: On 31 occasions after the 3 week evaluation, treadmill tests were performed, but ambulatory electrocardiographic recordings were not obtained because equipment was not available. In addition, 17 follow-up visits were not made because of coronary events occurring after the 3rd week and another 27 visits were not made because of scheduling problems. The remaining 285 visits on which both ambulatory electrocardiography and treadmill exercise testing were carried out form the basis of this study. After the 1st year, follow-up of patients continued by mail or telephone contact with the patient or his private physician concerning the occurrence of recurrent infarction, cardiac arrest or sudden death. The criteria for recurrent infarction were the same as for initial infarction. Cardiac arrest was defined as sudden collapse in a patient in whom ventricular fibrillation was demonstrated on electrocardiography immediately before emergency defibrillation. Sudden death was defined as death within 1 hour in the absence of other contributory medical conditions. All patients were followed up for 2 years, even those in whom one or more visits were missed.

Statistical analysis: The reproducibility of premature ventricular complexes from one visit to the next was expressed by the kappa coefficient. This method considers discrete responses for each test, that is, absence as well as presence, and expresses reproducibility as a single number ranging from 1.0 (perfect agreement) to 0.0 (chance agreement). A multiple kappa procedure was used to test the reproducibility of responses in patients with all four visits. McNemar's test[14] was used to evaluate the significance of a change in prevalence of discrete test responses from one visit to the next. Cochran's Q test[15] was used to evaluate the significance of a change in prevalence of discrete responses in patients with all four visits. Differences in the prevalence of discrete responses for treadmill testing and ambulatory electrocardiography were tested with chi square methods. In patients with all four visits, analysis of variance was used to compare the frequency of premature ventricular complexes between visits. The degree of association between complex types of ventricular ectopic activity was expressed by the odds ratio.[16]

Stepwise multiple logistic regression analysis[17] was used to compare the prognostic significance of (1) clinical characteristics, (2) the results of treadmill exercise testing, and (3) characteristics of premature ventricular complexes recorded with ambulatory electrocardiography. The analysis quantitates the association between candidate variables and recurrent coronary events (myocardial infarction, sudden death and nonfatal cardiac arrest). These candidate variables are listed in Table III. Analyses were performed using Statistical Programs for the Social Sciences. Details of the multiple regression analysis appear in the Appendix.

Results

Prevalence of premature ventricular complexes: *The prevalence of any treadmill-induced premature ventricular complex* increased significantly between 3 and 11 weeks after infarction (from 42 to 53 percent; $p < 0.05$) and remained relatively constant thereafter (Fig. 1). The prevalence of complex treadmill-induced premature ventricular complexes ranged from 25 to 31 percent, without a significant change after the 3 week test. In the 50 patients whose 3 week tests were stopped by symptoms at a heart rate of 130 beats/min or less, the mean (± standard error of the mean) maximal heart rate was 119 ± 11 beats/min, equivalent to 71 percent of their age-predicted maximal heart rate. In 40 patients the 3 week test was discontinued because of attainment of the arbitrary target rate of 130 beats/min, equivalent to 80 percent of their age-predicted maximal heart rate. The prevalence of premature ventricular complexes was not significantly different in these two patient groups at 3 or at 11 weeks.

The prevalence of any premature ventricular complex recorded with ambulatory electrocardiography ranged from 77 to 83 percent, without significant dif-

TABLE III

Variables Evaluated for Prognostic Significance

Continuous	Discrete
Clinical (during hospitalization)

Treadmill Test (3 weeks after MI)	
Maximal heart rate (HR) Maximal systolic blood pressure (SBP) Maximal HR X SBP/100 Maximal work load (METs) Magnitude of ischemic S-T depression (mV) Maximal PVC frequency/min	Exertional hypotension Exertional angina pectoris "Any" PVC "Complex" PVC
Ambulatory ECG (3 weeks after MI)	
Maximal PVC frequency/15 min	"Any" PVC "Complex" PVC

CK = creatine kinase; ECG = electrocardiographic, electrocardiogram; METs = multiples of resting energy consumption (estimated); MI = myocardial infarction; PVC = premature ventricular complex.

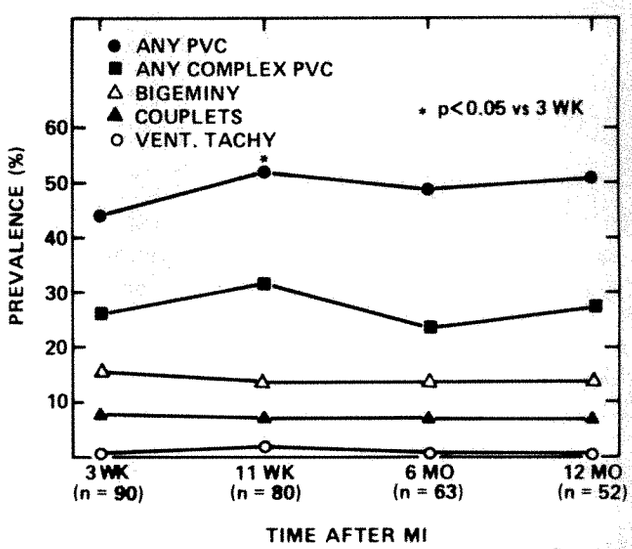

FIGURE 1. Prevalence of treadmill-induced premature ventricular complexes (PVC). MI = myocardial infarction; VENT. TACHY = ventricular tachycardia.

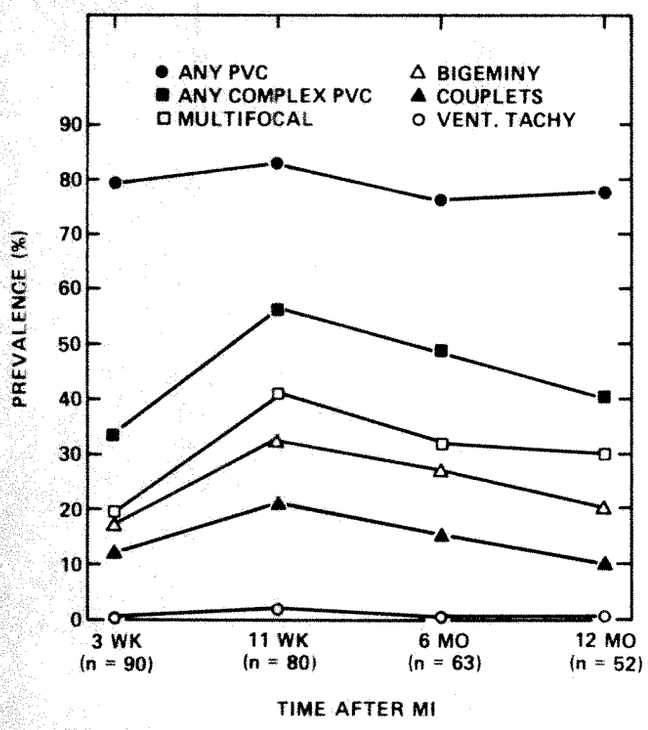

FIGURE 2. Prevalence of premature ventricular complexes (PVC) recorded on ambulatory electrocardiograms. MI = myocardial infarction; VENT. TACHY = ventricular tachycardia.

ferences between the 3 week and later tests (Fig. 2). The prevalence of complex premature ventricular complexes recorded with ambulatory electrocardiography ranged from 33 percent at 3 weeks to 53 percent at 11 weeks; this change was not statistically significant. The mean heart rate during the 12 hours of ambulatory electrocardiography was similar for visits at 3, 11, 26 and 52 weeks: 77 ± 11, 79 ± 10, 81 ± 17 and 79 ± 11 beats/min, respectively.

TABLE IV

Degree of Association Among Complex Premature Ventricular Complexes on Ambulatory Electrocardiography

	Couplets	VT	Multiform
Bigeminy	7.1*	1.1	5.3*
Couplets		2.3	6.8*
VT			2.2*

* $p < 0.001$.

Values represent odds ratios, or the relative likelihood of observing a second complex configuration if one is present.[16]

PVC = premature ventricular complex; VT = ventricular tachycardia.

Associations between complex premature ventricular complexes recorded with ambulatory electrocardiography are depicted in Table IV. Bigeminy, couplets and multiform premature ventricular complexes were highly associated with one another but not with ventricular tachycardia. Bigeminy and couplets were also highly associated on treadmill testing ($p < 0.001$). The two patients with exercise-induced ventricular tachycardia demonstrated couplets on the same test. In an additional 22 tests, couplets were noted in the absence of ventricular tachycardia.

Neither the prevalence nor the frequency of premature ventricular complexes was significantly different in the 17 percent of tests preceded by antiarrhythmic therapy than in the 83 percent of tests in which no antiarrhythmic therapy had been given.

Frequency of premature ventricular contractions: The peak frequency of premature ventricular contractions per minute on treadmill tests and per 15 minutes in ambulatory electrocardiograms did not change significantly during the year after infarction. The peak frequency of treadmill-induced premature ventricular complexes ranged from 6 ± 2 to 10 ± 2 beats/min and the peak frequency of such complexes recorded in ambulatory electrocardiograms ranged from 25 ± 15 to 45 ± 15/15 min.

TABLE V

Relation Between the Presence and Frequency of Premature Ventricular Complexes on Paired Consecutive Tests*

Discrete Test Responses	3 Wk–11 Wk Test Pair			11 Wk–6 Mo Test Pair			6 Mo–12 Mo Test Pair		
	n	3 Wk	11 Wk	n	11 Wk	6 Mo	n	6 Mo	12 Mo
A. Ambulatory Monitoring Averaged Peak Frequency ± SD of PVC's for Each Pair of Tests									
PVC on both tests	53	33 ± 78	39 ± 80	34	56 ± 106	30 ± 50	27	33 ± 55	45 ± 138
PVC on 1st test only	11	6 ± 8	0	12	5 ± 8	0	5	14 ± 21	0
PVC on 2nd test only	6	0	3 ± 2	8	0	3 ± 2	5	0	1 ± 0
PVC on neither test	7	0	0	3	0	0	5	0	0
B. Treadmill Testing: Averaged Peak Frequency ± SD of PVC's for Each Pair of Tests									
PVC on both tests	22	9.5 ± 10.4	8.1 ± 11.4	29	8.3 ± 10.3	6.9 ± 13.6	21	9.4 ± 15.5	8.9 ± 8.4
PVC on 1st test only	12	6.9 ± 7.5	0	12	3.8 ± 4.1	0	11	1.6 ± 1.5	0
PVC on 2nd test only	25	0	5.8 ± 5.7	13	0	2.9 ± 2.6	12	0	2.3 ± 1.5
PVC on neither test	26	0	0	21	0	0	19	0	0

* Sample interpretation: A total of 77 patients had ambulatory electrocardiograms at both 3 and 11 weeks. Of these, 53 demonstrated premature ventricular complexes on both visits, with a frequency of 33 ± 78 and 39 ± 80, respectively. In contrast, the frequency of premature complexes was only 6 ± 8 in the 11 patients with such complexes at 3 weeks only and 3 ± 2 in the 6 patients with such complexes at 11 weeks only. Seven patients had premature ventricular complexes on neither occasion.

PVC = premature ventricular complexes; SD = standard deviation.

Prevalence versus frequency of premature ventricular complexes: The prevalence of complex treadmill-induced ventricular ectopic activity and the prevalence of complex ventricular ectopic activity recorded with ambulatory electrocardiography were highly correlated ($p < 0.001$). Patients with frequent premature ventricular complexes recorded with either technique were likely to demonstrate ventricular ectopic activity on both of two consecutive paired tests. In contrast, patients with a low frequency of premature ventricular complexes often had no consistent response from test to test (Table V).

Overall prevalence of premature ventricular contractions: treadmill testing versus ambulatory electrocardiography (Fig. 3): Within the total of 285 visits, any premature ventricular complex was significantly more common with ambulatory electrocardiography than with treadmill testing (85 versus 50 percent; $p < 0.01$). Similarly, the overall prevalence of complex ventricular ectopic activity was significantly higher with ambulatory electrocardiography than with treadmill testing (42 versus 27 percent; $p < 0.01$). The frequency of premature ventricular contractions on treadmill tests and in ambulatory electrocardiograms was significantly ($p < 0.001$) correlated on each of the four visits ($r = 0.401, 0.334, 0.587$ and 0.554, respectively).

Reproducibility of premature ventricular contractions: The reproducibility of ventricular ectopic activity (presence versus absence) was significantly above the chance level for any treadmill-induced premature ventricular complex and for complex treadmill-induced ventricular ectopic activity (multiple kappa 0.174 [$p < 0.001$] and 0.191 [$p < 0.01$], respectively). The reproducibility of premature ventricular complexes recorded in ambulatory electrocardiograms was significantly above the chance level for any premature ventricular complex and for complex ventricular ectopic activity (multiple kappa 0.184 [$p < 0.05$] and 0.212 [$p < 0.001$], respectively).

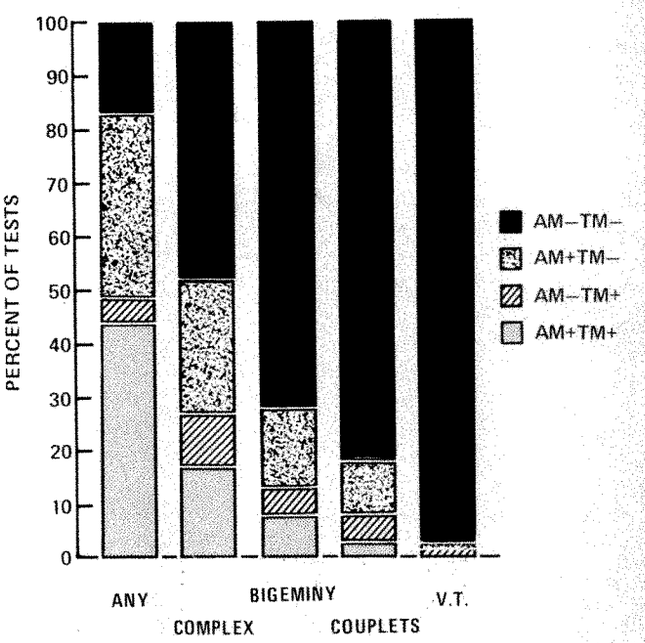

FIGURE 3. Treadmill (TM) testing versus ambulatory (AM) monitoring. AM− TM− = no premature ventricular complex with either method; AM+ TM− = premature ventricular complexes with ambulatory electrocardiography only; AM− TM+ = premature ventricular complexes with treadmill exercise only; AM+ TM+ = premature ventricular complexes with both methods. V.T. = ventricular tachycardia.

Relation between ventricular ectopic activity and ischemic S-T segment depression: The prevalence of any treadmill-induced premature ventricular complex and of complex ventricular ectopic activity was slightly but not significantly greater in tests with ischemic than in those with nonischemic results. Ischemic S-T segment depression was present on the treadmill tests of the two patients with exercise-induced ventricular tachycardia.

TABLE VI

Frequency and Configuration of Premature Ventricular Complexes in Patients With Subsequent Coronary Events*

		3 Wk		11 Wk		6 Mo		1 Yr

* The frequency of premature ventricular complexes (PVCs) is represented by numbers followed by configuration (simple [S] or complex [C]).
† No visit due to event.
‡ Missed visit.
AM = ambulatory electrocardiogram; AMI = acute myocardial infarction; complex (C) = bigeminy, couplets or ventricular tachycardia (AM or TM) or multiform (AM only); SCD = sudden cardiac death; simple (S) = no complex configurations; TM = treadmill exercise test.

The prevalence of any premature ventricular complexes and of complex ventricular ectopic activity in ambulatory electrocardiograms was slightly but not significantly greater in patients with treadmill-induced ischemic S-T segment depression on the same visit than in those without ischemia. Ventricular tachycardia was recorded in one ambulatory electrocardiogram in each of four patients, none of whom demonstrated treadmill-induced S-T segment depression.

Follow-up: Eleven patients experienced a recurrent coronary event within 24 months after infarction (Table VI). Recurrent events were not significantly more common in patients with treadmill-induced premature ventricular complexes 3 weeks after infarction than in those without treadmill-induced ventricular ectopic activity (11 percent [4 of 35] versus 13 percent [7 of 55] for any premature ventricular complex and 9 percent [2 of 22] versus 13 percent [9 of 68] for complex ventricular ectopic activity). Similarly, recurrent events were not significantly more common in patients with premature ventricular contractions in ambulatory electrocardiograms 3 weeks after infarction than in those without ventricular ectopic activity (13 percent [9 of 72] versus 11 percent [2 of 18] for any premature ventricular complex and 12 percent [4 of 33] versus 12 percent [7 of 57] for complex ventricular ectopic activity).

Of the variables evaluated for prognostic significance with the stepwise multiple logistic regression program, exercise-induced S-T segment depression of 0.2 mV or greater was the most valuable single variable. Four of 15 patients (27 percent) with this characteristic at 3 weeks had a subsequent coronary event, compared with 7 of 75 (9 percent) with S-T segment depression of less than 0.2 mV ($p < 0.05$). Three patients had a fatal or near fatal coronary event between 3 and 11 weeks after infarction. None of these patients had complex ventricular ectopic activity with either recording method, whereas all had treadmill-induced ischemic S-T segment depression of 0.2 mV or greater at 3 weeks.

A low peak treadmill work load was the next most valuable variable. In patients with S-T segment depression of less than 0.2 mV, 2 of 7 patients (28 percent) with a peak work load of less than 4 multiples of estimated resting energy expenditure at 3 weeks had a subsequent coronary event compared with 11 of 68 patients (16 percent) with a higher peak work load ($p < 0.05$). Thus, at 3 weeks, 6 of 11 patients (54 percent) with a subsequent coronary event had S-T depression of 0.2 mV or greater or a peak treadmill work load of less than 4 multiples of resting energy expenditure, or both, compared with 22 of 79 patients (28 percent) with these findings who did not have a coronary event. None of the remaining clinical, treadmill test or ambulatory electrocardiographic characteristics at 3 weeks, including "any" and "complex" classes of ventricular ectopic activity, were significantly associated with subsequent coronary events.

At 11 weeks and thereafter, neither ambulatory electrocardiographic nor treadmill test characteristics including ischemic S-T segment depression of 0.2 mV or greater were significantly associated with subsequent coronary events.

Discussion

Optimal timing and frequency of ambulatory monitoring for the diagnosis of ventricular ectopic activity after infarction: These guidelines have not been established. Moss et al.[18] noted an increase in the frequency and complexity of premature ventricular complexes in ambulatory electrocardiograms 4 to 5 months after hospital discharge compared with those in recordings made at the time of hospital discharge. In the study of Kotler et al.[19] the rate of detection of patients with premature ventricular complexes increased from 43 to 63 when the number of ambulatory electrocardiograms increased from 1 to 2.5 over a period of 36 months. The configuration and frequency of ventricular ectopic activity were not considered separate features in their study and the diagnostic contribution of each test was not evaluated relative to the others. The implication of these studies is that multiple tests are required for the diagnosis of ventricular ectopic activity. Our study showed no significant change in the prevalence, frequency or configuration of premature ventricular complexes recorded in ambulatory electrocardiograms in the year after uncomplicated infarction. There was therefore no apparent diagnostic advantage in performing additional ambulatory monitoring after the 3rd week.

Optimal timing and frequency of treadmill exercise tests to detect ventricular premature complexes after infarction: These guidelines, too, are not well established. Granath et al.[4] noted an increased rate of subsequent cardiac events in patients with exercise-induced ventricular ectopic activity 3 and 9 weeks after infarction, but they provided no data regarding the frequency or configuration of premature ventricular complexes and did not compare the diagnostic and prognostic utility of the two tests. In our present study, as in our prior experience,[20] the proportion of patients with treadmill-induced premature ventricular complexes increased significantly between 3 and 11 weeks after infarction but not thereafter. However, the mean frequency of treadmill-induced premature ventricular complexes did not change significantly between 3 and 11 weeks. Continuous measures of ventricular ectopic activity such as the frequency of premature ventricular complexes are superior to discrete measures such as the proportion of patients with premature complexes in characterizing the reproducibility of ventricular ectopic activity.[21] We[21] have previously reported good reproducibility for the detection of exercise-induced ventricular ectopic activity in individual patients between 3 and 11 weeks after clinically uncomplicated infarction. Even better reproducibility was found for tests performed between 11 weeks and 6 months or later after infarction.[21]

Like other workers[18,22] who have used ambulatory electrocardiography, we found a close association between various categories of complex ventricular ectopic activity and a close relation between the frequency and complexity of ventricular ectopic activity. Our study documents similar relations for premature ventricular complexes detected with treadmill exercise testing. We

also found a good correlation between the frequency of premature ventricular complexes detected with ambulatory monitoring and with treadmill exercise testing. This association was not examined in previous studies in which frequency and configuration of premature ventricular complexes were combined into a scoring system rather than being considered separately.

Comparison of sensitivity of ambulatory electrocardiography and treadmill testing: As others[7,8] have reported, we found ambulatory monitoring more sensitive than treadmill exercise testing in the diagnosis of ventricular ectopic activity. This was true for each of the four occasions on which these two modes of recording were compared. Ryan et al.[8] suggested that ambulatory monitoring and treadmill exercise might disclose different information regarding the electrophysiologic state of the myocardium. Our data support this view: There was no overlap between the two methods in the diagnosis of ventricular tachycardia in our patients. Moreover, ischemic S-T segment depression was present in both patients with treadmill-induced ventricular tachycardia whereas none of the four patients with ventricular tachycardia on ambulatory electrocardiography demonstrated treadmill-induced ischemic S-T segment depression. Whether both methods of recording should be employed to assure detection of ventricular tachycardia or other "malignant" forms of ventricular ectopic activity depends on the lethal potential of such arrhythmias within a specified population. Studies by Anderson et al.[23] and by Bigger et al.[9] have demonstrated that the prognosis of patients manifesting ventricular tachycardia on ambulatory electrocardiography at the time of hospital discharge after infarction is not significantly worse than that of patients without this arrhythmia.

Prognostic value of premature ventricular complexes detected with ambulatory monitoring and treadmill testing: The choice of ambulatory monitoring or treadmill exercise testing for the diagnosis of ventricular ectopic activity depends not only on the potential of each technique to reveal premature ventricular complexes but also on the prognostic significance of ventricular ectopic activity within a specified population. In our population of patients free of clinically significant left ventricular dysfunction, the greater diagnostic sensitivity of ambulatory monitoring was not translated into a greater prognostic utility compared to treadmill testing. In fact, *neither* technique of recording ventricular ectopic activity had prognostic utility within this population.
